#### Abstract

As part of a multi-year demographic population monitoring study of the federally endangered Pacific pocket mouse (Perognathus longimembris pacificus) on Marine Corps Base Camp Pendleton, population monitoring was performed during 2004 on two established trapping grids within the Oscar One training area. Between April and September, three primary sampling bouts were implemented on one grid and four primary sampling bouts were implemented on the other. Data was analyzed in program MARK (White and Burnham 1999) using a candidate set of 62 possible closed population models to generate individual trapping bout abundance estimates. Results reveal that the selected monitoring protocol is capable of producing precise abundance estimates with narrow confidence intervals. However, model comparisons reveal there is a high degree of model uncertainty, with support given to models indicating that time, behavior and individual capture heterogeneity all influence animal detection probabilities. Trapping data indicates that breeding activity had just been initiated by April and some female PPM were likely to have bred twice during the 2004 breeding season. The observed overall population trend was an increase in animal abundance between April and June, a moderate decrease in abundance between June and August, and a dramatic decline in abundance in late September. The sharp decline in numbers in late September suggests that animals had already started to enter seasonal dormancy at the time of the last sampling period. Examination of age class information across all sampling periods revealed a bi-modal trend in abundance for adults that was split by a unimodal peak for juveniles during the June sampling period. This is consistent with observations of a similar sized Perognathus species elsewhere (O'Farrell et al. 1975), and suggests that individual components or cohorts of the PPM population have brief and distinct periods of activity above ground on an annual basis.

## Introduction

The Pacific pocket mouse (Perognathus longimembris pacificus "PPM") historically occurred on the immediate coast of southern California from Marina del Rey and El Segundo in Los Angeles County, south to the vicinity of the Mexican border in San Diego County. It's known distribution is restricted to fine grain, sandy substrates within coastal strand, coastal dunes, river alluvium and marine terraces within 4-kilometers of the ocean. In 1993, following a 20-year period during which the subspecies was not detected, PPM were rediscovered at the Dana Point Headlands in Orange County, California. Based on this discovery, the U.S. Fish and Wildlife Service (Service) emergency listed the PPM in February 1994 (59 FR 5306). Upon expiration of the emergency listing, the subspecies was federally listed as endangered on September 29, 1994 (59 FR 49752).

In 1995, PPM were discovered in two general locations on Marine Corps Base Camp Pendleton in northern San Diego County, bringing the total number of known occurrences of this subspecies to three. Survey efforts suggest that of the three occurrences, the largest
concentration of PPM is found within the Oscar One training area of Camp Pendleton. In 1996, the United States Marine Corps proposed and the Service authorized, by means of a Biological Opinion (1-6-96-F-35), construction of the Crucible Challenge Course for troop training exercises within Oscar One.

Associated with the construction of the Crucible Challenge Course, the Marine Corps committed to developing and implementing a monitoring program to track the status of the PPM population within Oscar One. However, detailed life history studies have revealed that PPM is fossorial (burrows) with a complex life history that involves the use of torpor to remain dormant during the Fall and Winter (McCloskey 1972, Meserve 1976a, Meserve 1976b). A number of studies that detected PPM also found them at low concentrations (Brylski 1993, McCloskey 1972, Meserve 1976a, Meserve 1976b). Thus, PPM are not detectable for several months of the year and, when they are found, intensive sampling may be necessary to obtain sufficient sample sizes to support statistical abundance estimates for inferring trend.

The Marine Corps has been working in collaboration with the Service to refine sampling methods for use in their monitoring program. The initial strategy has involved development of a sampling methodology of sufficient intensity to obtain statistically robust abundance estimates at chosen locations within Oscar One. Repeated sampling during the period of above-ground animal activity has also been implemented to better understand within season population variability and to obtain estimates of other demographic parameters such as survivorship.

Because the Marine Corps' monitoring commitment involves sampling the Oscar One PPM population every other year, the present study augments the Marine Corps 2003 and 2005 efforts by implementing the same methods during 2004. This will provide important data on overwinter survivorship that can only be obtained by studying the population during consecutive years. Additionally, when combined with Marine Corps data for 2003 and 2005, this effort will provide several consecutive years of demographic data to better understand the life history variables important to PPM population dynamics. It is anticipated that the detailed demographic information collected from these combined efforts will be used to refine a long term monitoring strategy for PPM that can be implemented within Oscar One and elsewhere. This report focuses solely on the 2004 monitoring data which will be incorporated into a larger analysis to be reported elsewhere.

## Materials and Methods

Small mammal trapping was performed between April and September of 2004 within historically established trapping grids "A" and "D" within the Oscar One training area at Marine Corps Base Camp Pendleton (See Figure 1). The two trapping grids are approximately 1.5 kilometers from one another and are separated by several dirt and one paved road (MACS Road). The two grids were selected specifically because prior trapping data suggested they support moderate to high densities of PPM. They also are located in slightly different plant communities at different elevations and are sufficiently separated that they might provide a measure of environmental and
spatio-temporal variability across the Oscar One PPM population.
Grid A is located east of MACS road along a gentle southwesterly sloping hillside covered with an ecotonal mixture of annual and perennial grasses and forbs that is interspersed with white sage (Salvia apiana), deerweed (Lotus scoparius), lemonadeberry (Rhus integrifolia) and occasional cacti (Opuntia littoralis and O. prolifera). During Spring months, storksbill (Erodium sp.) provides a dense cover over much of this site, with other notable forbs including coastal wall flower (Erysimum sp.), croton (Croton californicus), slender wreath plan (Stephanomeria virgata), and a number of small stature forbs in the Boraginaceae. This area is removed from the Crucible Course obstacles where most military training is focused.

Grid D is located below Grid A, west of MACS Road along a coastal terrace with little topographic relief. This site is also covered with a mixture of annual and perennial grasses, forbs and shrubs, but with less shrub cover than Grid A. Interspersed shrubs include coastal goldenbush (Isocoma menzesii), coastal sagebrush (Artemesia californica), deerweed (Lotus scoparius), buckwheat (Eriogonum fasciculatum), laurel sumac (Malosma laurina) and coyote brush (Baccharis pilularis). Large stature annuals to short lived perennials include western ragweed (Ambrosia psilostachya), telegraph weed (Heterotheca grandiflora), cudweed (Gnaphalium sp.) and horseweed (Conyza canadensis). A portion of this site appears to remain vernally mesic, which is suggested by the presence of cordgrass (Spartina sp.) and rushes (Juncus sp.) towards the eastern end of the grid. Grid D is directly adjacent to several Crucible Course obstacles, but military training is restricted to the adjoining roads and obstacles. Therefore, there is little current disturbance to this vegetation community from troop training activites.

Each trapping grid supports a rectangular, 600-trap array ( $20 \times 30$ traps) with traps placed at 5 meter intervals. Thus, each trapping grid covers an area of about 1.38 hectares ( 3.4 acres).

All trapping was done using 9 -inch Sherman ${ }^{\mathrm{TM}}$ Live Traps with modified shortened doors. Traps were placed in a consistent orientation (i.e. all doors facing the same direction) and traps were baited with a 1: 4 ratio, by weight, of steamed flat rolled oats to white millet. Traps were baited at dusk and their contents checked at midnight and dawn. To prevent against attack of captured animals by ants, bait was emptied from traps each morning, and if ants were discovered convening around a trap at any time, a natural insect powder made of ground pyrethrum flowers (Ecozone® Roach, Ant, Flea, Silverfish Insect Powder) was sprinkled beneath the trap.

For each animal captured, the species, capture location (unique trap station number), animal identity, age, sex, reproductive condition, and capture/recapture status was recorded. Comparison of field observations with the skins and toothwear patterns of PPM specimens housed at the San Diego Natural History Museum led investigators to conclude that PPM subadults could not be reliably discerned from adults in the field based on pelage. Therefore, captured PPM were assigned either a juvenile or adult age class. Depending on capture rates and time availability, morphological measures were also recorded for PPM . Measurements of PPM
morphology included hind foot length, ear length at notch, tail length, body length and animal weight.

All PPM were uniquely marked upon initial capture using toe-clipping as the marking methodology. Toe codes involved clipping one to four toes per animal, with a maximum of one digit clipped per appendage. For purposes of inferring capture/recapture status of non-target animals, non-targets were marked beneath the chin with a Sharpie ${ }^{\circledR}$ permanent marker.

A total of four primary sampling bouts were implemented on Grid A and three sampling bouts were implemented on Grid D (See Table 1). Because 2004 represents a continuation of sampling initiated in 2003, and for consistency with reporting elsewhere, these are numbered bouts 4 through 7. The sixth trapping bout was skipped on Grid D. Sampling periods varied in length from four to ten days of consecutive trapping. Midnight and morning trapping data was combined for analysis and PPM populations were assumed to be closed to the effects of births, deaths, immigration and emigration within each primary sampling period. Combined, a total of 25,800 trap nights was performed.

Table 1
2004 PPM Sampling Periods

| Grid | Sampling <br> Bout | Sampling Period | No. of Nights Trapping | No. of Trap Nights |
| :---: | :---: | :---: | :---: | :---: |
| A | 4 | April 9-15 | 6 | 3600 |

|  | 5 | June 6-11 | 5 | 3000 |
|  | 7 | September 24-30 | 6 | 3600 |
| Total No. of Trap Nights |  |  |  | 25,800 |

Data Analysis
Program MARK (White and Burnham 1999) was used to estimate detection probability (p) and abundance ( N ) for each grid during each primary sampling period. Huggins closed capture models (Huggins 1989, Huggins 1991) were selected because these models can perform better than the classic closed captures model (Otis et al 1978) when low densities and low detection probabilities cause low sample sizes (Grant and Doherty 2006). The Huggins estimator differs from the classic closed model by conditioning population size ( N ) out of the likelihood function. Thus, the Huggins estimator directly estimates detection probability but calculates population size as a derived parameter.

The candidate model set (Burnham and Anderson 2002) used to estimate detection probability (p) consisted of 62 possible models derived from the eight basic closed capture model types described by Otis et al. (1978)(See Table 2). The eight basic model types estimate detection

${ }^{1}$ Otis et al. (1978) model notation.
probability by assuming there is no variation in capture probability (i.e. the null model) or by attributing observed variation in capture probabilities to three basic sources (time, behavior and heterogeneity) or combinations of these factors (time and behavior, time and heterogeneity, behavior and heterogeneity, or time, behavior and heterogeneity).

Briefly, the null model $\left(\mathrm{M}_{0}\right)$ is the simplest of all models and assumes that all members of the population are equally at risk of capture on any occasion (Otis et al. 1978). The time model $\left(\mathrm{M}_{\mathrm{t}}\right)$ assumes that all members of the population are equally at risk of capture on a given trapping occasion, but the probability of capture can vary from one occasion to the next (Otis et al. 1978). Thus, the time model estimates independent capture probabilities for each trapping occasion. The influence of weather or other environmental variables on animal behavior are commonly used to explain why capture probability might vary among occasions.

The behavior model $\left(\mathrm{M}_{\mathrm{b}}\right)$ deals with the failure of the assumption that initial capture does not affect the probability of capture on subsequent occasions. Thus, animals can exhibit a behavioral response to initial capture such as becoming trap "happy" or trap "shy." This expands the number of estimated parameters to include the likelihood of first capture (p) and the likelihood of recapture (c) (Otis et al. 1978).

The heterogeneity model $\left(\mathrm{M}_{\mathrm{h}}\right)$ rests on the assumption that there is no difference between trapping occasions and no behavioral response to capture, but each member of the population has its own probability of capture that is independent of other members of the population. Because this form of heterogeneity is not attributable to age or sex or other measurable attributes, in its full form this model is highly parameterized and theoretically leads to the estimation of as many parameters as there are animals in the population (Otis et al. 1978). A recent maximum likelihood approach (e.g. Pledger 1998, Pledger 2000) has reduced the number of estimated parameters for this model type by partitioning animals into a finite number of groups with relatively homogenous capture probabilities, or "mixtures," estimated as the parameter $\Pi$. Because most data sets are only capable of supporting two mixtures (e.g. animals that are easy to detect and those that are hard to detect) (Lukacs 2005), all heterogeneity models used in this analysis were constructed with two mixtures which differed in capture probability by an additive constant on the logit scale. Thus, the parameter $\Pi$ represents the relative proportions of the two mixtures as the value $\Pi$ for the first mixture, and $1-\Pi$ for the second mixture. Heterogeneity models were implemented in Program MARK using the Huggins Full Closed Captures with Heterogeneity data type.

As suggested above, the other four model types are more complex models that result from all of the possible combinations of the above factors. For example, the time and behavior model $\left(\mathrm{M}_{\mathrm{tb}}\right)$ partitions variability in capture probability according to both time and behavioral effects. Because other studies of mice have selected time and behavior as preferred models, and heterogeneity is expected in almost all natural populations (Chao and Huggins 2005), all eight basic model types were considered reasonable to test.

Program MARK provides flexibility to allow for different mathematical constructions of the basic model types described by Otis et al (1978). For example, models that attribute variation in capture probabilities to time can be constructed that allow one to test for group by time interactions (i.e. capture probability varies freely across time by groups), or capture probability can be allowed to vary through time, but groups are constrained to be different by an additive constant on the logit scale (Lukacs 2005). Because this analysis implemented in program MARK more complex versions of the models presented by Otis et al. (1978), the model notation presented here follows that suggested by Lukacs (2005). This is similar to the notation used for other models in MARK.

Because interaction models generally involve the estimation of a large number of parameters, and there were concerns that sparse data would not support such parameterized models, most models were constructed using an additive structure. However, some of the more simple model types were constructed with both additive and interaction-type structures to see if there was support for group by time interactions. The eight model types were also expanded into the candidate model set by further partitioning variation in detection probability according to various animal groupings. Animals were grouped according to sex, age, sex and age combined (g) or by ignoring these factors and treating all animals similarly (.). Thus, the various groupings resulted in several permutations for most selected model types.

Although the candidate model set consisted of 62 possible models, individual trapping bout data was considered when determining which models to apply to the analysis of each bout's data. In particular, no juvenile animals were detected on either grid during the April and September sampling periods. Therefore, models that tested for differences among age classes or treated each age and sex combination as a separate group were not applied to these bouts. This reduced the candidate model set to 26 possible models for the April and September sampling periods.

Akaike's Information Criterion with a small sample size correction ( $\mathrm{AIC}_{\mathrm{c}}$ ) was used to rank models (Burnham and Anderson 2002). For closely ranking models, model averaged abundance estimates were computed (Burnham and Anderson 2002).

## Results

## Grid A

Eight rodent species were detected on trapping Grid A between April and September of 2004 (See Table 3). Two species, cactus mouse and desert woodrat were only detected during one trapping bout and in each instance their capture histories represented the detection of just one individual. A third species, house mouse, was captured in trace amounts during three of the four trapping bouts.

Table 3
Total Number of Captures by Species on Grid A

| House mouse | Mus musculus |  | 9 |  |  | 9 |
| TOTAL |  | 413 | 1520 | 1537 | 396 | 3866 |

More commonly detected non-target species included San Diego pocket mouse, California pocket mouse, white-footed deer mouse and western harvest mouse. Because of overlap in the morphological characters used to identify California pocket mouse and San Diego pocket mouse (ear and foot length), field personnel sometimes had difficulty distinguishing these two species from one another and occasionally identified them only to genus. Because of the potential for mis-identification of these two species conclusions regarding their relative abundance or relative population dynamics should be made with caution.

Other than during bout 7, PPM were the most commonly captured animals on the trapping grid. Table 4 details the number of unique PPM, by age and sex class, that were marked and contributed to the capture totals for each trapping bout. Juvenile animals were only detected during the June and August trapping bouts, and pregnant females were only detected during the April, June and August sampling periods. This suggests that animals were just initiating reproduction in April and had probably concluded reproductive activity by September.

Two individual female PPM were documented to be pregnant during both the April and June sampling periods, and one female was reported to be pregnant during both the April and August sampling periods. A fourth female was recorded to be pregnant in April, June and August.

| INDIVIDUALS | 136 |  |  |  |
| TOTAL |  |  |  |  |
| CAPTURES | 352 |  |  |  |

The model that best fit the trapping data for the April trapping period (bout 4) according to AICc values was the simplest time and heterogeneity model that was tested $(\Pi(),. \mathrm{pa}(\mathrm{t})=\mathrm{ca}(\mathrm{t})=$ $\mathrm{pb}(\mathrm{t})+\mathrm{z}=\mathrm{cb}(\mathrm{t})+\mathrm{z})$ (See Appendix 1). This model suggests that there are two discernible groupings (i.e. "mixtures") of animals with relatively homogenous capture probabilities irrespective of sex, and capture probability also varies with time. Depending on capture occasion, estimated detection probabilities for the difficult to detect animals ranged between 0.16 and 0.35 (See Appendix 2). Similarly, detection probabilities for the easily detectable animals ranged between 0.57 and 0.79 (See Appendix 2). A majority of the population was comprised of animals that were hard to detect ( $\Pi=0.76,95$ percent confidence interval 0.54 to 0.90 ).

Based on the model comparisons, three alternative models fell within 2 AICc values of this model suggesting these models fit the April trapping data equally well. The first of these alternative models $(\Pi(\operatorname{sex}), \mathrm{pa}(\mathrm{t})=\mathrm{ca}(\mathrm{t})=\mathrm{pb}(\mathrm{t})+\mathrm{z}=\mathrm{cb}(\mathrm{t})+\mathrm{z})$ is also a time and heterogeneity model, but it suggests that males and females have different proportions (mixtures) of easy to detect and hard to detect animals. The second alternative model $(\Pi(),. \mathrm{pa}(\operatorname{sex}+\mathrm{t})=\mathrm{ca}(\operatorname{sex}+\mathrm{t})=$ $\mathrm{pb}(\operatorname{sex}+\mathrm{t})+\mathrm{z}=\mathrm{cb}(\operatorname{sex}+\mathrm{t})+\mathrm{z})$ is also a time and heterogeneity model but it suggests that while males and females have similar mixtures, the probability of an animal's detection varies with sex as well as time. The third model that performed well $(\Pi(),. \mathrm{pa}(\mathrm{t})=\mathrm{ca}(\mathrm{t})+\mathrm{x}=\mathrm{pb}(\mathrm{t})+\mathrm{z}=$ $\operatorname{cb}(\mathrm{t})+\mathrm{x}+\mathrm{z})$ is the simplest of the time, behavior and heterogeneity models that was tested. This model differs from the most preferred model by exhibiting an additive difference between initial capture probability and the probability of recapture.

Because the model comparisons for bout 4 as well as other trapping bouts suggests there is a high degree of model uncertainty, abundance estimates for this and other bouts were generated using model averaging unless otherwise indicated (Appendix 3). The abundance estimate for adult females during bout 4 is 72 ( 95 percent confidence interval for the weighted average estimate is 62 to 82 ) (See Figure 2). The abundance estimate for adult males during bout 4 is 84
( $95 \% \mathrm{CI}$ is 72 to 96 ). As 63 and 73 animals of each sex, respectively, were marked during this sampling period, this suggests that that a majority of PPM on the grid were detected during the six nights of sampling.

Figure 2: Grid A PPM Abundance by Bout

For the June trapping period (bout 5), the presence of juveniles as well as adults of each sex allowed for application of the complete candidate model set. In this instance, the preferred model is a time, behavior and heterogeneity model that uses age to help explain variability in capture probability ( $\Pi$ (age), $\mathrm{pa}(\mathrm{t})=\mathrm{ca}(\mathrm{t})+\mathrm{x}=\mathrm{pb}(\mathrm{t})+\mathrm{z}=\mathrm{cb}(\mathrm{t})+\mathrm{x}+\mathrm{z})$ (See Appendix 1). This model suggests the probability of capture and recapture varies with time, that there is an additive difference between the probability of initial capture and the probability of recapture, and that there are different mixtures among age classes. Based on the time of sampling, the probability of initial capture for difficult to detect animals was estimated to vary between 0.08 and 0.20 , and their probability of recapture was estimated to vary between 0.20 and 0.33 . Similarly, the probability of initial capture for easy to detect animals varied between 0.47 and 0.72 and their probability of recapture varied between 0.72 and 0.83 (Appendix 2). The parameter $\Pi$ was estimated to be 0.3 ( $95 \%$ CI 0.19 to 0.45 ) for adults and 0.59 ( $95 \%$ CI 0.45 to 0.72 ) for juveniles. This indicates that the pattern of detectability for adults and juveniles differed, with a majority of adult animals being behaviorally easier to detect and a majority of juveniles comprising the more difficult to detect grouping.

As with bout 4 , the model comparisons revealed some model uncertainty during bout 5 , with an
alternative time, behavior and heterogeneity model ( $\Pi$ (age), pa(age +t$)=\mathrm{ca}(\mathrm{age}+\mathrm{t})+\mathrm{x}=$ $\mathrm{pb}(\mathrm{age}+\mathrm{t})+\mathrm{z}=\mathrm{cb}(\operatorname{age}+\mathrm{t})+\mathrm{x}+\mathrm{z})$ falling within two AICc values (Appendix 1). This model only differs from the most preferred model through the use of age as well as time to help explain variability in capture and recapture probabilities. The model averaged abundance estimates also were close in value to the number of animals that were marked on the grid during this trapping bout suggesting that a majority of animals on the grid were captured during the six nights of sampling. However, relative to adults there were broader confidence intervals associated with abundance estimates for juvenile animals of each gender (See Figure 2).

For the August trapping period (bout 6) the most preferred model is the simplest of the behavior and heterogeneity models that were tested ( $\Pi(),. \mathrm{pa}()=.\mathrm{ca}()+\mathrm{x}=.\mathrm{pb}()+\mathrm{z}=.\mathrm{cb}()+\mathrm{x}+\mathrm{z}$.$) (Appendix$ 1). This model suggests there are two mixtures of capture probabilities irrespective of sex and age, and there is an additive difference between the probability of initial capture and the probability of recapture. Difficult to detect animals were estimated to have an initial capture probability of $0.30(95 \%$ CI 0.18 to 0.47$)$ and a recapture probability of $0.42(95 \% \mathrm{CI} 0.28$ to $0.58)$. Easy to detect animals were estimated to have an initial capture probability of $0.79(95 \%$ CI 0.68 to 0.87 ) and a recapture probability of 0.87 ( $95 \% \mathrm{CI} 0.79$ to 0.91 ) (Appendix 2). In this instance, a majority of animals fell in the easier to detect grouping ( $\Pi=0.64,95 \% \mathrm{CI} 0.44$ to $0.80)$.

As with the prior bouts, the model comparisons suggest there is a high degree of model uncertainty, with four alternative behavior and heterogeneity models falling within two AICc values of the most preferred model (Appendix 1). These models suggest different mixtures of capture probabilities could exist among the different sexes $(\Pi($ sex $), \mathrm{pa}()=.\mathrm{ca}()+\mathrm{x}=.\mathrm{pb}()$. $+\mathrm{z}=\mathrm{cb}()+\mathrm{x}+$.z ) or different age classes ( $\Pi$ (age), $\mathrm{pa}()=.\mathrm{ca}()+\mathrm{x}=.\mathrm{pb}()+\mathrm{z}=.\mathrm{cb}()+\mathrm{x}+\mathrm{z}$.$) or that$ capture probability varies with sex $(\Pi(),. \mathrm{pa}(\operatorname{sex})=\mathrm{ca}(\operatorname{sex})+\mathrm{x}=\mathrm{pb}(\operatorname{sex})+\mathrm{z}=\mathrm{cb}(\operatorname{sex})+\mathrm{x}+\mathrm{z})$ or age $(\Pi(),. \mathrm{pa}($ age $)=\mathrm{ca}($ age $)+\mathrm{x}=\mathrm{pb}($ age $)+\mathrm{z}=\mathrm{cb}($ age $)+\mathrm{x}+\mathrm{z}$ ). All four of the alternative models estimate one more parameter than the most preferred model, and are constructed with a single additive difference that is associated with either sex or age. These models all calculate very similar abundance estimates revealing that the calculated differences in detection probability among the models for each sex and age class is small in magnitude (Appendix 3). A comparison of the calculated detection probabilities among models reveals that the detection probabilities varied across of a range of 0.04 , which is well within the 95 percent confidence interval of all of the model estimates.

Compared to bouts 4 and 5, the model averaged abundance estimates for each sex and age class detected during bout 6 fell closest to the number of individuals that were marked during that bout. These abundance estimates also had relatively narrow confidence intervals (Figure 2). This suggests that the six nights of sampling during bout six was also very effective at detecting a majority of animals on the grid.

During the September sampling period (bout 7), extremely low capture rates relative to prior sampling periods led investigators to halt trapping after just four nights. Because only 20
individuals were detected over 2400 trap nights, and no juveniles were detected, it was apparent that PPM on Grid A had started to go into seasonal dormancy prior to the start of the sampling period. Thus, bout 7 had the sparsest data for estimation of model parameters.

Although the candidate model set had already been culled to 26 possible models based on the lack of juveniles, program MARK did a poor job of estimating parameters for most models, and parameter estimates were often unrealistic (e.g. detection probabilities of $10^{-4}$ ) with zero standard errors and/or confidence intervals that were bound by zero and one. Despite the seemingly poor performance of many of the selected models, models with unrealistic or meaningless parameter estimates were sometimes ranked highly in the model comparisons. Further complicating interpretation of the table of model comparisons, highly parameterized time models that did poorly at estimating $p$ values for a number of capture occasions sometimes appeared to generate reasonable derived parameter abundance estimates (i.e. in the vicinity of the actual number of animals detected) with non-zero standard errors.

However, because data sparseness led investigators to have very low confidence in the model based point estimates, particularly for the more complex models incorporating time as a factor, investigators chose to post-hoc delete all models that appeared to generate unrealistic real parameter estimates even if the derived abundance estimates appeared reasonable. This resulted in the elimination of most models that incorporate time as a factor and resulted in the loss of several models that ranked highly in the initial model comparisons

Of the models that were retained, the most preferred model for bout 7 was the simplest of the behavior and heterogeneity models $(\Pi(),. \mathrm{pa}()=.\mathrm{ca}()+\mathrm{x}=.\mathrm{pb}()+\mathrm{z}=.\mathrm{cb}()+\mathrm{x}+$.z ) (Appendix 1). No other models fell within 2 AICc units of this model.

This model requires the estimation of 4 parameters and is the same model that was most preferred during the August trapping bout. It suggests there are two mixtures of capture probabilities irrespective of sex and age, and there is also an additive difference between the probability of initial capture and the probability of recapture. It estimated that difficult to detect animals had an initial capture probability of 0.03 ( $95 \%$ CI 0.0 to 0.3 ) and a recapture probability of 0.24 ( $95 \%$ CI 0.04 to 0.74 ). Easy to detect animals were estimated to have an initial capture probability of 0.58 ( $95 \%$ CI 0.23 to 0.87 ) and a recapture probability of 0.94 ( $95 \%$ CI 0.53 to 1.0 ) (Appendix 2). A majority of animals were estimated to fall within the hard to detect grouping ( $\Pi=0.66,95 \%$ CI 0.27 to 0.91 ). The derived abundance estimate for adult females was 10 ( $95 \%$ CI 8 to 24) and the abundance estimate for males was 19 ( $95 \%$ CI 14 to 39). However, the broad confidence intervals for estimated detection probabilities, which include probabilities abutting zero and one, and broad confidence intervals surrounding $\Pi$ reveal that this model has poor precision and may be pushing the limits of what the bout 7 data is capable of supporting.

Because heterogeneity models are not thought to be well supported by closed capture-recapture studies with four or fewer sampling periods, it is worth comparing this model's results with the
best ranking model that did not incorporate heterogeneity. The best ranking non-heterogeneity model differed in ranking by 3.2 AICc units and is a simple two parameter behavior model ( $\mathrm{p}($.$) ,$ $\mathrm{c}($.$) ), which estimates independent likelihoods of first capture (p) and recapture (c) that are the$ same for each sex. This model estimated the probability of initial capture to be 0.46 ( $95 \% \mathrm{CI}$ 0.24 to 0.70 ) and the probability of recapture as 0.75 ( $95 \%$ CI 0.60 to 0.86 ). The derived abundance estimate for adult females was $8(95 \%$ CI 7 to 13$)$ and the abundance estimate for males was 14 ( $95 \%$ CI 13 to 22). Hence, the better supported behavior and heterogeneity model had broader confidence intervals around the abundance estimate than did the simple behavior model. Figure 2 depicts the weighted model average abundance estimates and associated confidence intervals for adult males and females.

## Grid D

Seven rodent species were detected on trapping Grid D between June and September of 2004 (See Table 5). Three species, cactus mouse, San Diego pocket mouse and desert woodrat were only detected during one trapping bout. Only one individual of two of those species, San Diego pocket mouse and desert woodrat was ever detected on the grid. With the exception of house mouse, which was detected on Grid A in trace numbers but not detected on Grid D, the two trapping grids appear to support the same complement of species. However, capture rates reveal that Grid D supports lower numbers of non-target species than Grid A, and some of the species may only reside on Grid D on an intermittent basis.

Table 5
Total Number of Captures by Species on Grid D

| GRID D | Bout |  |  |  |  |  |
| :--- | :--- | ---: | ---: | ---: | ---: | ---: |
| Common Name | Scientific Name | $4^{*}$ | 5 | $6 * *$ | 7 | TOTAL |
| Cactus mouse | Peromyscus eremicus |  |  | - | 5 | 5 |
| White-footed deer mouse | Peromyscus maniculatus |  | 16 | - | 6 | 22 |
| Western harvest mouse | Reithrodontomys mega lotus |  | 125 | - | 46 | 171 |
| California pocket mouse | Chaetodipus californicus | 72 | - | 34 | 106 |  |
| San Diego pocket mouse | Chaetodipus fallax |  | 1 | - |  | 1 |
| Pacific pocket mouse | Perognathus longimembris pacificus | 734 | 780 | - | 80 | 1594 |
| Desert woodrat | Neotoma lepida |  |  | - | 1 | 1 |
| TOTAL |  | 734 | 994 | - | 172 | 1900 |

* Non-target species data for bout 4 has yet to be entered into the computer database.
** Grid D was not trapped during Bout 6 .
As on Grid A, PPM were the most frequently captured animals on Grid D. Table 6 details the number of unique PPM by age and sex class that were marked and contributed to the capture totals for each trapping bout.

Table 6
Number of Unique PPM Captured on Grid D

| Grid D | Bout |  |  |  |
| :--- | :--- | :--- | :--- | :--- |
|  | 4 | 5 | 6 | 7 |
| Adult Females | 75 | 72 | - | 7 |
| Juvenile |  | 28 | - | 0 |
| Females | 0 | 78 | - | 13 |
| Adult Males | 98 | - | 0 |  |
| Juvenile Males | 0 | 228 | - | 20 |
| TOTAL |  | 780 | - | 80 |
| INDIVIDUALS | 173 |  |  |  |
| TOTAL | 734 |  |  |  |
| CAPTURES | 734 |  |  |  |

Consistent with Grid A, juvenile animals were not detected during the April and September trapping bouts, and PPM capture rates were extremely low during September. Similarly, pregnant females were only detected during the April and June sampling periods. Thus, across Oscar One it appears that animals were initiating reproduction in April and had likely concluded reproduction and started to enter dormancy by the end of September.

Interestingly, during the first night of trapping in April there was an extremely skewed sex ratio with only one female among 51 PPM that were captured. Consistent with this observation, the model that best fit the trapping data for the April trapping period (bout 4) was a behavior and heterogeneity model that included sex as an explanatory variable [ $\Pi$ (sex), $\mathrm{pa}(\operatorname{sex})=\mathrm{ca}(\mathrm{sex})+\mathrm{x}$ $=\mathrm{pb}(\operatorname{sex})+\mathrm{z}=\mathrm{cb}(\operatorname{sex})+\mathrm{x}+\mathrm{z}]($ See Appendix 4). This model suggests there are different proportions of easy to detect and hard to detect animals among the sexes, the different sexes have different detection probabilities, and there is an additive difference between the probability of initial capture and the probability of recapture.

This model estimates that difficult to detect females had an initial capture probability of 0.11 $(95 \% \mathrm{CI} 0.07$ to 0.18$)$ and a recapture probability of 0.20 ( $95 \% \mathrm{CI} 0.14$ to 0.29 ). Easy to detect females were estimated to have an initial capture probability of $0.49(95 \% \mathrm{CI} 0.33$ to 0.66$)$ and a recapture probability of $0.65(95 \%$ CI 0.51 to 0.78$)$. Difficult to detect males were estimated to have an initial capture probability of $0.16(95 \%$ CI 0.11 to 0.23$)$ and a recapture probability of $0.28(95 \%$ CI 0.22 to 0.35$)$. Easy to detect males were estimated to have an initial capture probability of $0.59(95 \%$ CI 0.48 to 0.70$)$ and a recapture probability of $0.74(95 \%$ CI 0.66 to 0.81 ) (Appendix 5). A majority of females fell in the difficult to detect grouping ( $\Pi=0.9,95 \%$ CI 0.66 to 0.98 ) as did a majority of males ( $\Pi=0.6,95 \%$ CI 0.45 to 0.73 ).

One other behavior and heterogeneity model $[\Pi(\operatorname{sex}), \mathrm{pa}()=.\mathrm{ca}()+\mathrm{x}=.\mathrm{pb}()+\mathrm{z}=.\mathrm{cb}()+\mathrm{x}+\mathrm{z}$.$] fell$
within 2 AICc units of the most preferred model suggesting it supported the data equally well (Appendix 4). This model also suggests that there are different mixtures among the sexes but it differed from the above model through the assumption that males and females have equivalent initial capture and recapture probabilities.

The model averaged abundance estimate for adult females was $100(95 \%$ CI 75 to 126$)$ and for adult males was 109 ( $95 \%$ CI 98 to 121)(Appendix 6, Figure 3). Despite 10 consecutive nights of trapping during this bout, comparison of these estimates with the number of unique animals that were captured ( 75 females and 98 males) suggests that there were still a number of animals that went undetected.

Figure 3: Grid D PPM Abundance by Bout

The model that best fit the trapping data for the June trapping period (bout 5) was a time and heterogeneity model ( $\Pi$ (age), $\mathrm{pa}($ age +t$)=\mathrm{ca}($ age +t$)=\mathrm{pb}(\mathrm{age}+\mathrm{t})+\mathrm{z}=\mathrm{cb}($ age +t$)+\mathrm{z})$ (Appendix 4). This model suggests there are different proportions of hard to detect and easy to detect animals among the age classes and that capture probability varies with both time and age. Depending on capture occasion, this model estimated that difficult to detect adult capture probabilities varied between 0.35 to 0.54 . Easy to detect adult capture probabilities varied over time between 0.87 to 0.93 . Difficult to detect juvenile capture probabilities were estimated to vary between 0.20 to 0.35 and easy to detect juvenile capture probabilities varied between 0.75 to 0.87 (Appendix 5). A slight majority of adults fell in the difficult to detect grouping ( $\Pi=0.54,95 \%$ CI 0.31 to 0.75 )
while almost one-fourth more juveniles were estimated to be difficult to detect ( $\Pi=0.78$, $95 \% \mathrm{CI}$ 0.62 to 0.88 ).

Among all of the trapping bouts on both grids there appears to be the greatest model uncertainty for this bout's data, with five other candidate models falling within 2 AICc values of the most preferred model (See Appendix 4). Like the most preferred model, three of the alternative models are time and heterogeneity models and the remaining two alternative models are time, behavior and heterogeneity models. Other than differences among initial capture and recapture probabilities, the chief factor that differed among the models was how three animal groupings (age, sex and age combined, or no grouping) were used to explain variability among mixtures or among detection probabilities.

The derived abundance estimates for bout 5 estimated there were 52 adult females ( $95 \%$ CI 47 to 57), 30 adult males ( $95 \%$ CI 25 to 35 ), 86 juvenile females ( $95 \%$ CI 67 to 105 ), and 96 juvenile males ( $95 \%$ CI 74 to 118) on the grid ( Appendix 6, Figure 3). As 50 and 28 unique adult females and adult males, respectively, were captured on the grid, these estimates closely matched the number of adult animals that were seen. However, as for bout 5 data on grid A, there were broader confidence intervals associated with abundance estimates for juvenile animals of each gender, and the estimates were further from the number of animals that were observed. This reflects the lower detection probabilities and greater proportion of animals with low detection probabilities that were estimated for juvenile animals (Appendix 5).

As on Grid A, very few animals were encountered during the September sampling period (bout 7), resulting in sparse data for estimation of model parameters. Therefore, as described above for Grid A, individual model outputs were reviewed and all models that appeared to generate unrealistic parameter estimates were post-hoc deleted from the model set on the basis that there was insufficient data to support estimation of those parameters.

Interestingly, despite continuation of trapping on Grid D for six days, in contrast to the four days that were implemented on Grid A, none of the heterogeneity models were retained within 2 AICc values of the most preferred behavioral model $[\mathrm{p}(),. \mathrm{c}()$.$] . This relatively simple two parameter$ behavioral model estimated a very low initial capture probability of 0.08 with a broad $95 \%$ confidence interval from 0.0 to 0.67 . It estimated recapture probability to be $0.62(95 \% \mathrm{CI} 0.48$ to 0.74 ) (Appendix 5). The broad confidence interval associated with initial capture probability suggests that even the most preferred model performed poorly, which is reflected in the broad confidence intervals associated with the derived abundance estimates for adult males 17 ( $95 \% \mathrm{CI}$ 8 to 133 ) and adult females 32 ( $95 \%$ CI 14 to 243). Because no other models ranked highly, model averaging was not used to generate the derived abundance estimates depicted in Figure 3.

## Discussion

This report focuses on a single year of data collected as part of a longer term demographic study of the Pacific pocket mouse population within the Oscar One training area on Marine Corps Base Camp Pendleton. The long term study has a number of goals that include refinement of sampling methods to obtain statistically robust abundance estimates, performing baseline sampling to understand natural population variability, and obtaining estimates of life history variables of importance to population management efforts (e.g. recruitment, survivorship, migration). Because some of these topics are best addressed through analysis of the more comprehensive data set, the following concentrates on closed capture-recapture analysis of 2004 data as well as other conclusions or suggestions that can be drawn from 2004 field observations.

## Periods of Activity

Based on studies of a similar sized species of Perognathus in the Great Basin, O'Farrell et al. (1975) observed that individual components of the population had brief periods of activity above ground on an annual basis. Once they commenced above ground activities the Great Basin pocket mice ( $P$. parvus) were trappable for an average of 60 days during years of adequate food supplies and an average of 90 days during years that food was scarce. However, during productive years, trapping late in the year primarily captured subadults that were produced from late litters, and animals captured earlier in the year had already ceased surface activity (O'Farrell et al. 1975). In laboratory trials, French (1977) observed that PELO stopped foraging even when food was always made available to them, suggesting that mice stay below ground once reproduction is completed and sufficient food stores are accumulated. This pattern of brief periods of above ground activity among components of the population appears consistent with age class data and qualitative observations of PPM on the monitoring grids.

However, as mentioned in the Materials and Methods section, upon capture PPM were only assigned to two age classes because investigators did not feel that subadults could be reliably discerned from adults based on pelage. Since only very young animals were assigned a juvenile age class, animals that were identified as juveniles during earlier trapping bouts were classified as adults during subsequent bouts. From a reproductive perspective this methodology is likely meaningful because $P$. longimembris become sexually mature at 41 days of age and can breed in their natal year during favorable conditions (Brylski 1993; French et al. 1974; Hayden et al. 1966). Observations within Oscar One during 2003 also confirm that PPM will engage in reproductive behavior and give birth within the same year that they are born (USFWS Unpublished data). However, the failure to identify animals as subadults or otherwise indicate that they are young of the year at the time of capture may obscure patterns that may otherwise be evident from more detailed age class information. Future reports will focus closely on individual capture histories to verify that the pattern suggested by O'Farrell et al. (1975) is observable in PPM.

Other subspecies of Perognathus longimembris associated with desert environments are reported to breed only once in the Spring between the months of April and June, though occasionally they may extend the breeding season and produce two litters in a year (Chew and Butterworth 1964; Cramer and Chapman 1990; Flake and Jorgensen 1969; French et al. 1967; Meserve 1972;
O'Farrell et al. 1975; Kenagy and Bartholomew 1985). Pregnant females were observed on the grids during the April, June and August sampling periods. Because juvenile animals were not detected in April, it appears that PPM may initiate breeding activity at the same time of year as desert subspecies. Observations of pregnant females during the August sampling period may suggest that the relatively benign coastal climate at Camp Pendleton allows PPM to sustain a longer period of reproductive activity than desert subspecies.

However, on Grid A, several females were observed to be pregnant during more than one sampling period. Gestation for Perognathus longimembris is reported to last for 23 days and young are weaned after 30 days (Hayden et al. 1966). Trapping bouts 4,5 and 6 were spaced about 50 days apart from one another. Based on the timing of the birth of their first litters, it is both possible and likely that these females produced at least two litters during 2004. Thus, as has been observed on occasion for desert subspecies, 2004 may have been a year of high resource availability that allowed some mice to produce more than one litter during that year. Although late reproduction was also observed in 2003 (USFWS Unpublished data), additional population monitoring will be necessary to determine whether this is common or an unusual occurrence for PPM.

## Closed Capture-Recapture Analysis

The closed capture-recapture analysis reveals that the 600-trap sampling protocol implemented on Grids A and D was effective at generating closed population abundance estimates with reasonably precise confidence intervals during most trapping periods. In most instances the abundance estimates were also fairly close in value to the number of unique animals that were captured during a sampling period, revealing that the high intensity trapping protocol is effective at capturing a majority, but not all, animals that are present.

Although the statistical models generated reasonably precise abundance estimates, model comparisons revealed there was quite a bit of model uncertainty for most bouts, with several competing models often receiving near equal support. Preferred models included models that combined the effects of time and heterogeneity; behavior and heterogeneity; and time, behavior and heterogeneity. However, model selection varied within grids among bouts and among grids within bouts. This suggests that each of the three factors, time, behavior and heterogeneity, are likely to influence PPM capture probability, but their relative importance may vary with capture occasion and possibly location.

In most instances, models that received near equal support were of the same general type. For
instance, the four models that ranked highly in the model comparisons for Bout 6, Grid A were all versions of a behavior and heterogeneity model. In that instance the models differed from one another depending on whether the mixtures were modeled as a function of age or sex or whether age or sex was modeled as an explanatory variable for detection probability. The equal support for these models and a comparison of parameter estimates reveals that the modeled differences were often of little magnitude and had little impact on the derived abundance estimates.

With the exception of the September trapping bout on Grid D, when there were problems with data sparseness, the preferred models invariably provided support for individual heterogeneity in capture probability. This heterogeneity was modeled as two groups, or mixtures, with relatively homogenous detection probabilities; one comprised of individuals that are easy to detect and the other with animals that are hard to detect. Although for most trapping bouts and animal groupings the relative proportion of hard to detect animals was greater than easy to detect animals, there was a greater proportion of easy to detect adults on Grid A during the June trapping bout. Additionally, among all groups there were more easy to detect animals estimated within the population in August.

That initial capture probability was found to vary with time, and the relative proportion of easy to detect and hard to detect animals was found to vary with trapping bout suggests that further analysis of the Oscar One population monitoring data will be needed to optimize survey protocols for PPM.

## Population Trends

The within season trend on Grid A was an increase in animal abundance from April to June, a moderate decrease in the population size from June to August, and a sharp decline in the number of animals estimated to be in the population in late September (Figures 2). Grid D exhibited the same pattern with the exception that the August trapping bout was not implemented on Grid D, so there is no information regarding Grid D's population size during that sampling period (Figure 3).

Since PPM go below ground and become dormant during the fall and winter months (McCloskey 1972, Meserve 1976a, Meserve 1976b), the sharp decline in abundance on both grids in late September is likely attributable to the on-set of seasonal dormancy. If this is the case, then dormant individuals can be regarded as having "temporarily emigrated" (sensu Kendall and Nichols 1995, Kendall et al. 1997 ) from the population by going below ground. It would then follow that the closed population estimate for September represents that proportion of the population that has remained active above ground and available for capture. Depending on the rate at which animals are entering dormancy, it is also possible that the loss of individuals from the population during the sampling interval could violate the assumption of population closure on which the statistical algorithms are based. Combined with the sparse data obtained during this sampling interval this could have contributed to the instability of many of the statistical
models for this trapping bout.
A closer examination of the population trends on the grids between April and June reveals a significant decrease in the number of adults between April and June. Thus, the increase in total abundance on the grids in June is attributable to the appearance of juveniles. Examining the population trends on Grid A between June and August reveals a significant increase in the number of adults in August and the near disappearance of juveniles from the Grid during this interval. This bi-modal trend in abundance for adults and unimodal peak for juveniles is consistent with the observations of O'Farrell et al. (1975) for P. parvus in the Great Basin, where animals captured late in the year were primarily subadults that were produced from late litters. As discussed above, since animals were only classified as adults or juveniles at the time of capture, the increase in adults during August appears to be primarily attributable to the maturation of juveniles detected during the prior bout. Thus, it appears likely that, similar to $P$. parvus, individual components of the PPM population exhibit brief periods of activity above ground on an annual basis. This suggests that late season population estimates, in particular, should be regarded as estimates of the number of individuals that remain above ground and available for capture, rather than as a true estimate of the number of animals that reside within the trapping grid.

By extension this may have implications for the interpretation of data on the relative proportions of males and females in the population. For all but one trapping bout on one grid (Bout 5, Grid D), the point estimates for abundance showed slightly fewer females than males in the population (See Figures 2 and 3). However, the confidence intervals associated with these estimates indicate that there is no discernible difference in the ratio of males to females.

For Bout 5 Grid D there were more adult females than adult males detected in the population. However, if different cohorts have different periods of above ground activity, this difference could be attributable to different patterns of survivorship among males and females or could mean that adult males had started to conclude breeding activity by the June sampling period and were beginning to reduce their above ground activity by this time.

## Management Recommendations

1. Incorporate the above analysis into a broader analysis of the Oscar One PPM monitoring data that involves the application of both open and closed population statistical abundance and survivorship estimates. This analysis should include an analysis of animal movement data for the purpose of extrapolating animal abundances into population densities.
2. Explore the possibility of implementing more frequent but less intensive population monitoring across the period of activity for PPM to better understand the period of activity for different aged cohorts within the population.

March 26, 2007
3. Work with the Marine Corps to incorporate a spatially explicit sampling scheme into PPM monitoring programs to better understand the dynamics and status of each PPM population across their entire distribution.
