Dear Mr. Clipperton and Department Officials:

This message constitutes the first of several correspondences that will contain supporting materials for our comments to the Department for consideration as part of its CESA status review for the Northern Spotted Owl.

Please note that our comments will be delivered later today. Also please note that we will not be delivering referenced-items that we believe the Department already has access to from other sources.

Thank you for your attention. Please do not hesitate to contact me at either of the numbers provided below as necessary.

Short-term effects of wildfires on spotted owl survival, site fidelity, mate fidelity, and reproductive success

Monica L. Bond, R. J. Gutiérrez, Alan B. Franklin, William S. LaHaye, Christopher A. May, and Mark E. Seamans

Abstract The effects of wildfire on wildlife are important considerations for resource managers because of recent interest in the role of fire in shaping forested landscapes in the western United States. This is particularly true of wildfire effects on spotted owls (*Strix occidentalis*) because of the uncertainty of impacts of controlled burning within spotted owl habitat. Therefore, we documented minimum survival, site fidelity, mate fidelity, and reproductive success for 21 spotted owls after large (>540 ha) wildfires occurred within 11 owl territories in California, Arizona, and New Mexico. In each territory, fire burned through the nest and primary roost sites. Eighteen owls (86%) were known to be alive at least 1 year after the fires, which was similar to reported annual adult survival probabilities for the species. Of 7 pairs of which both members were later resighted, all were located together on the same territories during the breeding season following fires, and 4 pairs produced a total of 7 fledglings. No pair separations were observed after fire. On 8 territories where fire severities were mapped, 50% experienced predominantly low- to moderate-severity fires while 50% experienced high-severity fires that burned large (>30%) areas of the territories. We hypothesize that wildfires may have little short-term impact on survival, site fidelity, mate fidelity, and reproductive success of spotted owls. Further, prescribed burning could be an effective tool in restoring habitat to natural conditions with minimal short-term impact on resident spotted owls. While we do not advocate wholesale prescribed burning in spotted owl territories at this time, we believe our observations justify large-scale experiments on effects of prescribed burning on spotted owls to corroborate our observations and to establish cause-and-effect relationships.

Key words prescribed burning, spotted owl, *Strix occidentalis*, wildfire

Wildfire is a natural process that has shaped the character of western forests (Agee 1990). In many areas, pre-settlement fire regimes consisted of frequent low-severity fires at 5–30-year intervals (Kilgore 1973, Horton and Mannan 1988, Weatherspoon et al. 1992, MacCracken et al. 1996). In central and southern California, the Southwest, and eastern slopes of the Cascades, low-severity fires created a mosaic of uneven- and even-aged forest stands (Kilgore 1973, Horton and Mannan 1988,

MacCracken et al. 1996). In northwestern California, the xeric end of the Pacific Northwest rainforest, fire frequency occurred at about 20-year intervals and the fire regime was more similar to southwestern than other northwestern regions (Agee 1990, 1993). However, western forests were not immune to higher-severity wildfires, which occurred infrequently and were patchy in nature (Stephenson et al. 1991, MacCracken et al. 1996). Therefore, both low- and high-severity fires have had significant impacts on forest structure, composition, and distribution. Risk of high-severity wildfires associated with drought, insect and disease epidemics, and global warming has increased significantly in the western United States following decades of fire suppression (Agee 1993).

Many studies have been conducted on indirect impacts of wildfire on bird populations (e.g., Marshall 1963, Biswell 1989). Indirect impacts include changes in vegetation type, canopy closure, and relative food abundance, which influence local densities of birds (Kilgore 1973, Horton and Mannan 1988). In addition to indirect effects, direct mortality of birds due to fire has been assumed or suspected (Robbins and Myers 1992, Smith 2000). Further, avian lungs may be more susceptible to damage from smoke exposure than mammalian lungs because of an apparent inability of the avian respiratory tract to repair itself (Rombout et al. 1991). While nest destruction caused by fires has been reported for some ground-nesting birds in North Dakota (Robbins and Myers 1992), few studies have examined avian mortality and behavior directly following fire (McMahon and deCalesta 1990).

Some biologists assume that large wildfires negatively impact long-term survival of the spotted owl (*Strix occidentalis*; e.g., Weatherspoon et al. 1992, MacCracken et al. 1996), and believe catastrophic or "stand-replacement" fires, which kill all vegetation within the fire boundary, pose the greatest natural risk to spotted owl habitat (United States Fish and Wildlife Service [USFWS] 1992, 1995; Verner et al. 1992). Management plans generally recommend reducing risk of catastrophic fire in forests occupied by spotted owls (e.g., Verner et al. 1992). One method of reducing risk of wildfire is the use of prescribed fire to remove fuels that can facilitate surface fires becoming crown fires (Biswell 1989). Because northern (*S. o. caurina*) and Mexican spotted owls (*S. o. lucida*) are federally listed as threatened subspecies, prescribed fires within owl areas require consultation with the USFWS. USFWS smoke and wildlife guidelines for prescribed burning currently exist for site-preparation of clearcut units located near northern spotted owl Habitat Conservation Areas (HCAs), but some agency biologists have proposed prescribed burns within northern spotted owl HCAs (J. Perkins, United States Forest Service [USFS], Klamath National Forest, unpublished report). Because of uncertainty over fire effects on owls, controlled burning as a habitat management tool is not conducted routinely within areas reserved for spotted owls. For example, researchers have examined occupancy of spotted owl territories in years following a wildfire (Elliot 1985, MacCracken et al. 1996, Gaines et al. 1997, Scott 1998, Jenness 2000), but short-term impacts on individuals could not be assessed because owls were not color-marked.

We describe minimum survival, site fidelity, mate fidelity, and reproductive success of color-marked spotted owls after wildfires burned nest and roost areas in northwestern California, southern California, Arizona, and New Mexico. After a fire occurred within an owl territory, we posed 4 questions:

1. Did the owl(s) survive the fire (minimum survival)?
2. If an owl survived, was it found in the same territory after the fire (site fidelity)?
3. If both members of a pair survived a fire, did they retain the same mates (mate fidelity)?
4. If both members of a pair survived a fire, did they nest successfully the year after the fire (reproductive success)?

Direct observations of fire effects on spotted owls are difficult to obtain because of the patchy and infrequent (due to fire suppression) nature of fire, and logistical or political limitations associated with conducting fire experiments on a meaningful scale. Nevertheless, we provide insight on short-term effects of fire on spotted owls by presenting observations gathered during 15 years of study throughout a large portion of the species' range.

Study areas

We recorded spotted owl responses to fires >540 ha that occurred on 4 long-term demographic study areas, representing all 3 subspecies of the owl. Study areas were located in northwestern California (292 km^2, 1985–2000, northern spotted owl);

San Bernardino Mountains, southern California (1,890 km^2, 1987–2000, California spotted owl [*S. o. occidentalis*]); Tularosa Mountains, New Mexico (323 km^2, 1991–2000, Mexican spotted owl); and Coconino Plateau, Arizona (585 km^2, 1991–2000, Mexican spotted owl).

Forests in northwestern California were primarily mixed evergreen (Sawyer et al. 1988), dominated by Douglas-fir (*Pseudotsuga menziesii*) with a hardwood subcanopy of madrone (*Arbutus menziesii*), tanoak (*Lithocarpus densiflora*), and canyon live oak (*Quercus chrysolepis*) below 1,200 m elevation. Above 1,200 m, forests were mainly subalpine forests (Sawyer and Thornburgh 1988) dominated by white fir (*Abies concolor*) and pines (*Pinus* spp.). Forests in the San Bernardino Mountains consisted of mixed evergreens (Sawyer et al. 1988) below 1,500 m, and ponderosa pine (*P. ponderosa*) and white fir-sugar pine (*P. lambertiana*) forests (Thorne 1988) above 1,500 m. Forests consisted of various combinations of white fir, ponderosa pine, sugar pine, incense-cedar (*Calocedrus decurrens*), and black oak (*Q. kelloggii*) at higher elevations, and canyon live oak and bigcone Douglas-fir (*Pseudotsuga macrocarpa*) at lower elevations. Forests in the Tularosa Mountains were primarily mixed-conifer and pine-oak. Douglas-fir and white fir were the dominant species in mixed-conifer forests. Pine-oak forest was dominated by ponderosa pine and Gambel oak (*Q. gambelii*). Piñon-juniper woodland, dominated by piñon pine (*P. edulis*) and alligator juniper (*Juniperus deppeana*), was an extensive community within the mountain range. Forests on the Coconino Plateau were pine-oak dominated by ponderosa pine and Gambel oak (Peet 2000). Other communities on the plateau included mixed-conifer forest having Douglas-fir, ponderosa pine, and white fir in the overstory and quaking aspen (*Populus tremuloides*) and Gambel oak in the understory; and piñon-juniper woodland dominated by piñon pine and junipers (*Juniperus* spp.; Peet 2000).

Methods

Owl surveys

We surveyed each study area annually for spotted owls during the breeding season from 1985–2001 following methods described by Forsman (1983) and Franklin et al. (1996). We captured adult and juvenile owls using snare poles, noose poles, and mist nets. All captured birds were marked with a locking aluminum USFWS band on 1 leg and a plastic band and tab with a unique color combination on the other leg (Forsman et al. 1996). We determined the sex of owls by calls and behavior (Franklin et al. 1996). Rate of band loss for spotted owls was negligible (Franklin et al. 1996). This project was approved by the University of Minnesota's Animal Care and Use Committee (Animal Subjects Code Number: 0003A42461).

Impacts of fire

We used USFS records of severity, extent, and duration of all fires >540 ha occurring within territories of individually color-marked spotted owls. We limited our study to fires at least this large because home-range sizes of spotted owls range from 422–591 ha in northwestern California (northern spotted owl; Zabel et al. 1995), 415–810 ha in the San Bernardino Mountains (California spotted owl; Zimmerman et al. 2001), and 648 ha in Arizona (Mexican spotted owl; Ganey and Balda 1989). In each case, nest and roost areas were located within the fire perimeter, and all were burned. Detailed information about conditions (e.g., weather condition, fuel moisture, humidity, and fuel load) at owl nests and roosts was unavailable. We used available USFS data to describe the extent of each fire at the landscape and territory scales. At the landscape scale, we obtained the name, season, and year of the fire, as well as total size and duration of each fire. We addressed fire at the territory scale by estimating percent of each individual owl territory that burned, and percent of the fire-affected area in the territory that burned at high, moderate, or low severity. We defined an owl territory as a circle, with a radius of one-half the average nearest neighbor distance for each study area (see Bingham and Noon 1998) around the nest or roost site during the breeding season, at the time of or prior to the fire (northern spotted owl = 710 m [Franklin et al. 2000]; California spotted owl = 748.5 m [Smith et al. 2002]; Mexican spotted owl, AZ = 1,178 m [May 2000]; and NM = 1,060 m [Peery et al. 1999]). To estimate percent of each territory that burned and nest or roost area location within the fire, we overlaid owl territories onto digitized fire maps obtained from the USFS using ArcView GIS 3.2 (Environmental Systems Research Institute 1996).

Fire-severity classifications for each coverage were conducted by each USFS district within which the fire occurred. Coverages were classified as follows: 1987 autumn King Titus fire (24,282 ha) in northwestern California (3 owl territories) into low (<30% canopy kill), moderate (31–70% canopy kill), and high severity (>70% canopy kill); 1995 summer HB fire (5,261 ha) in New Mexico (3 owl territories) into low (≤35% canopy kill) and high (>35% canopy kill) severity; 1987 autumn Cold fire (4,876 ha) in northwestern California (1 owl territory) into high (small and subcanopy trees killed, and many to most overstory trees killed) and moderate (most small trees killed, some subcanopy trees killed or heavily damaged, and occasional mortality of overstory trees) severity; and 1996 spring Pot fire (2,833 ha) in Arizona (1 owl territory) into crown ("standing black sticks" with no live trees), high (>70% crown scorch of standing overstory trees), medium (30–70% crown scorch of standing overstory trees), and low/underburn (<30% scorch of standing overstory trees or generally on flanks or heel of fire area). Severity on the King Titus and HB fires was estimated using aerial photography; satellite imagery was also used on the HB fire. The Cold fire severity was estimated from ground surveys. The Pot fire map was developed using satellite imagery followed by ground verification. Unfortunately, USFS GIS data for the remaining 3 summer fires in southern California (Verbena, 1995 [9,308 ha], Mill, 1997 [541 ha], Willow, 1999 [25,091 ha]) portrayed only boundaries. We recognized that a boundary may be over-simplified, but severity maps for these fires were unavailable. We did not include more detailed pre- and post-fire habitat information in our analysis because our study focused on short-term effects of fire on survival and movements of owls rather than long-term habitat changes. No salvage logging or other major anthropogenic changes to vegetation within owl territories occurred between the time of the fire and the time we surveyed owls the following year.

We qualitatively described impacts of fire on survival, site fidelity, mate fidelity, and reproductive success of individuals and pairs because these were opportunistic observations taken over a long period of time. We pooled data across subspecies because sample sizes for each subspecies were small (≤4 territories) and we were describing observational responses rather than conducting comparative statistical analyses. We defined minimum survival rate as percent of individuals resighted alive at least 1 year after the fire ($n=21$ owls). We defined site fidelity as percent of individuals resighted alive within the same territory before the fire occurred and 1 year after the fire occurred ($n=$ 18 owls). We defined mate fidelity as percent of pairs that survived the fire ($n=7$ owl pairs) and both original pair members remained together (i.e., resighted in same territory as a social pair) 1 year after the fire occurred. Our evaluation of mate fidelity does not imply cause and effect if a pair-bond was broken. Rather, we interpreted it to mean only that a fire did not mediate a pair dissolution if they remained together. Reproductive success was defined as average number of fledglings per pair of owls that survived ($n=7$ owl pairs) 1 year after the fire occurred.

We compared overall estimates of annual adult spotted owl survival and reproductive success for each study area from our previous research (W. S. LaHaye, unpublished data; Seamans et al. 1999, Franklin et al. 2000) with qualitative findings from this study. Our previous survival estimates were based on mark-recapture estimators, whereas fire survival estimates were empirical estimates from a small sample size. Therefore, confidence limits for empirical estimates did not reflect uncertainty due to recapture probability. We compared short-term (1-year) reproductive success of owls surviving fires with general rates of owl reproduction. However, caution must be used when drawing conclusions about reproduction because spotted owl reproduction was more variable than survival and differences from overall averages could have been due to annual variation rather than effects of fire.

We also estimated overall annual site fidelity for each study area based on long-term data. We calculated annual site fidelity by dividing number of owls remaining on territories from year t to year t+1 by total number of owls surviving from year t to year t+1. Only banded, adult owls were used in site-fidelity calculations.

Results

Data were gathered from 4 study areas representing 38 observation years, >2,000 banded owls, >300 owl territories, and 7 wildfires. Wildfires occurred in 11 spotted owl territories (10 pairs and 1 single owl) during the period of investigation (1985–2001). Fires occurred in 4 northern, 3 California, and 4 Mexican spotted owl territories. All territories were >80% burned (83–100%). In all cases, nest and roost areas were burned. Four of 8 territories where fire severities were mapped burned primarily at low to moderate severity. However, the remaining 4 territories experienced fires that burned 36–88% of the territory at high-severity levels.

Eighteen of 21 (86%) individual owls affected by fires were resighted at least 1 year after the fires, and 16 of the 18 (89%) resighted owls were located in the same territories in the breeding season after the fire. Among 7 owl pairs in which both members were resighted after a fire, all were site- and mate-faithful. Among 3 individuals whose mates were never resighted, 2 females were resighted after the fire on different territories with different males, and 1 male exhibited site fidelity after the fire but was found paired with a different female. Four of 7 surviving owl pairs (57%) produced 7 fledglings the year following fire.

Minimum survival of spotted owls experiencing fires was similar to overall annual survival rates reported for the 3 subspecies (Table 1). Site fidelity among fire-impacted birds was also similar to overall estimates from the 4 demographic studies (Table 1). Reproductive success of spotted owls 1 year after fire occurred was higher than overall annual rates of reproduction (Table 1).

Discussion

Results from previous studies on impacts of wildfires on spotted owls have been equivocal. In some cases, large stand-replacing wildfires appeared to have a negative impact on owl occupancy (Elliot 1985, MacCracken et al. 1996, Gaines et al. 1997). Other reports have suggested that low- to moderate-severity wildfires did not adversely impact spotted owls (Yasuda 1997, Scott 1998, Jenness 2000). Although high-severity fires may displace some owls from territories (Elliot 1985, Gaines et al. 1997), it was unknown whether birds moved or died because owls in these studies were not marked. Since we monitored fates of color-marked owls, we could derive modest inference on effects of fire on individual survival, site fidelity, mate fidelity, and reproductive success. In our study, fates of only 3 of 21 owls exposed to fire were unknown. Relatively large wildfires that burned nest and roost areas appeared to have little short-term effect on survival, site fidelity, mate fidelity, and reproductive success of spotted owls, as rates were similar to estimates independent of fire. While post-fire reproductive rates were higher than background rates for these populations, they were well within the range of variation seen in these populations. Most (6 of 8) territories burned ≥50% at low to moderate severity. Therefore, we hypothesize that spotted owls may have the ability to withstand the immediate, short-term (1-year) effects of fire occurring at primarily low to moderate severities within their territory.

Horton and Mannan (1988) noted that animals that occupied forests having frequent fire intervals

Table 1. Estimates (95% confidence intervals) of minimum post-fire survival, site fidelity, and average number of fledglings per pair for 21 spotted owls (*Strix occidentalis*) that experienced fire in their territories in northwestern California, southern California, Arizona, and New Mexico, compared with overall average annual survival, site fidelity, and average number of fledglings per pair for the 4 populations at the above locations, 1987–2001.

		Estimates

[a] Northwestern California: survival estimate from 1985–1998 (source: Franklin et al. 2000). Site fidelity estimate from 1985–2000; n = 42–68 owls per year for 15 years. Reproduction estimate from 1985–2001; n = 1019 pair observations.

[b] Southern California: survival estimate from 1987–1998 (source: W. S. LaHaye, unpublished data). Site fidelity estimate from 1987–1998; n = 35–93 owls per year for 11 years. Reproduction estimate from 1987–1998; n = 840 pair observations.

[c] New Mexico: survival estimate from 1991–1997 (source: Seamans et al. 1999). Site fidelity estimate from 1991–2000; n = 21–41 owls per year for 10 years. Reproduction estimate from 1991–2001; n = 203 pair observations.

[d] Arizona: survival estimate from 1991–1997 (source: Seamans et al. 1999). Site fidelity estimate from 1991–2000; n = 19–36 owls per year for 10 years. Reproduction estimate from 1991–2001; n = 241 pair observations.

should be adapted to repeated fires. While pre-settlement fire regimes of western forests consisted of frequent low-intensity burns, infrequent high-severity fires also occurred and were important determinants of forest structure, composition, and distribution (Agee 1990, Stephenson et al. 1991). Given historical fire regimes within its range, the spotted owl may be adapted to survive wildfires of various sizes and severities. Therefore, prescribed burning could be an effective tool in reducing current fire risk and restoring forests to natural conditions with minimal short-term impact to owls. However, we believe that programmatic prescribed burning in spotted owl territories cannot be justified solely on the observations we report here. Experiments testing effects of fire on spotted owls are still needed to corroborate the effects we observed, establish cause-and-effect relationships, and determine long-term impacts on spotted owls.

Acknowledgments. We thank the following United States Forest Service Ranger Districts for information on wildfires: Mountain Top (San Bernardino National Forest), Hayfork (Shasta-Trinity National Forest), and Happy Camp (Klamath National Forest), California; Reserve (Gila National Forest), New Mexico; and Long Valley (Coconino National Forest), Arizona. J. Anderson, R. Armstrong, C. Beyerhelm, J. Fox, B. Greco, R. Hall, M. Kolu, S. Redar, and S. Vaughn were particularly helpful in securing data on fires. We also thank J. Hunter for valuable advice, as well as numerous research assistants for collecting field data. Funding for this study was provided by the USDA Forest Service (contract #FS53-91S8-00-EC14 to RJG) and the University of Minnesota.

ABSTRACT The northern spotted owl (*Strix occidentalis caurina*) is one of the most intensively studied raptors in the world; however, little is known about the impacts of wildfire on the subspecies and how they use recently burned areas. Three large-scale wildfires in southwest Oregon provided an opportunity to investigate the short-term impacts of wildfire and salvage logging on site occupancy of spotted owls. We used Program MARK to develop single-species, multiple-season models of site occupancy using data collected during demographic surveys of spotted owl territories. In our first analysis, we compared occupancy dynamics of spotted owl nesting territories before (1992–2002) and after the Timbered Rock burn (2003–2006) to a reference area in the south Cascade Mountains that was not affected recently by wildfire. We found that the South Cascades had greater colonization probabilities than Timbered Rock before and after wildfire ($\hat{\beta} = 1.31$, 95% CI = 0.60–2.03), and colonization probabilities declined over time at both areas ($\hat{\beta} = -0.06$, 95% CI = -0.12 to 0.00). Extinction probabilities were greater at South Cascades than at Timbered Rock prior to the burn ($\hat{\beta} = 0.69$, 95% CI = 0.23–2.62); however, Timbered Rock had greater extinction probabilities following wildfire ($\hat{\beta} = 1.46$, 95% CI = 0.29–2.62). The Timbered Rock and South Cascades study areas had similar patterns in site occupancy prior to the Timbered Rock burn (1992–2001). Furthermore, Timbered Rock had a 64% reduction in site occupancy following wildfire (2003–2006) in contrast to a 25% reduction in site occupancy at South Cascades during the same time period. This suggested that the combined effects of habitat disturbances due to wildfire and subsequent salvage logging on private lands negatively affected site occupancy by spotted owls. In our second analysis, we investigated the relationship between wildfire, salvage logging, and occupancy of spotted owl territories at the Biscuit, Quartz, and Timbered Rock burns from 2003 to 2006. Extinction probabilities increased as the combined area of early seral forests, high severity burn, and salvage logging increased within the core nesting areas ($\hat{\beta} = 1.88$, 95% CI = 0.10–3.66). We were unable to identify any relationships between initial occupancy or colonization probabilities and the habitat covariates that we considered in our analysis where the β coefficient did not overlap zero. We concluded that site occupancy of spotted owl nesting territories declined in the short-term following wildfire, and habitat modification and loss due to past timber harvest, high severity fire, and salvage logging jointly contributed to declines in site occupancy.

KEY WORDS colonization, extinction, northern spotted owl, occupancy, salvage logging, site occupancy, southwest Oregon, *Strix occidentalis caurina*, wildfire.

Northern spotted owls (*Strix occidentalis caurina*, hereafter spotted owl) are a medium sized, forest-dwelling owl with high levels of mate and site fidelity (Forsman et al. 1984, 2002; Thomas et al. 1990; Zimmerman et al. 2007). Nesting territories of spotted owls have greater proportions of mature and older forest than surrounding landscapes (Ripple et al. 1991, 1997; Meyer et al. 1998; Swindle et al. 1999). Forest stands used by spotted owls have large proportions of downed woody debris and snags, high canopy cover and high structural diversity (Hershey et al. 1998, North et al. 1999, Irwin et al. 2000). The features that provide structural complexity within spotted owl habitat also serve as ladder fuels that increase the likelihood of stand-replacing wildfire (Agee 1993, Wright and Agee 2004). As a result, forest stands that provide favorable habitat conditions for spotted owls within dry forest ecosystems are at risk of stand-replacing wildfire (Agee 1993, Agee et al. 2000). Presently, wildfire is the leading cause of spotted owl habitat modification on

[1]*E-mail: darren.clark@oregonstate.edu*

federally administered lands, and the rate of habitat modification due to wildfire within dry forest ecosystems has exceeded predictions (Davis and Lint 2005). Consequently, the viability of owl populations in dry forests has been questioned (Spies et al. 2006), and wildfire has been identified as a threat to the persistence of spotted owls occupying dry forest ecosystems (U.S. Fish and Wildlife Service [USFWS] 2011).

Despite the perceived threat of wildfire, little is known about the effects of wildfire on spotted owls, and the hypothesized effects come from research conducted in unburned landscapes. Numerous studies have documented that spotted owl survival, reproduction (Franklin et al. 2000, Olson et al. 2004, Dugger et al. 2005), and territory occupancy (Blakesley et al. 2005, Dugger et al. 2011) were positively associated with increased amounts of late-successional forest within their core use areas or home range. Furthermore, owl territories with large reductions in the amount of older forest will have low reproduction or be abandoned (Bart and Forsman 1992, Bart 1995). These studies suggest that loss of older forests negatively affects spotted owls; however, the response of spotted owls to high severity fire and subsequent harvest of dead standing trees is unknown. Conversely, survival rates of spotted owls were greater at territories that were not entirely composed of late-successional forests (Franklin et al. 2000, Olson et al. 2004), which suggests that spotted owls may be adapted to natural disturbances such as wildfire that create a mosaic of forest conditions. Territory occupancy and nest success of spotted owls decreased as the amount of the territory composed of clear-cuts increased (Thraillkill et al. 1998), which suggests widespread post-fire salvage logging may negatively affect spotted owls.

The few studies that have been conducted on spotted owls in burned landscapes have provided equivocal results regarding the effects of wildfire on the species. Lack of consensus between studies may be owing to the confounding effects of salvage logging, the short-term nature of studies, small sample sizes from which to draw inference, treating the effect of fire as a binomial variable (i.e., burned or unburned), or potentially different responses of the 3 subspecies of spotted owls to wildfire. Radio-marked northern and California spotted owls (*Strix occidentalis occidentalis*) used forest stands that burned with low to high severities (Clark 2007, Bond et al. 2009); however, survival rates of radio-marked northern spotted owls occupying a burned area that was subsequently salvage logged were less than others reported throughout the subspecies' range (Clark et al. 2011). Conversely, short-term (<1 yr) survival rates of northern, Mexican (*Strix occidentalis lucida*), and California spotted owls in burned landscapes that were not subjected to post-fire salvage logging were similar to annual survival rates (Bond et al. 2002). The number of reproductive spotted owl pairs and the number of occupied spotted owl territories declined 1 year post-fire on the eastern slope of the Washington Cascade Range (Gaines et al. 1997); however, only 6 territories were surveyed in this study, 1 of which had a large amount of stand-replacing fire. Other studies indicate low and moderate severity burns may have minimal impacts on spotted owls. Territory occupancy of Mexican spotted owls in burned areas was similar to unburned areas (Jenness et al. 2004). Probability of territory occupancy for California spotted owls in the Sierra Nevada Mountains of California were similar between randomly selected burned and unburned sites (Roberts et al. 2011).

Because spotted owls are territorial and have high site fidelity (Forsman et al. 2002, Zimmerman et al. 2007), occupancy of nesting territories is essential for successful survival and reproduction. Occupancy models (MacKenzie et al. 2003, 2006) are well suited for investigating territory occupancy by spotted owls because the structure of existing spotted owl surveys (Franklin et al. 1996) fits the model framework well. Furthermore, occupancy models allow the inclusion of site-specific covariates, which allows the investigation of fire severity and habitat influences on site occupancy dynamics (i.e., extinction and colonization rates). The Biscuit, Quartz, and Timbered Rock burns in southwest Oregon provided an opportunity to investigate the impacts of wildfire and subsequent salvage logging on site occupancy by spotted owls. Our first objective was to determine if occupancy rates changed substantially following wildfire and subsequent salvage logging when compared to pre-burn occupancy rates and to occupancy rates in a landscape that had not been recently affected by wildfire. We met this objective by comparing occupancy rates of spotted owls before (1992–2002) and after (2003–2006) the Timbered Rock burn to an adjacent unburned landscape in the southern Oregon Cascades. We predicted that occupancy rates of spotted owls would be similar between study areas prior to the Timbered Rock burn but occupancy rates would decline substantially following the Timbered Rock burn in response to modification and loss of owl habitat from wildfire and subsequent salvage logging. Our second objective was to model the impacts of fire severity, salvage logging, and habitat characteristics on site occupancy of spotted owls at the Biscuit, Quartz, and Timbered Rock burns from 2003 to 2006. We predicted that extinction probabilities would increase as the amounts of past timber harvest, high severity burn, and salvage logging within a territory increased. We also predicted that initial occupancy and colonization probabilities within the 3 burned areas would be greater at territories with decreased levels of disturbance. In particular, we predicted that initial occupancy and colonization probabilities within the 3 burned areas would be greater at territories that had more intermediate-aged and older forest that burned with low or moderate severities.

STUDY AREA

We studied site occupancy by spotted owls at the Biscuit, Quartz, and Timbered Rock burns in southwest Oregon. Each burn was located within a distinct geographic region: the mid-Coastal Siskiyou Mountains (Biscuit burn), the Siskiyou Mountains (Quartz burn), and the southern Oregon Cascades (Timbered Rock burn). We also analyzed site occupancy of spotted owls at the South Cascades Demographic Study Area, which was adjacent to the

Timbered Rock burn and was not affected by a large scale wildfire within the last 100 years. Consequently, site occupancy by spotted owls in this area served as a reference for comparison to the Timbered Rock study area.

Common tree species within our study areas included ponderosa pine (*Pinus ponderosa*), sugar pine (*P. lambertiana*), Douglas-fir (*Pseudotsuga menziesii*), incense cedar (*Calocedrus decurrens*), white fir (*Abies concolor*), California red fir (*A. magnifica)*, mountain hemlock (*Tsuga mertensiana*), Oregon white oak (*Quercus garryana*), California black oak (*Q. kelloggii*), tanoak (*Lithocarpus densiflorus*), and Pacific madrone (*Arbutus menziesii*). Prior to the implementation of active fire suppression policies by state and federal agencies, most of southwest Oregon was characterized by frequent low-intensity fires and occasional stand-replacing fires at higher elevations (Agee 1993, Taylor and Skinner 1997, Heyerdahl et al. 2001). After active fire suppression policies were implemented, fire frequencies declined and high-intensity wildfires became more common (Agee 1993, Agee and Skinner 2005). The climate regime in southwest Oregon is characteristically temperate with hot, dry summers and cool, moist winters. During our study, the warmest and coldest average daily temperatures occurred in July (21° C) and December (4° C), respectively. Average annual rainfall was lowest at the Quartz burn (66 cm) and highest at the Biscuit burn (113 cm; Oregon Climate Service, Oregon State University, unpublished data).

The Biscuit burn originated from several lightning strikes in July 2002. The small fires eventually merged into a complex fire that covered 201,436 ha. Land ownership within the burn was predominantly public (U.S. Forest Service [USFS], Bureau of Land Management [BLM], Oregon Department of Forestry [ODF], and Josephine County). Fifty documented spotted owl territories were within the burn. We non-randomly selected a sample of 9 territories on the eastern side of the burn to include in our study that were similar to forest types at the Timbered Rock and Quartz burns and provided reasonable access. The 9 territories included in this study were located within the Briggs Creek, Silver Creek, Deer Creek, and Illinois River watersheds, ranging in elevation from 300 to 1,400 m. The remaining 41 territories were not included in our study because of logistical concerns or because they were located in mesic forest types on the western side of the burn. The 9 study territories were surveyed annually from 2003 to 2006. The area within 2.2 km of the 9 study territories burned with a mixed severity and received the least amount of salvage logging of the 3 burns (Table 1).

The Quartz burn was ignited by lightning in August 2001 and burned 2,484 ha of public (USFS, BLM, and ODF) and private (primarily industrial forest) lands. The fire burned portions of the Glade Creek, Little Applegate, and Yale Creek watersheds at elevations ranging from 600 to 1,850 m. The fire completely or partially burned (i.e., burned the majority of a 2.2-km buffer around the territory center) 9 spotted owl territories. All 9 territories were surveyed annually from 2003 to 2006. The study area burned with a mosaic of fire severities and was subjected to substantial amounts of salvage logging, primarily on private lands (Table 1).

The Timbered Rock burn was ignited by lightning in July 2002 and burned 11,028 ha of land within the Elk Creek watershed at elevations ranging from 450 to 1,350 m. Land ownership was dominated by a checkerboard pattern of public (BLM) and private industrial forest lands in the southern two-thirds of the burn and contiguous USFS managed lands in the northern third. Twenty-two spotted owl territories were within the burn perimeter and were surveyed annually from 2003 to 2006. These 22 territories were also surveyed prior to the burn from 1992 to 2002. The study area burned with a mixed severity and much of the private land was salvage logged (Table 1).

The South Cascades Demographic Study Area (South Cascades) is 1 of 8 study areas included in the range-wide monitoring program for spotted owls (Lint et al. 1999, Anthony et al. 2006), and it served as a reference area for our analyses. From 1992 to 2006, surveys to locate spotted owls were consistently conducted on an annual basis at 103 spotted owl territories by the Oregon Cooperative Fish and Wildlife Research Unit (OCFWRU). The South Cascades area encompasses approximately 223,000 ha of lands managed by the USFS at the southern terminus of the Oregon Cascades and at elevations ranging from 900 to 2,000 m. No large-scale wildfires occurred within the study area from 1992 to 2006. Forest conditions have been influenced historically by mixed-severity wildfire and more recently by forest management, livestock grazing, and fire suppression. Forest management has included individual tree selection, stand thinning, and even-aged management (U.S. Department of Agriculture [USDA] 1997, 1998). Current management activities are guided by the objectives set forth by the Land-use Allocations of the Northwest Forest Plan.

Table 1. The percentage (±SE) early seral, intermediate-aged or older forest that burned with a low, moderate, or high severity or was salvage logged within 2,230 m of 40 northern spotted owl territories at the Biscuit, Quartz, and Timbered Rock burns in southwest, Oregon, USA from 2003 to 2006.

		Intermediate-aged or older forests			
Study area	**Non-forest or early seral**	**Low severity**[a]	**Moderate severity**[b]	**High severity**[c]	**Salvage logged**[d]
Biscuit	27.2 ± 6.1	40.5 ± 6.7	13.6 ± 1.8	17.1 ± 3.6	1.6 ± 0.7
Timbered Rock	27.8 ± 1.6	35.9 ± 4.1	10.1 ± 0.7	9.3 ± 1.4	16.9 ± 3.2
Quartz	21.7 ± 1.5	48.5 ± 4.4	6.6 ± 1.5	10.0 ± 2.3	13.2 ± 2.7

[a] ≤20% of the forest canopy removed by wildfire.
[b] 21–70% of the forest canopy removed by wildfire.
[c] >70% of the forest canopy removed by wildfire.
[d] Areas that were intermediate-aged or older forest prior to the burn that were salvage logged.

The main purpose of matrix lands is timber production, whereas the late-succesional reserves are for conservation of older forests and silvicultural treatments are intended to promote forest stand structures similar to historical conditions or old forest characteristics (USDA and U.S. Department of the Interior [USDI] 1994).

METHODS

Data Acquisition and Preparation

To assess the effects of wildfire on occupancy of spotted owl territories, we created post-fire habitat maps in ArcGIS 9.1 (ESRI, Redlands, CA) by merging 3 data layers: 1) a pre-fire habitat map (Davis and Lint 2005), 2) a fire severity map, and 3) the boundaries of salvage logged areas (see Clark 2007 for additional details). The final map output had 8 distinct habitat classes (Table 2) and a minimum mapping unit of 2 ha. We used ground plot data to calculate map accuracies, which we estimated to be 68% for the Timbered Rock burn, 69% for the Biscuit burn, and 75% for the Quartz burn. Seventeen of 20 (85%) classification errors at the Biscuit burn, 10 of 15 (67%) at the Quartz burn, and 11 of 22 (50%) at the Timbered Rock burn were within 1 habitat or fire severity class of the correct classification. Based on these estimates, overall map accuracy within 1 habitat or fire severity class was 95% at the Biscuit burn, 92% at the Quartz burn, and 84% at the Timbered Rock burn (Clark 2007).

We conducted annual surveys between 1 March and 31 August to determine the occupancy of spotted owls on nesting territories according to established survey protocols (Franklin et al. 1996) and Oregon State University, Institutional Animal Care and Use Committee guidelines (IACUC Number 3040). Post-fire surveys were conducted as a collaborative effort between the OCFWRU, the BLM, the USFS, and private timber companies. From 1992 to 2006, we surveyed 22 and 103 territories at the Timbered Rock and South Cascades study areas, respectively. We also surveyed 9 territories at both the Biscuit and Quartz burns from 2003 to 2006. The average number of visits conducted varied by study area and year (range: 1.9 [Timbered Rock 2002]–5.8 [Timbered Rock 1994]). The maximum number of surveys at individual spotted owl territories ranged from 7 to 9 depending on the year. The variability in survey effort was a function of occupancy and nesting status (i.e., territories that were occupied by a pair of non-nesting owls were visited less). Occasionally, some territories were not surveyed every year, which was most often because of limited access during years of high snowfall. Fortunately, differences in survey effort and missing observations can easily be accounted for in open population models if you assume that occupancy dynamics are the same at territories that are and are not surveyed (MacKenzie et al. 2006), which is a reasonable assumption as long as survey effort is unbiased.

We used results from demographic surveys to create site-specific detection histories for owl pairs. Owl pairs represent the appropriate ecological unit of interest when modeling site occupancy. Protocols for adapting survey data from spotted owls using methods outlined in Franklin et al. (1996) to fit an occupancy modeling framework were established by Olson et al. (2005). These protocols were used in subsequent occupancy analyses for spotted owls (Kroll et al. 2010, Dugger et al. 2011) and this analysis. If a pair of owls was detected, we coded the visit as a 1 and if 1 or no owls were detected, we coded the visit as a 0. However, if 1 owl was detected and the owl exhibited nesting behavior (e.g., the owl was observed on a nest) or if young were observed with an adult owl, we coded the visit as a 1. If a survey was not conducted, we coded the visit as a missing observation (·). A hypothetical detection history of 10.1 would indicate that a pair of owls was detected on the first and fourth surveys, no owls or a single owl was detected on the second survey, and the territory was not visited during the third survey.

Data Analyses

Basic modeling procedures.—We estimated site occupancy in Program MARK (White and Burnham 1999) using single-species, multiple-season models (MacKenzie et al. 2003, 2006). This analysis generated estimates of 4 parameters: Ψ, the probability that a site is occupied in the first year of the study (initial occupancy); ε, the probability an occupied site became unoccupied the subsequent year (extinction); γ, the probability an unoccupied site was occupied the subsequent year (colonization); and P, the probability of detection (detection). In our analyses, primary sampling occasions were years and secondary sampling occasions were visits to

Table 2. Definitions of habitats used in the assessment of the impacts of wildfire and salvage logging on northern spotted owl site occupancy at the Biscuit, Quartz, and Timbered Rock burns in southwest Oregon, USA, from 2003 to 2006.

Habitat class	Description
Early seral	Non-forested areas, early seral, and pole sized conifer stands
Intermediate forest[a]—low severity burn	Intermediate-aged conifer stands with ≤20% of the canopy removed by fire
Intermediate forest—moderate severity burn	Intermediate-aged conifer stands with 21–70% of the canopy removed by fire
Older forest[b]—low severity burn	Older conifer forest with ≤20% of the canopy removed by fire
Older forest—moderate severity burn	Older conifer forest with 21–70% of the canopy removed by fire
High severity	Intermediate-aged and older conifer forests with >70% of the canopy removed by fire
Salvage	Intermediate-aged and older conifer forests that were salvage logged
Edge	The interface between the combined area of intermediate-aged and older forest that burned with a low or moderate severity and all other habitat types

[a] Forest stands that provide suitable roosting and foraging habitat for spotted owls.
[b] Forest stands that provide nesting habitat for spotted owls.

territories within years. This modeling framework was flexible and allowed for time-specific parameter estimates, inclusion of site-specific covariates, the ability to include missing observations, the direct estimation of colonization and extinction, and it assumed detection probabilities were <1 (MacKenzie et al. 2003, 2006).

We modeled the 4 occupancy parameters using a step-wise approach (Olson et al. 2005, MacKenzie et al. 2006, Dugger et al. 2011). We first determined the most parsimonious model for within year detection probabilities followed by among year detection probabilities, retained that model, and then proceeded to model initial occupancy. We then retained the most parsimonious model for initial occupancy and proceeded to model colonization and extinction parameters. We followed the conventions of Lebreton et al. (1992) and White and Burnham (1999) when developing and naming models. We considered several possible temporal effects on detection probabilities both within and among years that included constant detection (·), linear (*T*), log-linear (ln *T*), and quadratic (*TT*) trends. We did not evaluate time-specific models (*t*) within years because they required estimation of too many parameters to obtain reasonable estimates (Olson et al. 2005); however, we considered models that included time-specific effects among years (year). We also considered models that included differences in detection probabilities between study areas, because experience and effort of survey personnel may have differed. We considered 2 initial occupancy models that contrasted differences between study areas (area) and constant initial occupancy (·). When modeling extinction and colonization parameters, we considered models that compared differences between study areas (area) and no differences between areas (·), and we considered several biologically plausible temporal effects including constant rates among years (·), variable rates among years (*t*), and linear (*T*), log-linear (ln *T*), and quadratic (*TT*) trends over time. Models that included $\geq$2 study areas included additive and interactive effects between study area and temporal effects, where appropriate.

We used Akaike's Information Criterion corrected for small sample sizes (AIC_c) and the difference between the AIC_c value of the best model and the *i*th model (ΔAIC_c) to rank and compare candidate models at each step of the analysis. We used Akaike weights to evaluate the strength of evidence for 1 model versus another model (Burnham and Anderson 2002). We considered models that were $\leq$2.0 AIC_c of the best model as competitive. We used estimates of regression coefficients ($\hat{\beta}$) and their 95% confidence intervals to evaluate the relative effect and measure of precision of various covariates in our models. Following the approach outlined by Anthony et al. (2006), we used 95% confidence intervals for the coefficients as a relative measure of support for observed relationships rather than a strict test of the hypothesis that $\beta = 0$. Covariates whose 95% confidence intervals did not overlap 0 had strong evidence for an effect, those that narrowly overlapped 0 had some evidence for an effect, and those that broadly overlapped 0 had little or no evidence for an effect on the parameter of interest. We used this approach because significance testing is not valid under an information theoretical approach (Burnham and Anderson 2002), and it is best to present estimates of effect size and precision under this analysis paradigm (Anderson et al. 2000).

Comparison of South Cascades and Timbered Rock.—We compared occupancy at Timbered Rock and South Cascades from 1992 to 2006. Our objective was to determine if extinction and colonization probabilities following the Timbered Rock burn were different from unburned landscapes in the South Cascades (i.e., the control) during the same time period. In this analysis, we considered all study area and temporal effects on site occupancy parameters that are outlined above in the basic modeling procedures. In addition, we considered 10 models for colonization and extinction that were modifications of common study area and time effect models (Fig. 1). We considered these models because they may identify distinct changes in extinction and colonization rates following a disturbance such as wildfire and subsequent salvage logging. We predicted that under model [Pre-burn(·)Post-burn(area)] the South Cascades and Timbered Rock would have similar, constant extinction probabilities prior to the Timbered Rock burn, but extinction probabilities would be greater at Timbered Rock following the burn. In contrast, we predicted the opposite for colonization probabilities (e.g., under model [Pre-burn(·)Post-burn(area)], colonization rates would be equal at Timbered Rock and South Cascades prior to the Timbered Rock burn, but colonization rates would be less at the Timbered Rock study area following the burn). We retained the best ranked initial occupancy, extinction, colonization, and detection probability models and combined them to determine our best overall model. We used the best overall model to calculate estimates of year-specific probabilities of site occupancy in Program MARK using the equation from MacKenzie et al. (2003):

$$\hat{\Psi}_t = \hat{\Psi}_{t-1}(1 - \hat{\varepsilon}_{t-1}) + (1 - \hat{\Psi}_{t-1})\hat{\gamma}_{t-1}$$

Relationship between wildfire, salvage logging, and spotted owl site occupancy.—We modeled occupancy of nesting territories after fires from 2003 to 2006 at the Biscuit, Quartz, and Timbered Rock burns. Our objective was to model the potential influence of fire severity, salvage logging, and habitat covariates on site occupancy of spotted owls. In this analysis, we used a multiple step approach outlined in previous occupancy analyses for the species (Olson et al. 2005, Dugger et al. 2011). This approach included 3 steps: 1) determine the occupancy model that best described temporal and study area effects, 2) retain the best model from step 1 and model individual covariates to determine the best spatial scale and relationship of the covariate, and 3) retain the best model from step 1 and the best spatial scale and relationship of covariates from step 2 to test specific hypotheses regarding the effects of covariates on site occupancy.

Our first step was to determine the best model that only included study area and temporal effects by following the methods outlined in the basic modeling procedures. Our objective in this step was to develop a base model upon

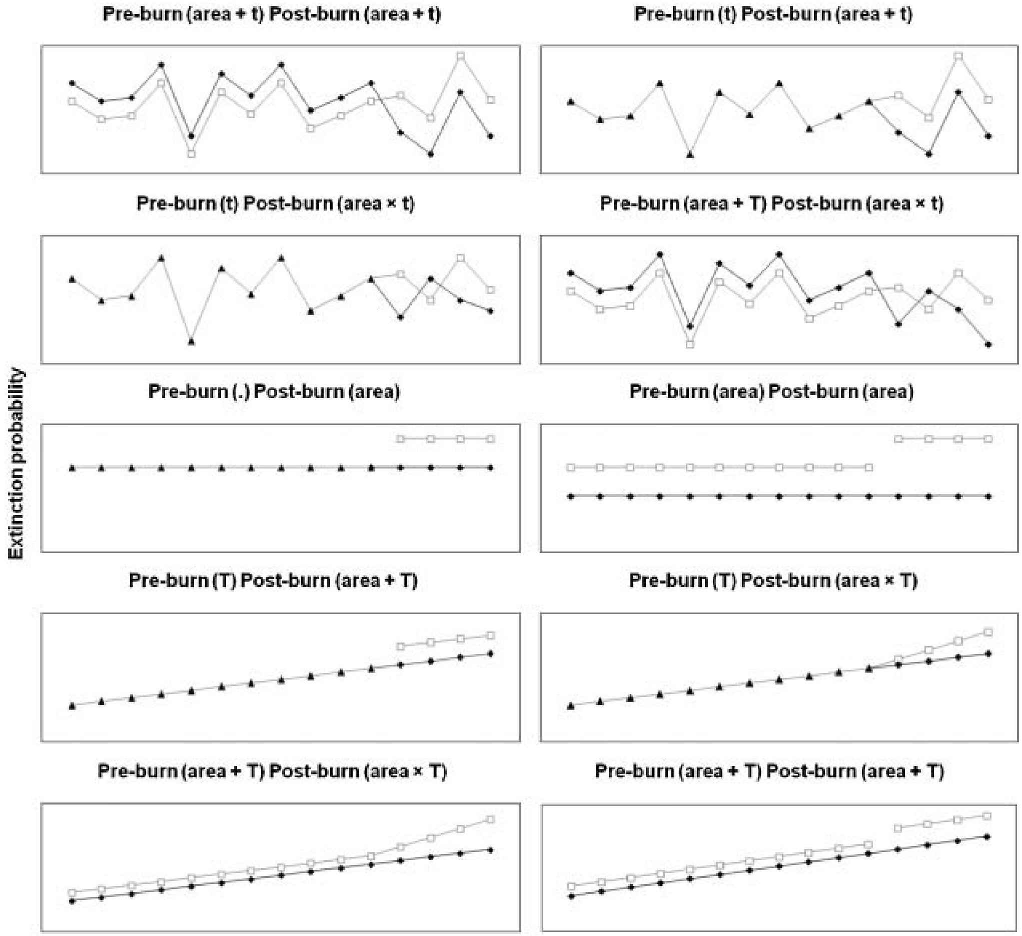

Figure 1. Visual representation of 10 hypothetical models comparing extinction rates of northern spotted owl territories at the Timbered Rock burn and South Cascades Demographic Study Area. We considered models that compared differences between study areas (area) and no differences between areas (·), and we considered several biologically plausible temporal effects including constant rates among years (·), variable rates among years (*t*), and linear (*T*) trends over time. The last 4 intervals represent the predicted changes in extinction probabilities following the Timbered Rock burn. The opposite relationship was predicted for colonization rates. Grey lines with open boxes represent the Timbered Rock study area, black lines with black diamonds represent the South Cascades Demographic Study Area, and gray lines with black triangles represent no differences between study areas.

which we modeled the effects of covariates. We considered all models outlined in the basic modeling procedures and 3 additional study area covariates for initial occupancy, extinction, and colonization models that incorporated various study area combinations including, 1) the Quartz and Timbered Rock burns would have similar occupancy dynamics because they include large amounts of private land (BIS $\neq$ TR $=$ Q), 2) the Timbered Rock and Biscuit burns would have similar occupancy dynamics because they occurred 1 year after the Quartz burn (BIS $=$ TR $\neq$ Q), and 3) the Quartz and Biscuit burns would have similar occupancy dynamics because they are both located in the Siskiyou Mountains (BIS $=$ Q $\neq$ TR). Our primary objective during this portion of the analysis was to develop a parsimonious model on which to model covariates; consequently, we did not consider competing models in this step of the analysis. After determining the best study area and temporal effects model, we retained this model and proceeded to the second step of the analysis.

In the second step of this analysis, our objective was to determine the spatial scale and relationship that best explained the effect of various covariates on initial occupancy, extinction, and colonization probabilities. We calculated site-specific covariates at 2 spatial scales (territory and core area) and with 2 relationships (linear and log-linear), which represented 4 possible models for each covariate. We calculated covariate values in ArcGIS 9.1 from post-fire habitat maps as the percent of each cover type within a 2,230-m radius (1,560 ha; territory scale) and a 730-m radius (167 ha; core area scale) of the territory center. We selected these spatial scales because they were used to model spotted owl survival and reproduction in the same geographic region (Dugger et al. 2005).

For initial occupancy and colonization probabilities, we modeled 9 covariates (Table 3) to determine the best spatial scale and relationship of the covariate. All of the covariates we modeled on initial occupancy and colonization parameters were thought to represent the quality of habitat remaining at the territory and were based on biologically meaningful relationships. Forested areas that burned with a low or moderate severity likely had minimal changes in the amount of canopy cover, snags, and downed woody debris, which are

Table 3. Candidate model sets for initial occupancy, extinction, and colonization parameters in the analysis of covariate effects on site occupancy of northern spotted owls at the Biscuit, Quartz, and Timbered Rock burns in southwest Oregon, USA, from 2003 to 2006.

Initial occupancy (Ψ) and colonization (γ)[a]	Extinction (ε)[b]
INTL + INTM + OLDL + OLDM	EARLY + HIGH + SALVAGE
INTL + OLDL	HIGH + SALVAGE
INT + OLD	HARVEST + HIGH
OLDL + OLDM	EARLY + HISALV
OLDL	HISALV
OLD	HARVEST
LOW + MOD	SALVAGE
LOW	HIGH
EDGE	EARHISALV
	EDGE

[a] INTL, intermediate-aged forest that burned with a low severity; INTM, intermediate-aged forest that burned with a moderate severity; OLDL, older forest that burned with a low severity; OLDM, older forest that burned with a moderate severity; INT, intermediate-aged forest that burned with a low or moderate severity (combined area of INTL and INTM); OLD, older forest that burned with a low or moderate severity (combined area of OLDL and OLDM); LOW, intermediate-aged and older forest that burned with a low severity (combined area of INTL and OLDL); MOD, intermediate-aged and older forest that burned with a moderate severity (combined area of INTM and OLDM); EDGE, the interface between forested areas that burned with low or moderate severity and areas that were early seral stands, burned with high severity, or were salvage logged; EDGE was modeled as an additive effect with the best ranked covariate model to determine if it improved model fit.

[b] EARLY, non-forested areas early seral stands that burned with any severity; HIGH, the combined area of intermediate-aged and older forest that burned with a high severity; SALVAGE, any intermediate-aged or older forest that was salvage logged; HARVEST, any forested area, that was harvested before or after the burn (combined area of EARLY and SALVAGE); HISALV, any forested area, excluding early stands, that burned with a high severity or was salvage logged (combined area of HIGH and SALVAGE); EARHISALV, any early seral stand or forested area that burned with high severity or that was salvage logged (combined area of EARLY, HIGH, and SALVAGE).

all critical components of spotted owl habitat (Hershey et al. 1998, North et al. 1999, Irwin et al. 2000). Intermediate-aged forests contribute to landscape heterogeneity, which influenced spotted owl survival in other studies (Franklin et al. 2000, Olson et al. 2004), so we hypothesized that it would also influence site occupancy by the subspecies. Spotted owl territories usually have high proportions of mature and older forests (Ripple et al. 1991, 1997; Meyer et al. 1998; Swindle et al. 1999), so we expected that initial occupancy and colonization probabilities would be influenced by the amount of older forest within the territory.

We elected to use a different set of covariates on extinction probabilities because of the highly correlated nature of extinction and colonization probabilities (MacKenzie et al. 2006). Modeling the same set of covariates on extinction and colonization parameters can result in counter-intuitive results. This is because sites that went extinct are the sites available for colonization. As a result, factors that contribute to increased extinction probabilities could also contribute to increased colonization probabilities. For extinction models, we modeled 7 covariates (Table 3) to determine the best spatial scale and relationship of the covariate. All of the covariates considered for extinction were thought to be related to the impacts of habitat loss and modification attributable to past timber harvest, high severity fire, and salvage logging. We hypothesized that all 3 of these factors would negatively affect site occupancy. Spotted owl territories that had increased amounts of clear-cut timber harvest had decreased occupancy (Thrailkill et al. 1998). Timber harvest and post-fire salvage commonly results in large-scale clear-cuts; as a result, site occupancy by owls should be negatively affected by these factors. High severity fire removes downed woody debris and reduces canopy cover and structural diversity. All of these factors influence spotted owl habitat selection (Hershey et al. 1998, North et al. 1999, Irwin et al. 2000), so we hypothesized that increased amounts of high severity fire may increase extinction probabilities.

We considered the effects of the amount of edge habitat on initial occupancy, extinction, and colonization probabilities because we suspected edge could have positive or negative impacts on site occupancy. Greater amounts of edge habitat may increase site occupancy by increasing prey availability, particularly woodrats (*Neotoma* spp.), which are common in edge habitats (Zabel et al. 1995, Ward et al. 1998) and are a primary prey item in this portion of the spotted owl's range (Forsman et al. 2004). In contrast, increased amounts of edge habitat may decrease the amount of interior forest available to owls, which has been associated with decreased spotted owl survival (Franklin et al. 2000). To avoid the potential correlation between extinction and colonization parameters (MacKenzie et al. 2006), we only used edge in 1 of the parameters, not both, in the same model. We used edge as an additive effect with the best ranked covariate model for initial occupancy and extinction or colonization to determine if it improved model fit (i.e., decreased the AIC_c value).

We modeled each of the 4 possible models of each covariate individually, as an additive effect, with the best model from the first step of our analysis. We took this approach to reduce redundancy in the potential list of covariates due to spatial scales and relationships of covariates being correlated and to reduce the number of candidate models that would be considered in the final step of the analysis. We ranked each model using AIC_c values to determine the best spatial scale and relationship of each covariate.

The third step of our analysis combined the best individual covariates from the second step of our analysis into more complex models to test a specific set of biologically plausible hypotheses (Table 3). We did not use covariates on detection probabilities because they are nuisance parameters for which we had minimal interest. Our most complex initial occupancy and colonization models included 4 covariates (combinations of intermediate-aged and older forests and low and moderate burn severity; Table 3). Other models were variations of the most complex model that included a subset of these covariates or combined 2 covariates into a single covariate. Our most complex extinction model included 3 covariates (early seral stands, forests with high burn severity, and salvage logged forests; Table 3). The remaining candidate models were variations of the most complex model that had fewer covariates or combined 2 or more covariates into a single covariate. Prior to fitting our candidate model set (Table 3), we looked for correlations between variables that may be included in the same model. We did not include candidate models with highly correlated variables ($r^2 > 0.70$). After determining the best covariate model for initial occupancy, extinction, and colonization probabilities, we retained these models and combined them to determine our best overall model.

RESULTS

Comparison of the South Cascades to Timbered Rock

The best model for detection probabilities was *P* (year + area + ln *T*), and the second ranked model [*P* (year + ln *T*)] was not competitive ($\Delta AIC_c = 13.18$; Table 4). The best model indicated that detection probabilities varied among years, differed between areas, and followed a log-linear time trend within years. Detection probabilities were greater at South Cascades than at Timbered Rock in 10 out of 15 years. In most years (8 out of 15), detection probabilities declined over the survey season, but in the remaining 7 years, detection probabilities increased over the survey season. Detection probabilities during 1 survey over the 15 years of the study varied considerably and ranged from 0.24 to 0.82 at the South Cascades and 0.11–0.79 at Timbered Rock. The range of detection probabilities within years was less variable. The best model for initial occupancy was Ψ (area), and the second ranked model [Ψ(·)] was not competitive ($\Delta AIC_c = 7.21$). The best model indicated that the South Cascades had greater initial occupancy ($\hat{\beta} = 2.21$, 95% CI = 0.65–3.76) than Timbered Rock. We estimated initial occupancy probabilities in 1992 to be 0.94 (95% CI = 0.88–1.00) at South Cascades compared to 0.65 at Timbered Rock (95% CI = 0.44–0.86).

The best model for extinction probabilities was ε[Pre-burn (area + *t*)Post-burn(area + *t*)], and 2 models were highly competitive (i.e., $\Delta AIC_c < 2.0$) with the best extinction model (Table 4). However, model ε[Pre-burn(area + *t*)Post-burn(area + *t*)] had a weight of 0.42, indicating strong support for the best model. Interpretation of the best model was that extinction rates varied by year and study area, but the study areas followed the same pattern over time (Fig. 2). We found some evidence that the South Cascades had greater extinction probabilities than Timbered Rock prior to the burn because the 95% confidence interval barely overlapped 0 ($\hat{\beta} = 0.69$, 95% CI = −0.06 to 1.43). Following wildfire and subsequent salvage logging at the Timbered Rock study area, extinction probabilities were greater than at the South Cascades ($\hat{\beta} = 1.46$, 95% CI = 0.29–2.62; Fig. 2). Model ε[Pre-burn(*t*)Post-burn(area + *t*)] was the second ranked extinction probability model ($\Delta AIC_c = 1.53$; Table 4). This model suggested that extinction probabilities varied by year and the Timbered Rock and the South Cascades study areas had similar extinction probabilities prior to the Timbered Rock burn, but extinction probabilities were greater at Timbered Rock following wildfire and subsequent salvage logging. Model ε (*t*) was the third ranked extinction model ($\Delta AIC_c = 1.84$; Table 4). This model suggested that extinction probabilities varied by year, and the Timbered Rock and South Cascades study areas had similar extinction probabilities before and after the Timbered Rock burn. We did not consider this model further, because the 2 best ranked models had similar interpretations with a combined model weight of

Table 4. Model selection results for extinction (ε), colonization (γ), and detection (*P*) probability models in the analysis of site occupancy of northern spotted owls at the South Cascades Demographic Study Area and the Timbered Rock study Area in southwest Oregon, USA, from 1992 to 2006. We presented only models with an Akaike weight ≥0.01. We considered models that compared differences between study areas (area) and no differences between areas (·), and we considered several biologically plausible temporal effects including constant rates among years (·), variable rates among years (*t*), and linear (*T*), log-linear (ln *T*), and quadratic (*TT*) trends over time. For all extinction, colonization, and detection probability models, the best initial occupancy (Ψ) model was Ψ (area).

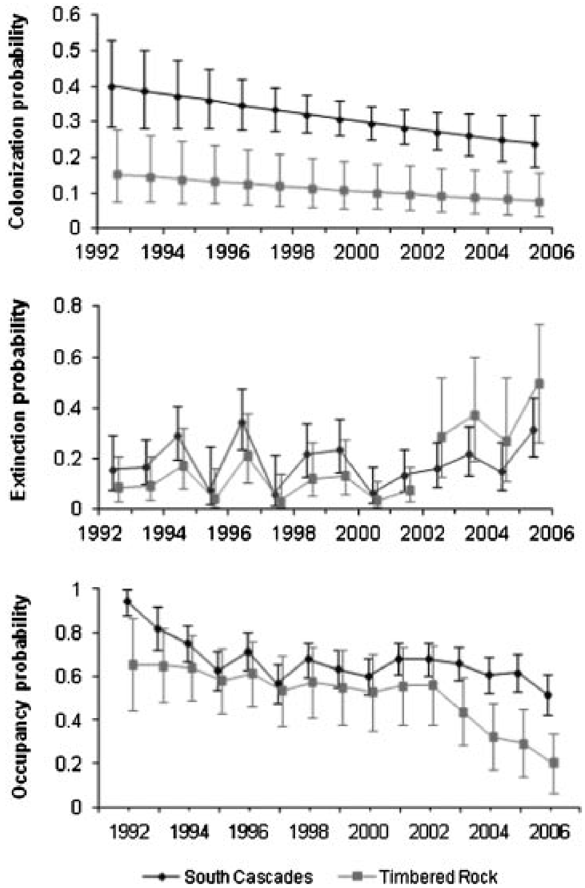

Figure 2. Estimated extinction, colonization, and site occupancy probabilities (95% CI) of northern spotted owls at the Timbered Rock and South Cascades study areas in southwest Oregon, USA from 1992 to 2006.

0.62 and indicated that post-burn, extinction probabilities were greater at Timbered Rock.

The best model for colonization was γ (area + T), and no models were within 2.0 AIC_c units of the best model (Table 4). Model γ (area + T) had a weight of 0.43 indicating strong support for this model. Interpretation of the best model was that colonization probabilities differed between study areas and declined linearly over time. Colonization probabilities were greater at the South Cascades ($\hat{\beta} = 1.31$, 95% CI = 0.60–2.03) than at Timbered Rock and declined over time ($\hat{\beta} = -0.06$, 95% CI = -0.12 to 0.00) at both areas (Fig. 2). Wildfire and salvage logging did not appear to influence post-burn colonization probabilities at Timbered Rock because models that included changes in colonization probabilities following wildfire were not competitive (i.e., $\Delta AIC_c > 2.0$) with the best model (Table 4).

We combined the best ranked models for initial occupancy, extinction, colonization, and detection probabilities to obtain our best overall model (Table 4), which we used to contrast trends in occupancy probabilities over time at the Timbered Rock and South Cascades study areas. We used the best overall model [Ψ(area)ε[Pre-burn(area + t)Post-burn(area + t)]γ(area + T)P(year + area + ln T)] to calculate year-specific occupancy estimates for each study area.

Site occupancy by spotted owls at the South Cascades declined from 1992 to 1994, remained relatively stable from 1995 to 2005, and declined again in 2006 (Fig. 2). In contrast, site occupancy by spotted owls at Timbered Rock declined slightly from 1992 to 2002 and declined in an almost linear fashion from 2003 to 2006, which corresponded to the years following the Timbered Rock burn (Fig. 2). Between 2002 and 2006, the estimated proportion of spotted owl territories occupied by a pair at South Cascades declined from 0.68 to 0.51, a 25% reduction in site occupancy. In contrast, the estimated proportion of spotted owl territories occupied by a pair at Timbered Rock declined from 0.56 to 0.20, a 64% reduction in site occupancy during the same time period. This indicated that occupancy of territories by spotted owls in a recently burned landscape that was subjected to salvage logging declined at a greater rate than in a recently unburned landscape.

Relationship Between Wildfire, Salvage Logging, and Spotted Owl Site Occupancy

Our objective in this portion of the analysis was to determine the best model prior to modeling habitat covariates; consequently, we did not consider any competing models. The best model that described study area and temporal effects on spotted owl site occupancy at the Biscuit, Quartz, and Timbered Rock burns from 2003 to 2006 was $\Psi(\cdot)\varepsilon(\text{BIS} \neq \text{TR} = \text{Q} + T)\gamma(\cdot)P(\cdot)$ (Table 5). Detection probabilities were constant within and among years, and equal between study areas. The probability of detecting a spotted owl pair on any 1 visit was 0.46 (95% CI = 0.39–0.53). The probability of initial occupancy was similar between study areas and was 0.46 (95% CI = 0.30–0.62) in 2003 at all 3 study areas. Colonization probabilities were also similar among study areas and constant over time. The probability that an unoccupied territory would be colonized the subsequent year was 0.15 (95% CI = 0.07–0.26). Extinction probabilities were greater at the Biscuit burn ($\hat{\beta} = 5.58$, 95% CI = 1.25–9.91) than the Quartz and Timbered Rock burns and increased from 2004 to 2006 ($\hat{\beta} = 2.96$, 95% CI = 0.97–4.94) at all 3 study areas. Extinction probabilities at the Quartz and Timbered Rock burns increased from 2004 to 2006 (0.11, 95% CI = 0.03–0.36; 0.72, 95% CI = 0.41–0.90, respectively). In contrast, extinction probabilities increased from 0.37 (95% CI = 0.11–0.73) in 2004 to 0.92 (95% CI = 0.58–0.99) in 2006 at the Biscuit burn. Based on the point estimates, extinction probabilities have increased dramatically for all areas (11–92%).

We modeled individual covariates as an additive effect with the best study area and temporal effects model (Table 5) to determine the spatial scale (core or territory) and relationship (linear or log-linear) that best described the effect of the covariate on initial occupancy, extinction, and colonization parameters (Table 6). In most cases, the models for alternative spatial scales and relationships were competitive (i.e., $\Delta AIC_c < 2.0$) with the best model for each covariate; however, our objective was to reduce redundancy between models and reduce the number of models in the final step of our

Table 5. Model selection results for initial occupancy (Ψ), extinction (ε), colonization (γ), and detection (*P*) probability models in the analysis of site occupancy of northern spotted owls without site-specific covariates at the Biscuit (BIS), Quartz (Q), and Timbered Rock (TR) burns in southwest Oregon, USA, from 2003 to 2006. We presented only models with an Akaike weight ≥0.05. We considered models that compared differences between study areas (area) and no differences between areas (·), and we considered several biologically plausible temporal effects including constant rates among years (·), variable rates among years (*t*), and linear (*T*), log-linear (ln *T*), and quadratic (*TT*) trends over time.

analysis. As a result, we did not consider competing models and assumed the highest ranked model best described the relationship of the covariate on each occupancy parameter. After determining the best spatial scale and relationship of each covariate, we looked for correlations between variables that were included in the same model. None of the variables that were included in the same model were highly correlated ($r^2 < 0.31$ in all contrasts). Consequently, we did not exclude any variables from our candidate model set because of colinearity (Table 3).

Fire severity and habitat effects.—The best model that described the relationship between site occupancy and fire severity, salvage logging, and habitat covariates at the Biscuit, Quartz, and Timbered Rock burns from 2003 to 2006 indicated that initial occupancy was best predicted by intermediate-aged and older forest that burned with a moderate severity at the core scale and amount of edge at the core scale. Extinction was best predicted by early seral stands that burned with high severity or were salvage logged at the core scale and amount of edge at the territory scale with extinction rates differing across time and at Biscuit sites. Colonization was best predicted by intermediate-aged older forests with low and moderate burn severity at the core scale and detection was constant across variables (Table 6). One model was within 2.0 AIC_c units of the best model for extinction probability (Table 6). However, this model was a slight variation of the best model and did not include the covariate representing edge at the territory scale, so it was not considered further because the amount of edge at the territory scale improved model fit. No models competed with the best initial occupancy and colonization probability models (Table 6). The best overall covariate model ranked substantially higher ($\Delta AIC_c = 27.12$) than the model that only included study area and temporal effects (Table 6). This indicated that the covariates used in this model explained some of the variability observed in post-fire site occupancy by spotted owls at the Biscuit, Quartz, and Timbered Rock burns.

Our best initial occupancy model included variables for the amount of low severity burn and edge (km) within the core use area (Table 6). The confidence intervals of the beta coefficients for the amount of low severity burn within the core area ($\hat{\beta} = 0.52$, 95% CI = −0.22 to 1.26) and the amount of edge (km) in the core area ($\hat{\beta} = -0.42$, 95% CI = −0.92 to 0.10) broadly overlapped zero, which indicated that neither of these variables influenced initial occupancy probabilities. Extinction probabilities increased as the combined area that was previously harvested, burned with a high severity, or salvage logged increased ($\hat{\beta} = 1.88$, 95% CI = 0.10–3.66; Fig. 3a). We found some evidence that the amount of edge (km) within a territory had a positive effect on extinction probabilities as the 95% confidence intervals overlapped 0 slightly ($\hat{\beta} = 0.18$, 95% CI = −0.01 to 0.37; Fig. 3b). We found weak support that colonization proba-

Table 6. Initial occupancy (Ψ), extinction (ε), and colonization (γ) models in the analysis of covariate effects on site occupancy of northern spotted owls at the Biscuit (BIS), Quartz (Q), and Timbered Rock (TR) burns in southwest Oregon, USA, from 2003 to 2006. We presented only models with an Akaike weight ≥0.05. For all initial occupancy, extinction, and colonization models the best detection probability model was constant detection among and within years (*P*(·, ·)).

bilities increased as the amount of intermediate-aged forest that burned with a low severity within the core area increased ($\hat{\beta} = 0.10$, 95% CI = −0.01 to 0.38; Fig. 4a) as the amount of older forest that burned with a low severity within the core area increased ($\hat{\beta} = 0.10$, 95% CI = −0.01 to 0.22; Fig. 4b), and as the amount of older forest that burned with a moderate severity within the territory increased ($\hat{\beta} = 0.82$, 95% CI = −0.05–1.69; Fig. 4c). We found no evidence that colonization probabilities were associated with the amount of intermediate-aged forest that burned with a moderate severity within the core area ($\hat{\beta} = -1.20$, 95% CI = −3.21 to 0.80).

DISCUSSION

Comparison of the South Cascades to Timbered Rock

As predicted, the Timbered Rock and South Cascades study areas had relatively similar trends in site occupancy prior to the Timbered Rock burn. However, extinction probabilities increased at Timbered Rock following wildfire and subsequent salvage logging, which combined with the lesser colonization rates at Timbered Rock contributed to greater declines in site occupancy than were observed in recently unburned landscapes at the South Cascades (Fig. 2). The Timbered Rock study area had an approximately 64% reduction in site occupancy following wildfire, whereas the South Cascades study area had a roughly 25% reduction in site occupancy during the same time period. This supported our prediction that occupancy rates in burned and salvage logged landscapes would decline at a greater rate than unburned landscapes. Our results contrast with those of previous studies that compared occupancy rates of spotted owls in burned and unburned landscapes. Jenness et al. (2004) found that territory occupancy of Mexican spotted owls in burned areas was similar to unburned areas. Roberts et al. (2011) found that site occupancy of California spotted owls in randomly selected burned and unburned areas were similar. Neither of these studies was affected by the high degree of salvage logging we observed following the Timbered Rock

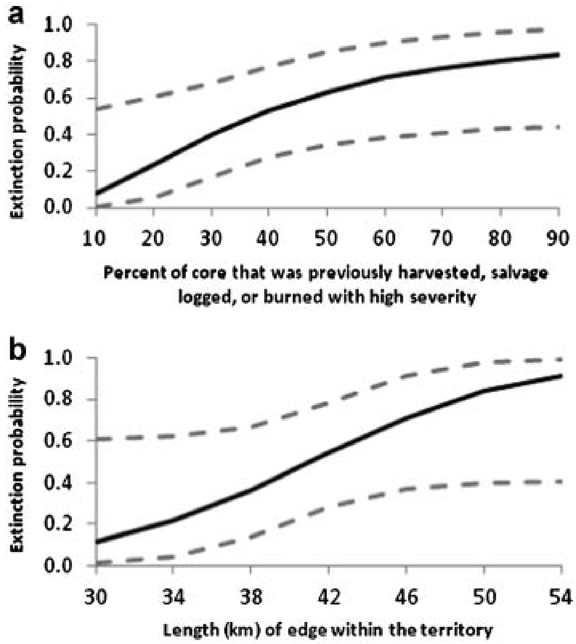

Figure 3. The estimated effects of the percent of (a) forested area that burned with a high severity or was previously harvested or salvage logged and (b) forest edge on extinction probabilities of northern spotted owls at the Biscuit, Quartz, and Timbered Rock burns in southwest Oregon, USA from 2003 to 2006. The 95% confidence intervals for the estimated effects are represented by gray, dashed lines. The median values of the additional covariates in the model were held constant while varying the covariate of interest over the observed range of values.

burn, which may explain the difference between our results and those of previous studies.

The approximately 25% reduction in site occupancy at the South Cascades from 2002 to 2006 was somewhat surprising given that the study area did not have any large scale disturbances during this time. However, several spotted owl populations have been declining throughout the subspecies' range (Anthony et al. 2006, Forsman et al. 2011), and declines in site occupancy at the South Cascades could be related to ongoing population declines that are unrelated to natural disturbances. Dugger et al. (2011) found that barred owls (*Strix varia*) had negative impacts on site occupancy by spotted owls by decreasing colonization rates and increasing extinction rates. This likely explains much of the nearly 25% decline in site occupancy we observed from 2002 to 2006 at the South Cascades. The 64% reduction in site occupancy at Timbered Rock from 2002 to 2006 was substantially greater than the roughly 25% decline observed at South Cascades, which suggests that wildfire, subsequent salvage logging, and past timber harvest contributed to the greater declines in site occupancy at Timbered Rock. We estimated that following the Timbered Rock burn only 46% of the area within 2,230 m of spotted owl territories were intermediate-aged or older forests that burned with a low or moderate severity (Table 1). This amount of habitat is marginal for successful reproduction (Bart and Forsman 1992) and may cause decreases in survival rates of the subspecies (Franklin et al. 2000, Dugger et al. 2005).

The large declines in site occupancy following the Timbered Rock burn are most likely explained by dispersal

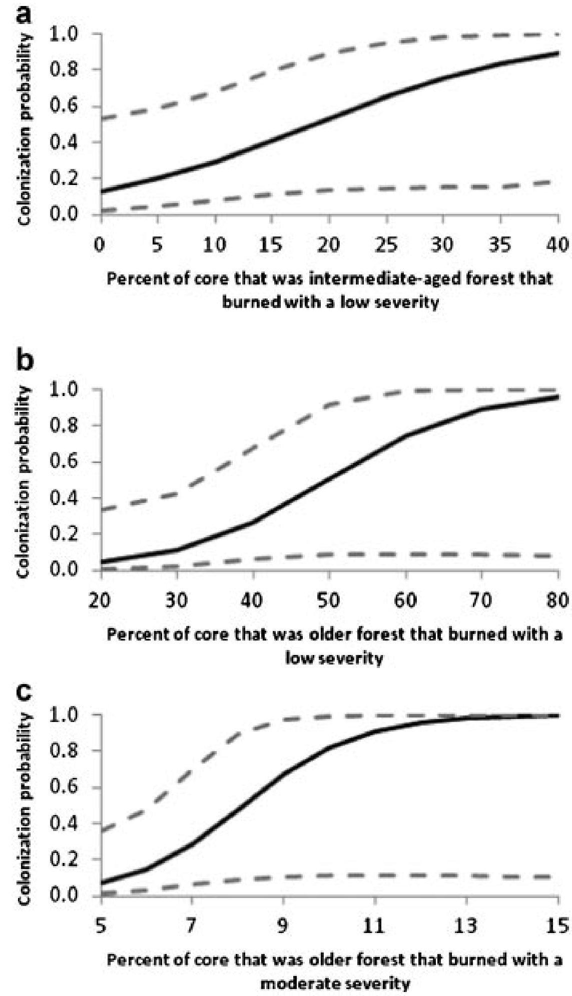

Figure 4. The estimated effects of the percent of (a) intermediate-aged forest that burned with a low severity, (b) older forest that burned with a low severity, and (c) older forests that burned with a moderate severity on colonization probabilities of northern spotted owls at the Biscuit, Quartz, and Timbered Rock burns in southwest Oregon, USA from 2003 to 2006. The 95% confidence intervals for the estimated effects are represented by gray, dashed lines. The median values of the additional covariates in the model were held constant while varying the covariate of interest over the observed range of values.

out of the burn (i.e., emigration) and decreased survival of spotted owls. Several color-banded, adult spotted owls at the Timbered Rock burn (2 pairs and 1 individual, 25% of the known pre-fire population) dispersed to an unburned territory adjacent to the burn, 1–2 years post-fire (OCFWRU, unpublished data). Adult dispersal is a relatively rare occurrence in spotted owls throughout their range (Forsman et al. 2002: 5%, Zimmerman et al. 2007: 2%); however, owl territories may be abandoned when large amounts of mature and older forest are lost (Bart and Forsman 1992, Bart 1995). We believe that the relatively high rate of adult dispersal following the Timbered Rock burn suggests that insufficient habitat remained at abandoned territories to support a spotted owl pair. In addition, radio-marked spotted owls that maintained a territory within the Timbered Rock burn had lower survival rates ($\hat{S} = 0.69 \pm 0.12$; Clark et al. 2011) than reported throughout the subspecies' range ($\hat{\Phi} = 0.75$ to

0.91 ± 0.01 to 0.05; Anthony et al. 2006). Annual survival of spotted owls was positively associated with greater amounts of older forest within their home ranges or core use areas in other studies (Franklin et al. 2000, Olson et al. 2004, Blakesley et al. 2005, Dugger et al. 2005). High severity wildfire and salvage logging removed and modified 26% of the intermediate-aged and older forests within 2,230 m of spotted owl territories at the Timbered Rock burn, and 28% of the remaining area was previously harvested (i.e., early seral forest; Table 1). Consequently, the large degree of habitat loss and modification from past timber harvest, high severity fire, and salvage logging following the Timbered Rock burn likely contributed to the high levels of dispersal out of the burn, decreased survival rates and subsequent declines in site occupancy that we observed. These declines in site occupancy appear to have continued past the conclusion of our study because no spotted owls were detected during surveys conducted during the 2011 breeding season at the Timbered Rock study site (OCFWRU, unpublished data).

Increased extinction rates following the Timbered Rock burn may have been exacerbated by the checkerboard land ownership pattern of private and BLM lands (Richardson 1980). Private lands within the area of the Timbered Rock burn are managed as industrial forests and are frequently subjected to large-scale timber harvest, which creates large tracts of early seral forest. Following the Timbered Rock burn, much of the private land was salvage logged (17% of the study area), which created large clear-cuts throughout the landscape. Territory occupancy by spotted owls was negatively associated with increased areas of clear-cuts within the territory in another study (Thraillkill et al. 1998). Consequently, the large areas of clear-cuts created by salvage logging and past timber harvest (approx. 45% of the area within 2,230 m of spotted owl territories; Table 1) potentially exacerbated declines in site occupancy following the Timbered Rock burn or confounded the effects of wildfire. Declines in site occupancy may not be as large in burned areas that were not subjected to previous timber harvest or substantial amounts of post-fire salvage logging.

Relationship Between Wildfire, Salvage Logging, and Spotted Owl Site Occupancy

Extinction.—We predicted that occupancy of nesting territories by spotted owls after fires would decline because of increased extinction probabilities attributable to habitat loss and modification from past timber harvest, high severity fire and salvage logging. Our results supported this prediction because extinction probabilities increased as the combined area of high severity burns, salvage logging, and early seral forest increased (Fig. 3a; $\hat{\beta} = 1.88$, 95% CI = 0.10–3.66). This was the strongest relationship we observed in this analysis because it was the only habitat covariate where the 95% confidence interval for the regression coefficient did not overlap 0. Unfortunately, we were unable to separate the impacts of these 3 variables on extinction probabilities. When these 3 variables were included separately, the models were not competitive with the model that combined these variables into a single covariate (Table 6). This may indicate that we lacked the precision to separate the impacts of these 3 variables or they were confounded. However, our results suggest that these 3 variables work in concert and generate synergistic effects. Any 1 disturbance event may not generate negative effects on occupancy of territories, but the combined loss and modification of habitat from these 3 factors negatively affected spotted owls in our study. The combined influence of these 3 factors may reduce spotted owl habitat to such an extent that a threshold is passed and spotted owls are no longer able to occupy the territory.

Spotted owls are associated with late-successional forests (Forsman et al. 1984, Thomas et al. 1990), and their territories have greater amounts of older forests than surrounding landscapes (Ripple et al. 1991, 1997; Meyer et al. 1998; Swindle et al. 1999). Forest stands used by spotted owls have large proportions of downed woody debris and snags, high canopy cover, and high structural diversity (Hershey et al. 1998, North et al. 1999, Irwin et al. 2000). Timber harvest, salvage logging, and high severity fire remove or alter many of these structural characteristics associated with spotted owl habitat. As a result, we were not surprised that these factors were associated with increased extinction probabilities and declines in site occupancy. Spotted owls have high site fidelity (Forsman et al. 1984, 2002; Zimmerman et al. 2007), and survival rates are positively correlated with increased amounts of older forest in their territories (Franklin et al. 2000, Olson et al. 2004, Dugger et al. 2005); consequently, owls that occupied territories with a large degree of past timber harvest, salvage logging, and high severity fire were likely forced to emigrate out of the burned area or risk decreased survival.

Radio-marked spotted owls at the Timbered Rock burn were located closer to edge habitats than at random (Clark 2007), which suggests edge habitat may provide a benefit to the subspecies. Spotted owls may prefer to forage in habitat edges because of greater densities of some prey in early seral forests (Carey and Peeler 1995, Franklin and Gutiérrez 2002), particularly woodrats in southwest Oregon and northwest California (Zabel et al. 1995, Ward et al. 1998). Our results provided some evidence that extinction probabilities increased as the amount (km) of edge increased within nesting territories increased (Fig. 3b; $\hat{\beta} = 0.18$, 95% CI = −0.01–0.37), suggesting a negative impact of edge habitat on spotted owl territory occupancy. In our analysis, edge represented a metric of habitat fragmentation. Dugger et al. (2011) observed greater colonization probabilities at spotted owl territories when older forest was less fragmented, and our results were similar. Franklin et al. (2000) indicated that spotted owls are likely to have decreased survival at territories with reduced amounts of interior forest, suggesting that habitat fragmentation negatively affects spotted owls. The patchy nature of high severity fire and salvage logging created large amounts of edge habitat, which likely reduced the amount of interior forest available to owls and contributed to declines in site occupancy in our study. Furthermore, increases in edge may be correlated with increased amounts of nonhabitat (i.e., nonforested and early seral stands) and increases in nonhabitat have contributed to declines in territory occupancy of California spotted owls (Blakesley et al. 2005) and increases in extinction probabilities in this study. Despite indications that spotted owls are negatively affected by habitat fragmentation, the mechanism of these effects is not well understood (Franklin and Gutiérrez 2002). We calculated the amount of edge as the interface between intermediate-aged and older forests that burned with a low or moderate severity and all other habitat types (Table 2). This classification of edge habitat delineated distinct boundaries between stands of larger living trees and high severity burns or early seral stands. Additional types of edge habitats exist at the interface between intermediate-aged and older forests or the interface between low and moderate severity burns, and these types of edges may provide foraging habitat for spotted owls. Additional research between the association of various edge habitats on spotted owl demography and site occupancy is needed to clarify this relationship.

Colonization.—Overall, our estimated effects of habitat covariates on colonization probabilities were relatively imprecise. We attributed this lack of precision to the fact that we observed only 6 colonization events at our 3 study areas from 2003 to 2006. Despite the fact that we observed relatively few colonization events, we were still able to document several biologically meaningful associations between post-fire habitat and colonization probabilities. We suspect that if additional colonization events had occurred during the course of our research, our estimated effects of habitat on colonization probabilities would be more precise.

We found some evidence that colonization probabilities in our study were positively associated with increased amounts of older forest that burned with a low severity within the core area (Fig. 4b; $\hat{\beta} = 0.10$, 95% CI $= -0.01$ to 0.22). Although this estimated effect had weak support, this finding was expected and follows the well documented association between spotted owls and older forest (Forsman et al. 1984, Thomas et al. 1990). Furthermore, previous research indicated that territory occupancy of California spotted owls was positively associated with older forest (Blakesley et al. 2005), extinction probabilities at northern spotted owl territories were greater at territories with lesser amounts older forest (Dugger et al. 2011) and site occupancy by California spotted owls in areas that primarily burned with a low and moderate severity was similar to unburned areas (Roberts et al. 2011). Older forests that burned with a low severity are likely the highest quality spotted owl habitat in post-fire landscapes. These areas likely retained much of the canopy cover, downed woody debris, snags, and structural diversity that is selected by spotted owls (Hershey et al. 1998, North et al. 1999, Irwin et al. 2000). As a result, unoccupied territories that have high quality habitat (i.e., older forest that burned with a low severity) will have the greatest probability of being colonized by spotted owls. Within the Timbered Rock burn, radio-marked spotted owls strongly selected for older forest that burned with a low severity (Clark 2007), further demonstrating the influence of this habitat on spotted owls in post-fire landscapes.

Moderate severity burns likely remove and modify more of the forest stand features selected by spotted owls than low severity burns, yet many critical habitat features are likely retained and allow moderately burned areas to provide habitat for spotted owls following wildfire. Our analysis provided weak support that colonization probabilities were positively associated with increased amounts of older forest that burned with a moderate severity (Fig. 4c; $\hat{\beta} = 0.82$, 95% CI $= -0.05$ to 1.69). In addition to potentially providing many of the critical habitat features of forest stands that burned with a low severity, moderately burned stands likely have decreased risk of stand-replacement in the future because of removal of ladder fuels (Agee 1993), which likely increases the resilience of the forest stand to future disturbance. Spotted owls have been shown to disproportionately forage in habitats that have high levels of prey abundance (Carey et al. 1992, Carey and Peeler 1995, Zabel et al. 1995). Moderate severity burns may increase habitat heterogeneity and prey abundance, similar to the effects of heterogeneous thinning of young forest stands (Carey 2001). However, we did not test this hypothesis, and the potential benefits of moderate severity burns in older forests for spotted owls are unclear.

Previous studies have suggested a quadratic relationship between survival and reproduction of spotted owls and the amount of older forest surrounding nesting territories (Franklin et al. 2000, Olson et al. 2004). These studies suggest that territories that are not entirely comprised of older forests are beneficial to spotted owls and that spotted owls may be adapted to natural disturbances such as wildfire that create a mosaic of forest conditions. Our results provided weak support for this hypothesis because owl territories in our study that had increased amounts of intermediate-aged forest that burned with a low severity have a greater probability of being colonized by a pair of owls (Fig. 4a; $\hat{\beta} = 0.10$, 95% CI $= -0.01$ to 0.38). However, we expect a threshold exists in this relationship because spotted owls are associated with older forest (Forsman et al. 1984, Thomas et al. 1990) and spotted owls that occupy territories with insufficient amounts of older forest will have decreased survival and reproductive rates (Franklin et al. 2000, Olson et al. 2004, Dugger et al. 2005). The amount of intermediate-aged forest that burned with a low severity at any 1 owl territory in our study ranged from 0 to 38%. Territories that have insufficient amounts of older forest will likely not be occupied by spotted owls, but our results provided some evidence of a benefit of habitat heterogeneity for spotted owls.

Initial occupancy.—We were unable to identify any relationships between initial occupancy probabilities and the habitat covariates that we considered in our analysis. Our best model for initial occupancy probabilities (Table 6) included variables for the amount of the core area that burned with a low severity ($\hat{\beta} = 0.52$, 95% CI $= -0.22$ to 1.26) and the amount of edge habitat ($\hat{\beta} = -0.42$, 95% CI $= -0.92$ to 0.10); however, both of these estimates were imprecise and the 95% confidence intervals broadly overlapped zero, which suggested these relationships were not meaningful. Since these relationships were not supported by the data, additional research is needed to investigate the influence of low severity fire and edge habitat on spotted owl site occupancy.

Our analysis of site occupancy at the Biscuit, Quartz, and Timbered Rock burns indentified several meaningful relationships between site occupancy and amount of post-fire habitat. All of these relationships were based on biologically plausible hypotheses and have implications for spotted owl management. However, the relationships we observed were based on small sample sizes, non-random samples at the Biscuit burn, and our estimated relationships were often imprecise. Furthermore, our study was opportunistic and observational, which prevents us from assigning cause and effect relationships. Consequently, we suggest a cautionary approach when applying our findings to future land management decisions. In particular, the relationships we observed in our analysis may not be applicable to spotted owls in post-fire landscapes that are not affected by post-fire salvage logging.

Both wildfire and barred owls have been identified as threats to the persistence of spotted owls (USFWS 2011). Barred owls have expanded throughout the entire range of the northern spotted owl (Dark et al. 1998, Pearson and Livezey 2003) and are negatively affecting spotted owls (Kelly et al. 2003, Olson et al. 2005, Dugger et al. 2011). Furthermore, barred owls have a more generalized diet (Hamer et al. 2001, Wiens 2012) and use a wider range of habitats (Hamer et al. 2007) than spotted owls, which suggests that barred owls may be better adapted to persist in burned landscapes. We only detected 2 barred owls at the Biscuit, Quartz, and Timbered Rock burns during demographic surveys conducted between 2003 and 2006, so we believe that barred owls had little to no effect on our results.

Jointly, our analyses suggest that site occupancy by spotted owls in burned landscapes is likely to decline, at least in the short-term. These declines in site occupancy are driven by large increases in extinction probabilities in post-fire landscapes and are attributable to past timber harvest, high severity fire, and salvage logging. Although territories that had increased amounts of older forest that burned with a low severity had the greatest colonization probabilities, we only observed 6 colonization events at our 3 study areas from 2003 to 2006, and this level of colonization was insufficient to offset the high extinction probabilities we observed. This suggests that insufficient habitat remained at many of the spotted owls territories included in our analyses to support a pair of spotted owls following wildfire. Site occupancy by Mexican and California spotted owls in landscapes that burned primarily with low or moderate severities was similar to unburned landscapes (Jenness et al. 2004, Roberts et al. 2011), which suggests that spotted owls may be able to persist in burned landscapes. These findings contrast our results, which suggested that spotted owl site occupancy will decline in burned landscapes; however, our results were confounded by the effects of past timber harvest and salvage logging. Additional research in post-fire landscapes that have not been impacted by past timber harvest and salvage logging are needed to help clarify these relationships.

MANAGEMENT IMPLICATIONS

We identified several factors that influenced occupancy of nesting territories by spotted owls in post-fire landscapes; however, the strongest association we observed was that site occupancy declined because of increased extinction probabilities. Increased amounts of past timber harvest, salvage logging, and high severity burns jointly contributed to increased extinction probabilities and subsequent declines in spotted owl site occupancy. Past timber harvest negatively influenced site occupancy in our analysis, so we recommend increased protection of older forest in dry forest ecosystems to prevent future habitat loss to timber harvest and mitigate potential losses of older forest to stand-replacing fire and subsequent salvage logging. High severity fire was 1 of 3 factors that combined to increase local-extinction probabilities of spotted owls in our study; however, we were unable to separate the impacts of wildfire from land management activities. As a result, we recommend future research to clarify the relationship between high severity fire and spotted owl site occupancy in the absence of past timber harvest and salvage logging. We believe that widespread, stand-replacing wildfires will negatively affect site occupancy by spotted owls, so we suggest efforts should be made to reduce the risk of widespread, stand-replacing wildfire in spotted owl habitat. However, a precautionary approach should be taken when implementing fuel reduction techniques that will reduce that risk of stand-replacing wildfire. Research is needed to ensure that fuel reduction techniques, particularly commercial or non-commercial thinning, are not detrimental to spotted owls, their habitat, or prey before fuel reduction techniques are implemented on a large scale. Our results also indicated a negative impact of salvage logging on site occupancy by spotted owls. We recommend restricting salvage logging after fires on public lands within 2.2 km of spotted owl territories (the median home range size in this portion of the spotted owl's range) to limit the negative impacts of salvage logging. Our results indicated a negative response of spotted owls to wildfire in the short-term, but the response is likely to vary over time; however, little is known about the long-term response of spotted owls to wildfire. As a result, long-term monitoring studies should be implemented in post-fire landscapes to determine the response of spotted owls to wildfire over time.

ACKNOWLEDGMENTS

Funding for this research was provided by the Joint Fire Science Program under Project JFSP 04-2-1-52. We thank E. Forsman, B. Ripple, and 3 anonymous reviewers for comments on early drafts of this manuscript. J. Harper of the BLM; D. Clayton, L. Webb, and R. Miller of the USFS; and B. Kernohan and T. Burnett of Forest Capital Partners LLC helped coordinate and conduct demographic surveys. We thank the following biologists who are part of the OCFWRU for their help conducting demographic surveys: S. Adams, L. Friar, T. O'Brien, T. Phillips, T. Sabol, D.

Strejc, and F. Wagner. Collection of demographic survey data was assisted by biologists at Turnstone Environmental Consultants and Westside Ecological.

Experimental Removal of Barred Owls to Benefit Threatened Northern Spotted Owls

Final
Environmental Impact Statement

Prepared by:

Oregon Fish and Wildlife Office
U.S. Fish and Wildlife Service
Portland, Oregon

July, 2013

Executive Summary

This Final Environmental Impact Statement (Final EIS) describes and evaluates nine alternatives for an experimental removal of northern barred owls (*Strix varia varia*) (barred owl) on a scale sufficient to determine if the removal would increase northern spotted owl (*Strix occidentalis caurina*) (spotted owl) site occupancy and improve population trends. Results from these experiments would be used by the U.S. Fish and Wildlife Service (Service) to inform future decisions on potential long-term management strategies for barred owls.

S.1 Background

The purpose of the proposed action is to conduct research on the effects on spotted owls of the removal of barred owls. This research would require we obtain a permit under the Migratory Bird Treaty Act for scientific collection of barred owls, a Federal action. As a component of the issuance of that permit we are conducting a National Environmental Policy Act (NEPA) review. Because of the scope and controversy over the potential removal of a number of barred owls from the wild, we developed this Final EIS. We are also conducting a consultation under section 7 of the Endangered Species Act (ESA). Depending on the study area and land management agency involved, the experiment may require additional Federal and State permits. Any experiment on National Parks or Recreation Areas would require a research permit. Study areas on National Forests may require a special use permit. This Final EIS may serve as the NEPA documentation for issuance of these permits.

In the most recent review of the condition of northern spotted owls, the Revised Recovery Plan for the Northern Spotted Owl (Revised Recovery Plan) (USFWS 2011, entire) identified past habitat loss, current habitat loss, and competition from the recently arrived barred owls as the most pressing threats to the northern spotted owl (USFWS 2011, p. I-6.).

The Revised Recovery Plan states, "Barred owls reportedly have reduced spotted owl site occupancy, reproduction, and survival. Limited experimental evidence, correlational studies, and copious anecdotal information all strongly suggest barred owls compete with spotted owls for nesting sites, roosting sites, and food, and possibly predate spotted owls…. Because the abundance of barred owls continues to increase, the effectiveness in addressing this threat depends on action as soon as possible" (USFWS 2011, p. III-62).

Barred owls are native to eastern North America, but only recently arrived in the West. They were first documented in the range of the northern spotted owl in Canada in 1959 and in western Washington in 1973. The range of the barred owl in the western United States now completely overlaps with the range of the northern spotted owl. We observe that as the number of barred owls detected in historical spotted owl territories increase, the number of spotted owls decrease. In the Pacific Northwest, barred owl populations developed first in Washington and spotted owl populations have declined at the greatest rate in these areas.

Although northern spotted owl populations have been declining for many years, the presence of barred owls exacerbates the decline. Recent studies (Olson *et al*. 2005, p. 918; Forsman *et al*. 2011a, pp. 69-70, 75-76) have established negative relationships between barred owl presence and declines in spotted owl population performance across the range of the subspecies. This could result in the extirpation (local extinction) or near extirpation of the northern spotted owl from a substantial portion of their historical range, even if other known threats, such as habitat loss, continue to be addressed. Given the continuing range expansion and population growth of barred owl populations in the western United States and concurrent decline in northern spotted owl populations, information on the effectiveness of a removal program is urgently needed.

Recovery Action 29 in the Revised Recovery Plan focuses on acquiring the information necessary to help identify effective management approaches and guide the implementation of appropriate management strategies for barred owls. It proposes experimental removal of barred owls to determine if the removal would increase spotted owl site occupancy and improve population trends (USFWS 2011, pp. III-62, III-65).

> *"Recovery Action 29: Design and implement large-scale control [removal] experiments to assess the effects of barred owl removal on spotted owl site occupancy, reproduction, and survival.*

While the evidence of threat is strong and very persuasive, it is not yet sufficient for the Service to consider undertaking a wider removal effort. We need data on the effectiveness of barred owl removal in improving spotted owl population trends, as well as the efficiency of removal as a management tool. Conducting this experiment would allow us to develop a better understanding of the impacts barred owls are having on spotted owl populations. It would also allow us to determine our ability to reduce barred owl populations at a landscape level to permit spotted owl population growth. Finally, it would allow us to estimate the cost of barred owl removal.

This Final EIS is specific to implementation of Recovery Action 29—implementation of large-scale removal experiments to assess the effects of barred owl removal on spotted owl populations. This Final EIS is limited to addressing this portion of the barred owl threat, the removal experiment. The Service anticipates using the information from this experiment to assist with future barred owl management decisions. We have no specific direction for future management at this time, nor would the results of this experiment trigger any automatic actions. Future decisions could range from no active management of barred owls to a mix of strategies, including barred owl removal, other methods to reduce barred owl populations, or methods to change the competitive advantage of barred owls. Even if removal of barred owls is chosen as a component of barred owl management, this could range from small removal efforts in specific areas and over short time frames to landscape-level removal efforts for long periods, periodic removal programs, or other actions as yet not described. If a decision is made to manage barred owl populations in the future, implementation would be preceded by completion of any necessary legal requirements and NEPA compliance.

S.2 Purpose of and Need for the Action

The purpose of the proposed action is to contribute to fulfilling the intent of the Act by rapidly implementing experimental research necessary for conservation of the spotted owl in accordance with Recovery Action 29 of the Recovery Plan (USFWS 2011, p. III-65). More specifically, the purpose of the proposed action is to: (1) obtain information regarding the effects of barred owls on spotted owl vital rates of occupancy, survival, reproduction, and population trend through experimental removal; (2) determine the feasibility of removing barred owls from an area and the amount of effort required to maintain reduced barred owl population levels for the duration of the experiment; (3) estimate the cost of barred owl removal in different forested landscapes; and (4) develop the information necessary to make a future decision about the management of barred owls as expeditiously as possible.

The need for the action is that we lack desired information to: (1) determine the response of spotted owl site occupancy, survival, reproduction, and population trend to barred owl removal; (2) evaluate whether barred owls can be effectively removed from an area and level of ongoing removal required to maintain low population levels of barred owls; (3) determine the cost of removal in different types of forested landscapes to inform future management decisions; and (4) inform timely decisions on whether to move forward with future barred owl management.

S.3 Description of the Proposed Action

The proposed action is to conduct an experiment to provide scientifically rigorous results regarding the effects of barred owls on the spotted owl vital rates of occupancy, survival, reproduction, and population trend through experimental removal, and determine the feasibility of experimental removal of barred owls.

All action alternatives include the same experimental approach. Each study area is divided into two comparable portions; barred owls are removed from the treatment area and left in the control area. All areas are surveyed for spotted and barred owls. Spotted owl population data is compared between the control and treatment areas to determine if removal of barred owls in the treatment area resulted in a significant change in spotted owl population dynamics.

Potential study areas were selected from across the range of the northern spotted owl in Washington, Oregon, and California, and may include ongoing spotted owl demographic study areas, inactive spotted owl demographic study areas, or additional areas with varying levels of past spotted owl surveys. Most study areas are focused on Federal lands, including areas within National Forests, Bureau of Land Management managed lands, and National Parks and Recreation Areas (North Cascades National Park, Ross Lake National Recreation Area, Lake Chelan National Recreation Area, Olympic National Park, and Mount Rainier National Park). Some wilderness areas may be included. We are also considering a study area on the Hoopa Valley Indian Reservation. In some cases, interspersed private and State lands may occur within the boundaries of the study area. Where possible, we would seek cooperation from nonfederal landowners. Nonfederal lands would be included in the active experiment only if the landowners are willing.

The experiment will run until sufficient information is gathered to determine the effects of the removal of barred owls on spotted owl population trends. The experiment will begin as soon as possible, and results will be reviewed annually to determine when data are sufficient to answer the research questions. Removal activities will end when data are sufficient to meet the purpose and need. We set a maximum duration of 10 years of barred owl removal for the experiment. If the experiment has not provided enough information to reach a conclusion within 10 years, it is likely that removal of barred owls is not achieving the desired goal, thus other avenues should be considered and the experiment ended.

S.4 Considerations Used in Developing the Alternatives

S.4.1 Number of Study Areas

The alternatives range from 1 to 11 study areas. An experiment involving a single study area is logistically simpler to conduct, but would not fully represent the diversity of physical features, habitat types, barred owl density, and invasion history across the range of the northern spotted owl. Given that each study area represents a single experiment, a single study area does not provide for any replication, and results from a single study area may not be representative of effects of barred owl removal in other parts of the northern spotted owls' range. Multiple study areas have greater total costs and require more complicated logistics, but can better represent the range of conditions experienced by spotted owl populations, allowing better inferences across their range. Multiple areas also allow for replication of results. By providing alternatives with an array from 1 to 11 study areas, we can evaluate the costs and benefits of these different approaches.

S.4.2 Distribution of Study Areas

In alternatives with more than one study area, we selected from different portions of the northern spotted owl's range to best represent the variation in conditions across the range. We considered the following information:

- *History of barred owl presence.* Study areas in the north were invaded by barred owls earlier and have a longer history of barred owl site occupancy than areas in southern Oregon and northern California.
- *Current density of territorial barred owls.* Study areas in the north have generally higher densities of barred owls than study areas in southern Oregon and northern California, though this varies by study area.
- *Current density of territorial spotted owls.* Spotted owl population levels and site occupancy on study areas have declined substantially and are declining in northern Oregon. In southern Oregon and northern California, spotted owl populations and site occupancy are higher, but are declining on most study areas.

- *Different habitat types.* Spotted owl habitat varies across its range. There are large differences in habitat type between wet and dry forests (west to east) and between areas north and south of the Klamath Physiographic Province in Oregon.
- *Differences in spotted owl food habits.* North of the Klamath Physiographic Province in Oregon northern flying squirrels represent a primary food source for spotted owls. South of the Klamath Province the dusky-footed woodrat is a primary food source.

Based on these considerations, we divided the range of potential study areas into three basic regions: Washington, northern Oregon, and southern Oregon/northern California.

S.4.3 Type of Study

All experiments described in the alternatives are based on a treatment (removal) and control (non-removal) study design. Under this approach, study areas are divided into two comparable segments. Barred owls are removed from the treatment area but not from the control area. Spotted owl population parameters (e.g., site occupancy, demographic performance, population trend) are estimated using the same methodology in both areas and the population measurements are compared between the treatment and control areas.

Johnson *et al.* (2008, entire) described four basic study designs for barred owl removal experiments to evaluate potential effects on spotted owls: demographic studies, occupancy studies, site-specific studies, and invasion studies. We considered all of these approaches in developing the alternatives, and are proposing to utilize both a demographic and occupancy study approach.

DEMOGRAPHIC STUDY APPROACH. In demographic studies, individual spotted owls are banded with a uniquely numbered leg band and a uniquely colored leg band. Territories are surveyed every year in an effort to determine if the individual is still alive and present. Using this information, scientists can calculate survival and recruitment rates (the rate at which new individuals are added to the population). From this they can estimate the annual population growth rate of spotted owls on the study area (Forsman *et al.* 2011a, p. 8). Additionally, in most demographic studies data on the number of young fledged per year are recorded, allowing for examination of effects on spotted owl reproduction. A primary goal of this approach is to compare changes in population growth rates between treatment (removal) and control (non-removal) areas, with the untreated control areas used to distinguish population changes that might be occurring for other reasons.

A demographic experimental approach has several advantages. It allows us to estimate annual population growth rate for treatment and control areas and assess the effects of barred owl removal on spotted owl population trends. Because individual spotted owls are tracked, we can measure the underlying vital rates (e.g., annual survival and recruitment of new individuals into the population) of the population and determine which of these are influenced by barred owl competition (Johnson *et al.* 2008, p. 19).

However, the demographic experimental approach has some limitations. It requires the capture, banding, and following of individual spotted owls, a relatively intensive method of data collection.

OCCUPANCY EXPERIMENTAL APPROACH. In occupancy studies, spotted owl sites are monitored rather than individual owls (individuals are not banded). Scientists use the presence or absence of spotted owl detections, based on auditory surveys, to determine whether sites are occupied or not. In its simplest form, we record only presence or absence of spotted owl detections, though we can choose to gather information on the number of young produced on each site. Presence/absence data can be used to estimate the rate of population change if the study area is surveyed consistently. This approach provides less information on how the barred owl removal changes the spotted owl population dynamics than the demographic approach; because we cannot determine which vital rate (annual survival or recruitment) has changed in response to barred owl removal. Because individual spotted owls are not banded or followed, we cannot tell if any observed change occurs because individuals are on average surviving longer, or because they are constantly replaced.

An occupancy experimental approach has several advantages. It is a relatively simple process, only requiring comparable surveys on the treatment (removal) and control (non-removal) portions of the experiment. There is no need to capture, band, or relocate individual owls. The occupancy experimental approach has some limitations. Data collected in an occupancy experiment can be used to provide estimates of site occupancy and potentially the rate of population change, but do not provide estimates of annual survival or recruitment. Therefore, we cannot identify which vital rates (survival or recruitment) are most affected by barred owl competition, and obtain less information about the biological mechanisms of interspecies competition than with demographic studies (Johnson *et al.* 2008, p. 19). The lack of banded or individually identified spotted owls delays our ability to detect sink population dynamics, situations where site occupancy is high because a series of individuals continue to occupy the site while the overall population declines. Site occupancy may remain high and the actual loss of birds go undetected until the source of non-territorial spotted owls to fill behind territorial spotted owls is exhausted. Because we intend to terminate the experiment once we have statistically significant data, we could miss the actual population decline altogether. Additionally, occupancy studies provide data and conclusions with a lower ability to detect differences (strength of inference) than the demographic approach, given that few study areas have pretreatment data.

All experimental approaches and action alternatives include the following three basic components:

- Survey spotted owls—survey the entire study area using spotted owl recorded calls and current demographic survey protocols. The data collected varies by type of experiment.
- Survey barred owls—survey the entire study area using barred owl recorded calls to define barred owl density and locate barred owl sites.
- Remove barred owls—using the process described below; remove all barred owls from the treatment area.

S.4.4 Removal Method

All experiments described in the alternatives would substantially reduce barred owl populations in portions of the proposed study areas through the removal of barred owls. All removal methods would avoid removing breeding barred owls with dependent young. There are two basic methods to remove barred owls: lethal and nonlethal.

LETHAL REMOVAL METHOD. We selected a procedure for lethal removal that is as humane and efficient as possible. It is designed to minimize the risk of accidental removal of other species, particularly northern spotted owls and other listed species. The procedure is designed to maximize the potential for specimens to be collected and used for other scientific purposes, within the constraints of a quick and humane death. The general approach involves attracting territorial barred owls with recorded calls and shooting birds that respond when they approach closely

NONLETHAL REMOVAL METHOD. As with lethal removal, we designed a nonlethal removal method that is as humane as reasonably possible and reduces stress on the birds. To accomplish the experiment, any barred owls captured must be removed completely from the study area. To avoid undue stress and problems with inadequate housing, we require that we have a destination ready to take the birds before any capture is attempted. The procedure minimizes the risk to other species, though this is less of an issue with capture as non-target species can be removed from the capture apparatus and released in most cases. The approach involves attracting territorial barred owls with a recorded call, and catching the responding birds in nets or other trapping devices. Birds would be transported to temporary holding facilities, checked for injuries or other health concerns, stabilized, and transported to permanent facilities or release locations.

COMBINED REMOVAL METHOD. A combination of lethal and nonlethal removal may be applied on a single study area. In this instance, we would capture enough birds to meet placement opportunities and remove the remaining birds lethally.

S.5. The Alternatives

In addition to the No Action Alternative, we developed a Preferred Alternative and seven additional action alternatives, two with sub-alternatives, based on an array of considerations. These alternatives span the feasible and reasonable approaches to meeting the purpose and need described in Chapter 1 of this Final EIS. The alternatives vary in number of study areas, distribution of those study areas, type of study, method of removal, and presence or absence of pretreatment data.

S.5.1 No Action Alternative

Under the No Action Alternative, no experimental removal would be conducted by the Service. This would not prevent others from proposing such studies and seeking the necessary permits, but there is no guarantee that any such efforts would occur.

S.5.2 Action Alternatives

The action alternatives vary by location and number of study areas (1 to 11), type of experiment (demographic or occupancy), and removal method (lethal or combined). We did not include the nonlethal removal method because, based on early efforts, we do not anticipate being able to find placement for more than 100 barred owls. All the action alternatives require the removal of more than 100 barred owls. Since we would not capture barred owls without a location ready to accept them, none of the alternatives could be implemented if limited to nonlethal removal. Because of the limitations placed on using nonlethal removal methods for the experiment, the limited options for placement of captured birds, the stress on the birds, and the likely outcome if released elsewhere, use of nonlethal removal as the sole removal method in the experiment is not included in the action alternatives.

S.5.2.1 Preferred Alternative

This alternative involves a demographic study approach using a combination of lethal and nonlethal removal methods. This experiment would be conducted on four study areas with pre-treatment demography data spread across the range of the northern spotted owl, including the Cle Elum in Washington, one-half the combined Oregon Coast Ranges and Veneta in northern Oregon, the Union/Myrtle in southern Oregon, and the Hoopa (Willow Creek) in California. Given the size and number of spotted owl sites in the combined study areas, this alternative would require an estimated duration of 4 years of barred owl removal to detect significant results.

S.5.2.2 Alternative 1

This alternative involves a demographic study approach using lethal removal methods. This experiment would be conducted on a single study area, out of the nine ongoing spotted owl demographic study areas. We are considering the use of any one of these nine areas and are analyzing the effects for each area. The estimated duration of barred owl removal for this alternative varies from 4 to 7 years by study area, due primarily to the size of the study area and the number of spotted owl sites. Smaller study areas or areas with fewer spotted owl sites would take longer to detect statistically significant results.

S.5.2.3 Alternative 2

This alternative involves a demographic study approach using a combination of lethal and nonlethal removal methods. This experiment would be conducted on three study areas spread across the range of the northern spotted owl. To ensure that this represents the various conditions across the range of the northern spotted owl, the three study areas would be distributed such that one in Washington, one in northern Oregon, and one in southern Oregon or northern California. Given the size and number of spotted owl sites in the combined study areas, this alternative would require an estimated duration of 4 years of barred owl removal to detect significant results.

S.5.2.4 Alternative 3

This alternative involves a demographic study approach using a combination of lethal and nonlethal removal methods. This experiment would be conducted on two study areas in Oregon that are not spotted owl demographic study areas, but that have data to allow an estimate of pretreatment spotted owl population trends: Veneta and Union/Myrtle. The Union/Myrtle area has long-term monitoring data and the Veneta area has research and monitoring data that would allow us to estimate pretreatment spotted owl population trends and survival rates. Both have current or recent data on most spotted owl sites and banded spotted owls. Because they are relatively small, we paired these treatment (removal) areas with control (non-removal) areas on adjacent ongoing spotted owl demographic study areas. The Union/Myrtle area would be paired with the Klamath Spotted Owl Demographic Study Area; the Veneta area would be paired with a comparable portion of the Oregon Coast Ranges and Tyee Spotted Owl Demographic Study Areas. Given the size and number of spotted owl sites in the two study areas, this alternative would require an estimated duration of 4 years of barred owl removal to detect statistically significant results.

S.5.2.5 Alternative 4

This alternative involves a demographic study approach using a combination of lethal and nonlethal removal methods. This experiment would be conducted on two study areas that lack current demographic data—Columbia Gorge in Washington and McKenzie in Oregon. These two study areas have some past and current spotted owl survey data.

Alternative 4 includes two sub-alternatives. Under sub-Alternative 4a, we would take time to gather pretreatment demographic data before beginning the removal portion of the experiment. Under sub-Alternative 4b, we would start removal on the treatment portion of the study area after year 2, immediately after establishing a population of banded spotted owls, and rely on differences between the control and treatment areas to determine the effects of removal. Lack of pretreatment data reduces the strength of the experimental approach.

Sub-Alternative 4a would require 5 years of pre-removal data collection to establish demographic values (population trend, survival, recruitment), and 5 years of barred owl removal to establish changes in these demographic measures between the control and treatment areas, for a total of 10 years. Sub-Alternative 4b would require approximately 8 years: 2 years to develop a population of banded spotted owls for analysis, and 6 years of barred owl removal to develop the demographic measurements and detect differences between the control and treatment areas.

S.5.2.6 Alternative 5

This alternative involves an occupancy study approach using lethal removal methods. Occupancy studies can be done as simple occupancy (presence or absence of spotted owls on each site) or, with added effort, we can add information on reproductive success. This experiment would be conducted on three study areas with existing and recent occupancy data distributed across the range of the northern spotted owl. We selected the Cowlitz Valley, Veneta (Oregon Coast Ranges/Tyee), and Union/Myrtle (Klamath) Study Areas for this alternative. As described in Alternative 3, the Veneta and Union/Myrtle areas would be treatment (removal) areas paired with control (non-removal) areas on adjacent ongoing spotted owl demographic study areas.

Given the size and number of spotted owl sites on the three study areas, a simple presence/absence occupancy experiment would require 3 years of barred owl removal to detect differences between the control and treatment areas (Option 1). If we add reproductive success to the experiment, it would require an additional 2 years, bringing the duration to 5 years of barred owl removal (Option 2).

S.5.2.7 Alternative 6

This alternative involves an occupancy study approach using a combination of lethal and nonlethal removal methods. This experiment would be conducted on three study areas that do not have current occupancy data. The McKenzie and Horse/Beaver Study Areas would contain both treatment and control areas. Removal would occur on the Olympic Revised portion of the Olympic Revised (Olympic Peninsula) Study Area with a control (non-removal) area on the Olympic Peninsula Spotted Owl Demographic Study Area. These cover the three regions of the spotted owl range described in Alternative 2.

Alternative 6 includes two sub-alternatives. Under sub-Alternative 6a, we would take time to gather pretreatment occupancy data before beginning the removal portion of the experiment. Under sub-Alternative 6b, we would start removal on the treatment portion of the study area immediately and rely on differences between the control and treatment areas to determine the effects of the removal. Lack of pretreatment data reduces the strength of the experimental approach.

Sub-Alternative 6a would require 3 years of pre-removal data collection to establish occupancy values and 3 years of barred owl removal data to establish changes in occupancy between the control and treatment areas, for a total of 6 years for simple occupancy data, and 2 additional years of barred owl removal if we add reproductive success measurements. Sub-Alternative 6b would require approximately 4 years of barred owl removal for simple occupancy, and 2 additional years of barred owl removal if we add reproductive success measurements.

S.5.2.8 Alternative 7

This alternative involves both demography and occupancy study approaches, depending on the study area, using a combination of lethal and nonlethal removal methods. For this experiment, we selected a total of 11 study areas. We attempted to select one from each physiographic province to provide stronger information from across the range of the northern spotted owl. In some cases, where study areas have few potential spotted owl sites, more than one was selected within a province to provide sufficient sample size. In very large provinces, additional study areas were included to provide better distribution of results.

For most study areas we estimated the duration of barred owl removal based on the time required to detect achieve significant results relative to the effects of removal on spotted owls. These vary from 3 to 10 years. For four study areas spread across the range of the spotted owl, we chose to continue the barred owl removal for 10 years to determine if there were any different long-term effects of removal. For example, whether observed changes in spotted owl populations continue past the initial phase, taper off, or even reverse after the initial years of the experiment.

S.6. Action Area

For this Final EIS, the action areas are the study areas, and the action area for each alternative is made up of a combination of study areas. One study area may occur in more than one alternative, and alternatives may have more than one study area in the action area. In most cases, each study area is independent—actions on one study area do not affect those on other study areas. This is due to the distance between study areas and the lack of significant effects of the experiment beyond the study area boundary.

The study areas include Ross Lake, Wenatchee, Cle Elum, Olympic Peninsula, Olympic Revised (Olympic Peninsula), Rainier, Cowlitz Valley, and Columbia Gorge in Washington; Oregon Coast Ranges, Veneta (Oregon Coast Ranges/Tyee), Tyee, McKenzie, HJ Andrews, Union/Myrtle (Klamath), Klamath, South Cascades, and Rogue Cascade (South Cascades) in Oregon, and Horse/Beaver, Goosenest, Hoopa (Willow Creek), and Corral in California.

S.7. Environmental Consequences

For this Final EIS, we conducted an analysis of the potential effects to the human environment (environmental consequences and cumulative effects). We identified potential effects for the following resource areas: barred owls, northern spotted owls, other species, social and ethical, economic, cultural resources; and recreation and visitor use, and are summarized below. We determined no potential for effects to the remaining resource areas such as air, water, and wetlands.

S.7.1 Effects on Barred Owls

Under the No Action Alternative no barred owls would be removed from this experiment. The lowest number of barred owls we estimate would be removed, 321, occurs if we chose the Hoopa (Willow Creek) Study Area in Alternative 1. The highest estimated number, 8,892, would be removed under Alternative 7 (Table S-1). Under the Preferred Alternative, we estimate the removal of 3,603 barred owls over the course of a 4 year experiment.

There are no estimates of the total population of barred owls in the range of the northern spotted owl or throughout their range in North America with to compare these values. Therefore, to provide the regional and rangewide context, we considered the percent of habitat from which barred owls would be removed. Because no habitat estimates exist for barred owls, we used spotted owl habitat as a conservative estimate within the range of the northern spotted owl.

The smallest treatment area from which barred owls would be removed occurs if we chose the Tyee Study Area in Alterative 1. Removal would occur on approximately 0.31 percent of the habitat in the range of the northern spotted owl and 0.01 percent of the range of the barred owl. The largest treatment area occurs in Alternative 7, approximately 6.55 percent of the habitat in the range of the northern spotted owl and 0.20 percent off the range of the barred owl. Under the Preferred Alternative, removal would occur on 1.72 percent of the habitat in the range of the northern spotted owls and 0.05 percent of the range of the barred owl.

Table S-1. Summary of the estimated number of barred owls removed, percent of habitat in the range of the northern spotted owl, and percent of habitat in the range of the barred owl.

Alternative/ Sub-Alternative	Estimated Barred Owls Removed During Experiment	Percent of Total Habitat within Range of Spotted Owl [1]	Percent of North American Range of Barred Owl [2]
Preferred Alternative	3,603	1.72	0.05
Alternative 1	321 to 2,242	0.31 to 1.59	Less than 0.01 to 0.05
Alternative 2	1,450 to 5,784	1.33 to 3.90	0.04 to 0.12
Alternative 3	2,003	1.13	0.04
Sub-Alternative 4a	2,183	1.42	0.05
Sub-Alternative 4b	2,509	1.42	0.05
Alternative 5	2,494 to 3,463	2.05	0.07
Sub-Alternative 6a	2,007 to 2,787	2.08	0.10
Sub-Alternative 6b	2,397 to 3,175	2.08	0.10
Alternative 7	8,892	6.55	0.20

[1] Approximately 12,104,100 acres of spotted owl habitat occurs within the range of the northern spotted owl. We use spotted owl habitat as a surrogate for barred owl habitat which has not been mapped or defined.
[2] Range of barred owl within range of northern spotted owl is approximately 3 percent of total range of barred owl in North America.

S.7.2 Effects on Northern Spotted Owls

Depending on the study area(s) chosen, the percentage of spotted owl habitat from which barred owls would be removed ranges from 0.31 percent to 6.55 percent, and between 38 and 630 potential spotted owl sites within the treatment (removal) area may be reoccupied during the experiment. The Preferred Alternative would remove barred owls from 1.72 percent of the habitat in the range of the northern spotted owls, and effect up to 363 potential spotted owl sites in the treatment areas. The magnitude of positive effect would vary based on current barred owl population levels, likely being greatest where barred owl densities are low enough to have allowed some spotted owls to persist on the treatment area. The proportion of spotted owl sites with barred owl detections ranges from 18 percent to 71 percent within each of the study areas, and the overall magnitude of positive effect would vary based on current spotted owl site occupancy. Higher current occupancy allows spotted owls to reoccupy sites from which barred owls are removed more quickly. Current spotted owl site occupancy varies from 22 percent of the sites occupied, to 67 percent occupancy, and an average of 48 percent occupancy on the study areas of the Preferred Alternative

The primary effect we anticipate is a positive change in spotted owl demographic performance on the treatment portions of the study areas. Some minor and short-term negative effects may result from the survey and removal activities.

S.7.3 Effects on Ongoing Spotted Owl Demographic Study Areas

Alternative 4 does not include any ongoing spotted owl demographic study areas. Alternatives 3, 5, and 6 do not include any removal on ongoing spotted owl demographic study areas. We anticipate no significant effect from these surveys.

Alternatives 1, 2, and 7 include removal from up to one-half of one to three ongoing spotted owl demographic study areas. The Preferred Alternative includes removal on three ongoing spotted owl demography study areas, including two that are part of the Northwest Forest Plan Effectiveness Monitoring Program. This would reduce the sample size of spotted owls for the ongoing demographic study on the included study areas by up to 50 percent, increasing the variance of estimates of demographic rates for both treatment and control areas. Because three areas would be used for removal in the Preferred Alternative and Alternatives 2 and 7, the overall impact of these effects would be larger than for Alternative 1. Once the removal experiment is concluded and barred owl populations recover to levels comparable to the control areas, the treatment area(s) can be recombined with control area(s).

S.7.4 Effects on Other Species

Depending on the study area chosen, the treatment area would potentially provide temporary relief from predation and competition from 4 to 25 State- or Federal-listed species. Thirteen of the 21 potential study areas include at least some area within the likely inland range of the marbled murrelet: Ross Lake, Olympic Peninsula, Olympic Revised (Olympic Peninsula), Wenatchee, Cle Elum, Rainier, Cowlitz Valley, Oregon Coast Ranges, Veneta (Oregon Coast Ranges/Tyee) Tyee, Union/Myrtle (Klamath), Klamath, and Hoopa (Willow Creek). The Hoopa portion of the Hoopa (Willow Creek) Study Area lies within the potential inland range of the marbled murrelet; however, extensive surveys of the Hoopa portion of the Hoopa (Willow Creek) Study Area have not verified any marbled murrelet use. If any of these are chosen, some late-nesting marbled murrelets may be disturbed during barred owl removal. The overall primary effect on other wildlife species is reduced predation and competition from barred owls.

S.7.5 Effects on the Social Environment

Ethical considerations in the removal of barred owls are very important to individuals and will affect the way in which each person views the various alternatives in this Final EIS. The Service has taken these perspectives, as expressed by commenters and the Barred Owl Stakeholders Group into consideration in developing the approach and alternatives identified in this Final EIS, including setting a clearly defined end point for removals (until information is sufficient to answer the questions, and no more than 10 years) and a detailed removal protocol to ensure as humane a removal process as possible. However, these are individual-level issues. We do not anticipate that the proposed experimental removal of barred owls would change or impact individual values in a manner that would affect the larger regional social environment.

We have identified three ways in which the alternatives may impact the social environment: (1) public health and safety, (2) environmental justice, and (3) economic effects. The risk to public health and safety is insignificant due to the use of shotguns by trained, authorized professionals only, and a tight removal protocol. There are no foreseeable effects from any of the alternatives that create any pollution or other deleterious environmental justice effects. Therefore, the removal experiments do not raise concerns about environmental injustice. Potential effects to the economy are described in Chapter 3.8 of this Final EIS.

S.7.6 Effects on Recreation and Visitor Use

Selecting one of the three potential study area including National Parks, Ross Lake, Rainier or Olympic Peninsula Study Areas could result in impacts to the visitor experience through changes in the soundscape from the discharge of shotguns during removal. Selecting any of the other study areas would have no significant effect on recreation or visitor use as these Federal lands, nonfederal lands, and wilderness areas are all open to hunting. The sound of firearms would not significantly change the soundscape of the area. The Primary effect is a result of the use of lethal removal methods on National Parks where visitors are not anticipating the sound of firearms. National Parks may experience barred owl removal under Alternatives 1, 2, and 7. No removal on National Parks would occur under the Preferred Alternative.

S.7.7 Effects on the Economy

The primary mechanism for effect is the potential restriction on timber harvest around newly reoccupied spotted owl sites in the treatment areas. Due to State law and habitat conservation plans, there is no effect on timber harvest in study areas in Washington and California. For Oregon study areas, the potential economic effect is between zero and the value of the timber on 2,893 acres of land, for the 3- to 13-year duration of barred owl removal and recovery of barred owl populations, depending on the study area, habitat condition, flexibility of the landowner, and interest in a Safe Harbor Agreement. Any effect would be temporary, and the acres would likely be available for harvest within 3 years after cessation of the barred owl removal. The potential though temporary economic effect of the Preferred Alternative is up to the value of the timber on 2,400 acres of forest for the 4 years of the barred owl removal experiment and 3 years for recovery of the barred owl populations, again depending on habitat condition, flexibility of the landowner, and interest in a Safe Harbor Agreement.

S.7.8 Effects on Costs of the Experiment

The cost of the experiments described in the alternatives range from a total of $398,000 on the Hoopa (Willow Creek) Study Area in Alternative 1, to $11,831,000 to implement Alternative 7. The estimated cost of the Preferred Alternative is $2,910,000.

S.7.9 Effect on the Cultural Environment

We identified no effects to the cultural environment. If Hoopa (Willow Creek) is the selected study area, this would be responsive to the Hoopa Valley Tribe's concerns for maintaining the culturally significant spotted owl on their lands.

ACKNOWLEDGMENTS

We are particularly indebted to Rich Fredrickson, Rocky Gutiérrez, Patti Happe, Pete Loschl, Chuck Meslow, Gary Miller, Bruce Moorhead, Frank Oliver, Len Ruggerio, Erran Seaman, and Pat Ward, who were instrumental in the initiation of one or more of the 11 demographic studies of Northern Spotted Owls. Frank Oliver bent, drilled, and polished over 10,000 color bands that we used to mark Spotted Owls. This study would not have been possible without the assistance of a small army of dedicated field biologists who helped collect the data. There have been so many participants that we cannot remember all the names, but the ones who contributed the most were: Steve Adams, Steve Adey, Garth Alling, Meg Amos, David Anderson, Scott Armentrout, Duane Aubuchon, Keith Bagnall, Doug Barrett, Greg Bennett, Ryan Besser, Jennifer Blakesley, Wendi Bonds, John Bottelli, Robin Bown, Cheryl Broyles, Mathew Brunner, Erin Burke, Tim Burnett, Joe Burns, Patty Buettner, Sue Canniff, Adam Canter, Chris Cantway, Bruce Casler, Doug Chamblin, Rita Claremont, David Clarkson, Billy Colegrove, Alan Comulada, Caroline Crowley, Ron Crutchley, Sam Cuenca, Natalie Cull, Amy Cunkelman, David Delaney, Glenn Desy, Diane Doersch, Michelle Dragoo, Amy Ellingson, Roli Espinosa, Thomas Evans, Annie Farris, Mark Fasching, Tim Fetz, Helen Fitting, David Fix, Tracy Ford, Ray Forson, Gila Fox, Tim Fox, Shawna Franklin, Laura Friar, Ken Fukuda, Rudy Galindo, Dawn Garcia, Daniel George, Alan Giese, David Giessler, Charles Goddard, Teresa Godfrey, Jim Goode, Scott Graham, Eric Grant, Ashley Green, Allison Greenleaf, Tim Grubert, Gillian Hadley, Terry Hall, Tammy Hamer, Andy Hamilton, Keith Hamm, Timothy Hanks, Rick Hardy, Megan Harrigan, Steve Hayner, Amanda Heffner, Thomas Heinz, Marisa Herrera, Lorin Hicks, Connie Holloway, Taryn Hoover, Eric Hopson, Scott Horton, Gay Hunter, John Hunter, Mark Irwin, Eugene Jackson, Ryan Jackson, Colin Jewett, Aaron Johnston, Jennifer Jones, Leilani Jones, Timm Kaminski, Marc Kasper, Tom Kay, Debaran Kelso, Leah Kenney, Wendy King, Wes King, Charles Knight, Mike Koranda, Richard Kosteke, Stan Kott, Amy Krause, David Lamphear, Chris Larson, Megan Larsson, Kurt Laubenheimer, Richard Leach, Rich Lechleitner, Doug Leslie, Krista Lewiciki, Jeff Lewis, Patrick Loafman, Dan Loughman, Joanne Lowden, Rich Lowell, Hunter Lowry, Jessica Lux, Devin Malkin, Dave Manson, Kevin Maurice, Chris McCafferty, Aaron McKarley, Dawn McCovey, Andrew McLain, Brian Meiering, Merri Melde, Joel Merriman, William Meyer, Christine Moen, Jason Mowdy, Ellen Meyers, Ben Murphy, Michael Murray, Suzanne Nelson, Matt Nixon, Timothy Parker, Heidi Pederson, Kim Pederson, Nicole Nielson-Pincus, Melanie O'Hara, Mary Oleri, Eduardo Olmeda, Michell O'Malley, Ivy Otto, Rob Owens, Antonio Padilla, Lyle Page, David Pavlackey, John Perkins, Jim Petterson, Mark Phillip, Tom Phillips, Tim Plawman, Aaron Pole, Andrew Pontius, Clayton Pope, Amy Price, Laura Quattrini, Laura Ratti, Elise Raymond, Mary Rasmussen, Reba Reidner, Angela Rex, Gail Rible, Kurt Richardson, Melanie Roan, Ana Roberts, Susan Roberts, Rob Roninger, Trish Roninger, Jen Sanborn, Ted Schattenkerk, Anthony Scheiff, Britta Schielke, Jason Schilling, Matthew Schlesinger, Kary Schlick, Doreen Schmidt, Michael Schwerdt, Tim Selim, Shawn Servoss, Paula Shaklee, Erica Sisson, Gail Sitter, Steve Small, Denise Smith, Don Smith, Spencer Smith, Alexis Smoluk, Maurice Sommé, Noel Soucy, Susannah Spock, Amy Stabins, Peter Steele, Cynthia Stern, Lori Stonum, Michael Storms, Bob Straub, Denise Strejc, Keith Swindle, Jim Swingle, Margy Taylor, Campbell Thompson, Joel Thompson, Jim Thrailkill, Sheila Turner-Hane, Shem Unger, Jennifer Van Gelder, Andrew Van Lanen, Nick Van Lanen, Veronica Vega, Frank F. Wagner, Fred Wahl, Stephanie Waldo, Abe Walston, Fred Way, Kevin White, Mark Williams, Kari Williamson, Heather Wise, Jim Woodford, Sarah Wyshynski, Lance Wyss, Bryan Yost, Kendall Young, Jessica Zeldt, and Joe Zisa. We also thank all the data analysts who helped analyze the data at the workshop, including Simon Bonner, Wendell Challenger, Mary M. Conner, Greg Davidson, Paul Doherty, Kate Huyvaert, Jake Ivan, David Lamphear, Julien Martin, Brett McClintock, and Trent McDonald. We could not have asked for a better group to get us through this difficult task in one week. Reviews of the manuscript by John Marzluff, E. Chuck Meslow, Martin Raphael, John Laurence, and two anonymous reviewers were extremely helpful. Jane Toliver at the Oregon Cooperative Wildlife Research Unit provided administrative support for the workshop. Funding for demographic studies of Northern Spotted Owls on federal lands was provided primarily by the USDA Forest Service, USDI Bureau of Land Management, and USDI National Park Service. Funding for studies on non-federal lands came from the Green Diamond Timber Company, Plum Creek Timber Company, Louisiana Pacific Lumber Company, and the Hoopa Tribe. Funding for the workshop was provided by the USDA Forest Service, USDI Bureau of Land Management, and USDI Fish and Wildlife Service.

Population Demography of Northern Spotted Owls

Abstract. We used data from 11 long-term studies to assess temporal and spatial patterns in fecundity, apparent survival, recruitment, and annual finite rate of population change of Northern Spotted Owls (*Strix occidentalis caurina*) from 1985 to 2008. Our objectives were to evaluate the status and trends of the subspecies throughout its range and to investigate associations between population parameters and covariates that might be influencing any observed trends. We examined associations between population parameters and temporal, spatial, and ecological covariates by developing a set of *a priori* hypotheses and models for each analysis. We used information-theoretic methods and $QAIC_c$ model selection to choose the best model(s) and rank the rest. Variables included in models were gender, age, and effects of time. Covariates included in some analyses were reproductive success, presence of Barred Owls (*Strix varia*), percent cover of suitable owl habitat, several weather and climate variables including seasonal and annual variation in precipitation and temperature, and three long-term climate indices. Estimates of fecundity, apparent survival, recruitment, and annual rate of population change were computed from the best models or with model averaging for each study area. The average number of years of reproductive data from each study area was 19 (range = 17 to 24), and the average number of captures/resightings per study area was 2,219 (range = 583 to 3,777), excluding multiple resightings of the same individuals in the same year. The total sample of 5,224 marked owls included 796 1-yr-old subadults, 903 2-yr-old subadults, and 3,545 adults (≥3 yrs old). The total number of annual captures/recaptures/resightings was 24,408, and the total number of cases in which we determined the number of young produced was 11,450.

Age had an important effect on fecundity, with adult females generally having higher fecundity than 1- or 2-yr-old females. Nine of the 11 study areas had an even–odd year effect on fecundity in the best model or a competitive model, with higher fecundity in even years. Based on the best model that included a time trend in fecundity, we concluded that fecundity was declining on five areas, stable on three areas, and increasing on three areas. Evidence for an effect of Barred Owl presence on fecundity on individual study areas was somewhat mixed. The Barred Owl covariate was included in the best model or a competitive model for five study areas, but the relationship was negative for four areas and positive for one area. At the other six study areas, the association between fecundity and the proportion of Spotted Owl territories in which Barred Owls were detected was weak or absent. The percent cover of suitable owl habitat

was in the top fecundity model for all study areas in Oregon, and in competitive models for two of the three study areas in Washington. In Oregon, all 95% confidence intervals on beta coefficients for the habitat covariate excluded zero, and on four of the five areas the relationship between the percent cover of suitable owl habitat and fecundity was positive, as predicted. However, contrary to our predictions, fecundity on one of the Oregon study areas (KLA) declined with increases in suitable habitat. On all three study areas in Washington, the beta estimates for the effects of habitat on fecundity had 95% confidence intervals that broadly overlapped zero, suggesting there was less evidence of a habitat effect on fecundity on those study areas. Habitat effects were not included in models for study areas in California, because we did not have a comparable habitat map for those areas. Weather covariates explained some of the variability in fecundity for five study areas, but the best weather covariate and the direction of the effect varied among areas. For example, there was evidence that fecundity was negatively associated with low temperatures and high amounts of precipitation during the early nesting season on three study areas but not on the other eight study areas.

The meta-analysis of fecundity for all study areas (no habitat covariates included) suggested that fecundity varied by time and was parallel across ecoregions or latitudinal gradients, with some weak evidence for a negative Barred Owl (BO) effect. However, the 95% confidence interval for the beta coefficient for the BO effect overlapped zero ($\hat{\beta}$ = -0.12, SE = 0.11, 95% CI = -0.31 to 0.07). The best models from the meta-analysis of fecundity for Washington and Oregon (habitat covariates included) included the effects of ecoregion and annual time plus weak effects of habitat and Barred Owls. However, the 95% confidence intervals for beta coefficients for the effects of Barred Owls and habitat overlapped zero ($\hat{\beta}_{BO}$ = -0.104, 95% CI = -0.369 to 0.151; $\hat{\beta}_{HAB1}$ = -0.469, 95% CI = -1.363 to 0.426). In both meta-analyses of fecundity, linear trends (T) in fecundity were not supported, nor were effects of land ownership, weather, or climate covariates. Average fecundity over all years was similar among ecoregions except for the Washington–Mixed-Conifer ecoregion, where mean fecundity was 1.7 to 2.0 times higher than in the other ecoregions.

In the analysis of apparent survival on individual study areas, recapture probabilities typically ranged from 0.70 to 0.90. Survival differed among age groups, with subadults, especially 1-yr-olds, having lower apparent survival than adults. There was strong support for declining adult survival on 10 of 11 study areas, and declines were most evident in Washington and northwest Oregon. There was also evidence that apparent survival was negatively associated with the presence of Barred Owls on six of the study areas. In the analyses of individual study areas, we found little evidence for differences in apparent survival between males and females, or for negative effects of reproduction on survival in the following year.

In the meta-analysis of apparent survival, the best model was a random effects model in which survival varied among study areas (g) and years (t), and recapture rates varied among study areas, sexes (s), and years. This model also included the random effects of study area and reproduction (R). The effect of reproduction was negative ($\hat{\beta}$ = -0.024), with a 95% confidence interval that barely overlapped zero (-0.049 to 0.001). Several random effects models were competitive, including a second-best model that included the Barred Owl (BO) covariate. The estimated regression coefficient for the BO covariate was negative ($\hat{\beta}$ = -0.086), with a 95% confidence interval that did not overlap zero (-0.158 to -0.014). One competitive random effects model included a negative linear time trend on survival ($\hat{\beta}$ = -0.0016) with a 95% confidence interval (-0.0035 to 0.0003) that barely overlapped zero. Other random effects models that were competitive with the best model included climate effects (Pacific Decadal Oscillation, Southern Oscillation Index) or weather effects (early nesting season precipitation, early nesting season temperature). Ownership category, percent cover of suitable owl habitat, and latitude had little to no effect on apparent survival.

Apparent survival differed among ecoregions, but the ecoregion covariate explained little of the variation among study areas and years.

Estimates of the annual finite rate of population change (λ) were below 1.0 for all study areas, and there was strong evidence that populations on 7 of the 11 study areas declined during the study. For four study areas, the 95% confidence intervals for λ overlapped 1.0, so we could not conclude that those populations were declining. The weighted mean estimate of λ for all study areas was 0.971 (SE = 0.007, 95% CI = 0.960 to 0.983), indicating that the average rate of population decline in all study areas combined was 2.9% per year. Annual rates of decline were most precipitous on study areas in Washington and northern Oregon. Based on estimates of realized population change, populations on four study areas declined 40 to 60% during the study, and populations on three study areas declined 20 to 30%. Declines on the other four areas were less dramatic (5 to 15%), with 95% confidence intervals that broadly overlapped 1.0.

Based on the top-ranked *a priori* model in the meta-analysis of λ, there was evidence that ecoregions and the proportion of Spotted Owl territories with Barred Owl detections were important sources of variation for apparent survival (φ_t) and recruitment (f_t). There was some evidence that recruitment was higher on study areas dominated by federal lands compared to study areas that were on private lands or lands that included approximately equal amounts of federal and private lands. There also was evidence that recruitment was positively related to the proportion of the study area that was covered by suitable owl habitat.

We concluded that fecundity, apparent survival, and/or populations were declining on most study areas, and that increasing numbers of Barred Owls and loss of habitat were partly responsible for these declines. However, fecundity and survival showed considerable annual variation at all study areas, little of which was explained by the covariates that we used. Although our study areas were not randomly selected, we believe our results reflect conditions on federal lands and areas of mixed federal and private lands within the range of the Northern Spotted Owl because the study areas were (1) large, covering ≈ 9% of the range of the subspecies; (2) distributed across a broad geographic region and within most of the geographic provinces occupied by the owl; and (3) the percent cover of owl habitat was similar between our study areas and the surrounding landscapes.

Key Words: Barred Owl, fecundity, Northern Spotted Owl, Northwest Forest Plan, population change, recruitment, *Strix occidentalis caurina*, *Strix varia*, survival

During the last 40 years, the management philosophy on federal forest lands in the United States has undergone profound changes as government agencies have become increasingly aware of the importance of federal lands in species conservation. Nowhere has this change been more controversial than in the Pacific Northwest (Washington, Oregon, and northern California), where attempts to maintain viable populations of Northern Spotted Owls (*Strix occidentalis caurina*), Marbled Murrelets (*Brachyramphus marmoratus*), red tree voles (*Arborimus longicaudus*), and other plants and animals that thrive in old forests have resulted in large reductions in harvest of old forests on federal lands (Ervin 1989, Durbin 1996). Because of the controversial nature of these changes and the need to know whether management policies were achieving desired objectives, the U.S. Forest Service and U.S. Bureau of Land Management initiated eight long-term mark–recapture studies of Northern Spotted Owls during 1985 to 1991 (Lint et al. 1999). The primary objective of these field studies was to provide federal agencies and the public with data on the status and trends of Spotted Owl populations and to determine if the management plans adopted by the agencies were resulting in recovery of the owl, which was listed as a threatened subspecies in 1990 (USDI Fish and Wildlife Service 1990). In addition, the recent invasion of Barred Owls (*Strix varia*) into the range of the Spotted Owl represents a competitive threat that many research groups are trying to assess. The information generated in these studies has been featured in many publications (Franklin 1992, Burnham et al. 1994, 1996, Forsman et al. 1996a, Franklin et al. 2000, Kelly et al. 2003, Hamer et al. 2007, Olson et al. 2004, 2005, Anthony et al. 2006, Bailey et al. 2009, Singleton 2010) and has played a key role in several court cases and in the development of the Northwest Forest Plan (NWFP). The NWFP is an interagency plan that was designed to protect all native plants and animals on federal lands within the range of the Northern Spotted Owl, while at the same time providing jobs and wood products (USDA Forest Service and USDI Bureau of Land Management 1994). The data from the long-term demography studies were also considered by the team that prepared the 2008 recovery plan for the Northern Spotted Owl (USDI Fish and Wildlife Service 2008) and by a committee of The Wildlife Society (2008) who commented on the plan. Research on the long-term demography of the Spotted Owl has focused attention on forest management and conservation of forest wildlife in the western United States. This research, and the controversy it has created, have changed forest management in the region and helped to bring about a general reassessment of the role of forest management in species conservation, forest ecosystem management, and human health (Thomas et al. 1993, USDA Forest Service and USDI Bureau of Land Management 1994, Dietrich 2003).

With any large-scale, long-term monitoring program, important criteria are consistency in methods and funding, and a consistent protocol for analyzing the data and reporting the results. Standard protocols are especially important in cases like the Spotted Owl, where (1) the economic stakes are high, (2) there is occasional disagreement regarding the potential for bias in the estimates of demographic parameters (Loehle et al. 2005, Franklin et al. 2006), and (3) where many different agencies and stakeholders are responsible for collecting the data. For the Northern Spotted Owl, the methods for collecting, analyzing, and reporting demographic data have been described by Franklin et al. (1996), Lint et al. (1999), Anderson et al. (1999), and Anthony et al. (2006). Because of considerable scientific and public interest in these studies, one of the key features in the monitoring program has been regularly scheduled workshops in which all of the researchers who are conducting demographic studies of Northern Spotted Owls, meet and conduct a meta-analysis of all of the demographic data (Lint et al. 1999). Since 1993, there have been four cooperative workshops, the results of which have been described in three published articles (Burnham et al. 1994, 1996, Anthony et al. 2006) and one unpublished report (Franklin et al. 1999). The most recent of these workshops was conducted in January 2009, where we completed an updated meta-analysis in which we analyzed all of the demographic data currently available on the Northern Spotted Owl, including an additional five years of data from 2004 to 2008, and modeled the demographic parameters as a function of a new set of environmental covariates. Our demographic analyses, which represent the most complete and up-to-date summary of the population status of the subspecies, are the focus of this volume of Studies in Avian Biology.

Estimates of vital rates and population trends are more interesting when there is some understanding of the environmental factors that may influence those estimates. Anthony et al. (2006) included covariates for the cost of reproduction and presence of Barred Owls in their analyses of survival and population trends of Spotted Owls, but they were not able to include habitat or weather covariates in their analysis. In our analysis, we included the same covariates examined by Anthony et al. (2006) but add several new range-wide weather covariates and habitat

covariates in Washington and Oregon. Thus, our analysis is the most comprehensive to date in terms of the number of covariates examined. Our analysis also differed from earlier analyses of Spotted Owl populations (Burnham et al. 1994, 1996) in that we use the *f*-parameterization of Pradel's (1996) temporal symmetry model to estimate the annual rate of population change (λ), and examine trends in the components of population change, including survival and recruitment rates. Our analyses have led to some valuable insights regarding our ability to discern the possible influence of environmental covariates (e.g., habitat, Barred Owls, weather) on a species that has high temporal variation in survival and reproduction. Our general approach will be of interest to other research groups investigating population dynamics of other long-lived vertebrates with similar life histories.

Our purpose in this report is threefold. First, we wanted to determine if the declines in apparent survival and populations that were reported previously (Anthony et al. 2006) have continued or stabilized. Second, we used multiple covariates in the analysis of demographic rates in an attempt to better understand which environmental factors best explained annual and spatial variability in these rates. We reasoned that one or more of these covariates might explain the recent declines in demographic rates of the subspecies. Last, we report on the use of the *f*-parameterization of the Pradel (1996) temporal symmetry model to estimate components of the annual finite rate of population change (λ), including apparent survival and recruitment rates, one of the first applications of this new technique in demographic analyses of Northern Spotted Owl populations.

STUDY AREAS

We obtained data from 11 study areas, including three in Washington, five in Oregon, and three in California (Fig. 1). Study area names and acronyms used throughout the report are described in Table 1. Size of study areas ranged from 356 to 3,922 km^2 (Table 1). The total area covered by all 11 study areas (19,813 km^2) was equal to approximately 9% of the total range of the Northern Spotted Owl, which has been estimated at 230,690 km^2 (USDA Forest Service and USDI Bureau of Land Management 1994). Our study areas included one (GDR) that was entirely on private land, one (HUP) on an Indian Reservation, four (OLY, HJA, CAS, NWC) that were primarily on federal lands, and five (CLE, RAI, COA, TYE, KLA) that included a mixture of federal, private and state lands (Table 1). Of the 11 study areas, eight (OLY, CLE, COA, HJA, TYE, KLA, CAS, NWC) were established by the U.S. Forest Service and U.S. Bureau of Land Management to document the status of Northern Spotted Owls on federal lands within the region encompassed by the Northwest Forest Plan (Lint et al. 1999). In some analyses, we present results separately for these eight areas, which we refer to as "NWFP study areas" (Table 1, Appendix A). We made a distinction between types of study areas because the Northwest Forest Plan is the overarching interagency land management plan that applies to federal lands within the range of the Northern Spotted Owl, which is of special interest to federal land managers (USDA Forest Service and USDI Bureau of Land Management 1994).

Our study areas differed from those included in Anthony et al. (2006) in that data collection on three of the 14 study areas examined therein, was either discontinued or reduced, so data from those three areas (Wenatchee, Warm Springs, and Marin study areas) were no longer available for a meta-analysis. In addition, the OLY study area was reduced in size because of lack of funding, and the size of the GDR study area was expanded in 1998. In two cases (TYE, NWC), sizes of study areas in Table 1 are different than in Anthony et al. (2006), not because of any change in area, but because we mapped the boundaries based on boundaries used in analyses of population change. In contrast, the study area boundaries for the TYE and NWC study areas displayed in Anthony et al. (2006) included survey polygons in areas adjacent to the main study areas. Because of the changes in number and size of study areas and the addition of five years of data, results of

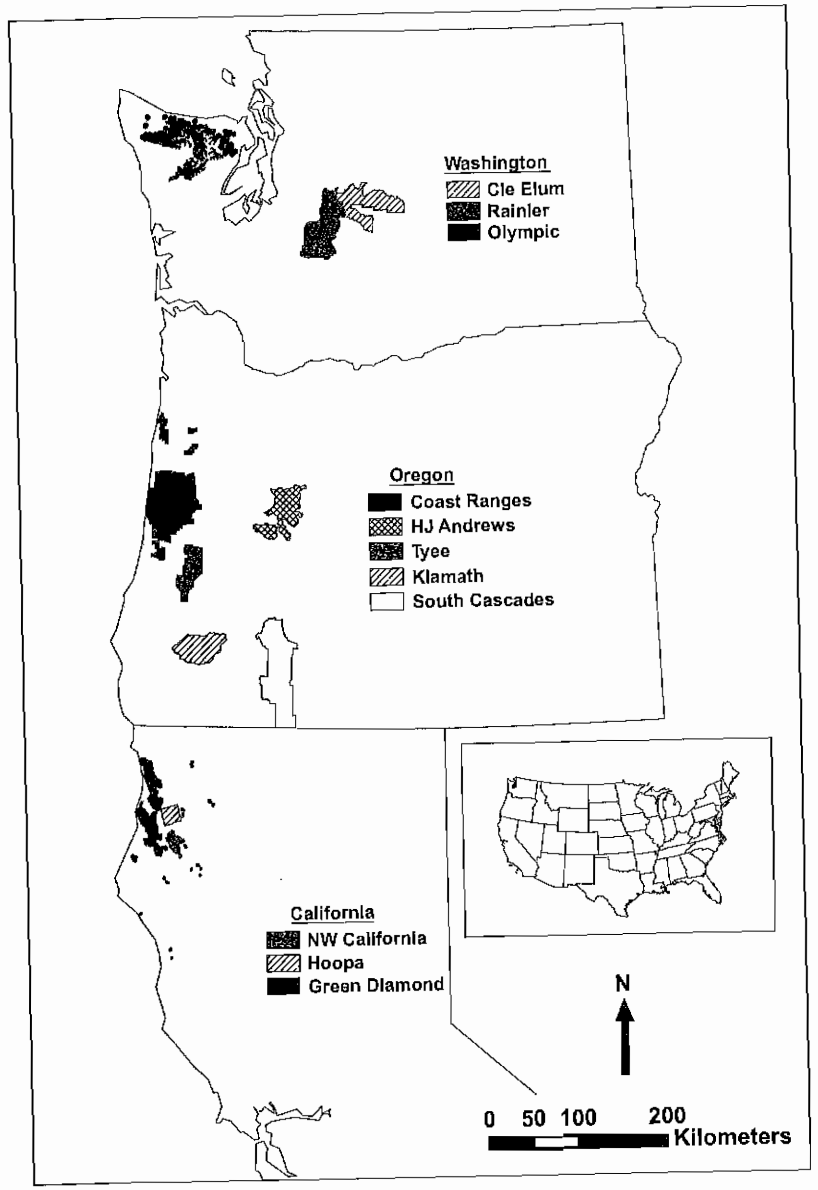

Figure 1. Locations of 11 study areas used in the analysis of vital rates and population trends of Northern Spotted Owls.

this analysis are not directly comparable to previous analyses conducted by Burnham et al. (1996) and Anthony et al. (2006).

The study areas were distributed across a broad geographic region, from central Washington south to northern California, and varied widely in climate, vegetation, and amount of topographic relief. Study areas in the coastal mountains of Oregon and California (COA, TYE, KLA, NWC, GDR, HUP) typically occurred at low to moderate elevations, where the highest elevations were $<$1,250 m, whereas study areas in the Cascades and Olympic Mountains (CLE, RAI, OLY, HJA, CAS) occurred in areas with high mountains, where forests extended from the lowland valleys up to timberline, at or above 1,500 m elevation. Climate varied from relatively warm and dry on study areas in southern Oregon and northwestern California to extremely wet in the temperate rain forests on the west side of the Olympic Peninsula, where annual precipitation ranged from 280 to 460 cm/year (Table 1). Study areas on the west slope of the Cascades Range (RAI, HJA, CAS) were typically warm and dry during summer and cool and wet during winter, with much of the winter precipitation falling as snow at higher elevations. The only study area that was entirely on the east slope of the Cascades (CLE) was characterized by warm, dry summers and cool winters, with most precipitation occurring as snow during winter.

Forests on all study areas were dominated by conifers, or mixtures of conifers and hardwoods, but there were regional differences in species composition. Forests on study areas in Washington and northern Oregon were comprised of mixtures of Douglas-fir (*Pseudotsuga menziesii*) and western hemlock (*Tsuga heterophylla*), or, in coastal areas, by mixed stands of western hemlock and Sitka spruce (*Picea sitchensis*). Ponderosa pine (*Pinus ponderosa*) was also a dominant species on the east slope of the Cascades in Washington. Study areas in southwestern Oregon and northwestern California had diverse mixtures of mixed-conifer forest or mixed-evergreen forest (Franklin and Dyrness 1973, Küchler 1977). Common canopy trees in mixed-conifer

[a] Age class codes indicate owls that were 1 year old (S1), 2 years old (S2), or ≥ 3 years old (Adults). Counts include owls first banded as S1's, S2's, or Adults, as well as owls first banded as juveniles that were subsequently recaptured when they were 1, 2, or ≥ 3 years old.
[b] All captures, recaptures, and re-sightings, excluding multiple encounters of individuals in the same year.

or mixed-evergreen forests included: Douglas-fir, grand fir (*Abies grandis*), western white pine (*P. monticola*), sugar pine (*P. lambertiana*), ponderosa pine, incense cedar (*Calocedrus decurrens*), tanoak (*Lithocarpus densiflorus*), Pacific madrone (*Arbutus menziesii*), California laurel (*Umbellularia californica*), and canyon live-oak (*Quercus chrysolepis*). The GDR study area in coastal northwestern California also included considerable amounts of coast redwood (*Sequoia sempervirens*) forest at lower elevations.

Forest age and structure varied widely among areas, ranging from one study area (GDR) that was mostly dominated by forests that were <60 years old to some study areas on federal lands (OLY, HJA, NWC, CAS) in which >60% of the landscape was covered by mature (80 to 199 years old) and old-growth forests (≥200 years old) with multilayered canopies of large trees that were typically 50 to 200 cm diameter at breast height (dbh). All study areas were characterized by diverse mixtures of forest age classes that were the product of a long history of logging, fire, windstorms, disease, and insect damage. Forests on the OLY and RAI study areas were also naturally fragmented by high-elevation ridges that were covered by snowfields and bare rock.

As stated by Franklin et al. (1996) and Anthony et al. (2006), the 11 study areas in our analysis were selected based on many considerations, including forest type, logistics, funding, land ownership boundaries, and local support from management agencies. As a result, the study areas were not randomly selected or systematically spaced. However, the study areas covered ~9% of the range of the subspecies, and an analysis by Anthony et al. (2006) indicated that the amount of suitable owl habitat in the study areas was similar to the surrounding areas. We believe, therefore, that the habitat conditions within our study areas were broadly representative of conditions on federal lands within the range of the owl, and that our results are indicative of population attributes of Northern Spotted Owls on federal lands in general. We are less confident that our estimates reflect typical trends on non-federal lands because our sample only included two study areas situated exclusively on non-federal lands (HUP and GDR). Both of those areas were in California, near the southern end of the range of the Northern Spotted Owl (Fig. 1) and were unique in that both landowners were actively managing to provide nesting and foraging habitat for Spotted Owls.

FIELD METHODS

We surveyed our study areas each year to locate owls, confirm bands, band unmarked owls, and document the number of young produced by each territorial female. Owls were trapped with a variety of methods, most commonly with a noose pole or snare pole (Forsman 1983). Each owl was marked with a U.S. Geological Survey numbered band on one leg and a unique color band on the other leg that could be observed without recapturing the owl (Forsman et al. 1996b, Reid et al. 1999). Surveys were conducted using vocal imitations or playback of owl calls to incite the owls to defend their territories, thereby revealing their presence (Franklin et al. 1996). However, once we became familiar with traditional nest and roost areas used by owls, it was often possible to locate owls by walking into traditional nest areas during the day and calling quietly while visually searching for owls near the nest. The number of visits to each survey polygon or owl territory within each study area was usually ≥3, although fewer visits were allowed in rare cases in which females either had no brood patch during the nesting season, or were observed for ≥30 min during the period when they should have been in the late incubation or early brooding stage, and showed no sign of nesting.

In most study areas, there were some Spotted Owl territories that were known from historical surveys before the studies began, but there were also many areas that had never been surveyed and where occupancy by Spotted Owls had never been reported. Because it took several years for surveyors to become familiar with their study areas and to locate and band the territorial owls within their study areas, we truncated the data to exclude the first 1 to 5 years of data on individual study areas. Truncation reduced the number of years in the sampling period, but eliminated some problems with small sample size and incomplete surveys in the early years on each study area. Once surveys began and a sample of owls was banded, new owls entered the study population when they were first detected and banded within the study area.

If owls were located on any of the visits to a given survey area, we followed a standard protocol to document the number of young fledged (NYF) by each female (Lint et al. 1999). The Lint et al. protocol took advantage of the fact that Spotted Owls are relatively unafraid of humans and will readily take live mice from human observers and carry the mice to their nest or fledged young (Lint et al. 1999, Reid et al. 1999). Except in the rare cases mentioned above, our protocol required that owls be located and offered ≥3 mice on two or more occasions each year to document their nesting status and the number of young that left the nest or "fledged" (NYF). If owls ate or cached all the mice offered, and no juvenile owls were detected, then pairs were considered to be non-nesting or failed nesters and were assigned a score of "0" for NYF. For owls that produced ≥1 young, the NYF was coded as the maximum number of young observed on at least two visits after the juveniles left the nest tree. The protocol included some exceptions that we adopted to reduce bias in fecundity estimates. For example, females were given a "0" for NYF if they (1) appeared to be non-nesting based on one or more visits during the spring and then could not be relocated on multiple return visits or (2) were determined to be nesting but could not be relocated on repeated visits to the area. We included these exceptions in our fecundity estimates because females that did not nest and females that nested but failed to produce young sometimes disappeared before the full protocol could be met, and excluding these birds would have caused a positive bias in fecundity estimates. Reproductive data from owls that did not meet the above protocols were recorded as "unknown" and excluded from our analyses.

ANALYTICAL METHODS

Development of Covariates

Barred Owl Covariate

We hypothesized that the presence of Barred Owls near areas occupied by Spotted Owls could have a negative effect on detectability, fecundity, survival, recruitment, or rate of population change of Spotted Owls within our study areas (Kelly et al. 2003, Olson et al. 2005). We did not specifically target Barred Owls in our surveys, but frequently heard or saw Barred Owls while conducting surveys for Spotted Owls, and we recorded the dates and locations of all such detections. The Barred Owl covariate that we used to evaluate our hypotheses was the annual proportion of Spotted Owl territories in each study area that had Barred Owls detected within a 1-km radius of the annual activity centers that were currently or historically occupied by the Spotted Owls on each territory. Consequently, the Barred Owl covariate was a random effect, time (year)-specific variable in analyses of individual study areas that was applied at the scale of the study area or owl population, not individual territories. In meta-analyses of survival and population change (λ), the Barred Owl covariate was a random effects variable that was applied at the meta-population level, but with data that were specific to each study area.

To develop the Barred Owl covariate, we identified an annual "activity center" for each Spotted Owl territory based on the most biologically significant records of the year, ranked in order of declining importance as follows: (1) active nest, (2) fledged young, (3) primary roost, (4) diurnal location, (5) nocturnal response to playbacks, or (6) most recent activity center if no Spotted Owls were located. The territory-specific frame of reference for this analysis was the cumulative area encompassed by 1-km-radius circles around all of the annual activity centers at each Spotted Owl territory. If there was only a single activity center within a territory in all years of the study, then the frame of reference was a single 1-km circle. If there were multiple activity centers used in different years in the same territory, then the frame of reference was the cumulative area encompassed by 1-km-radius circles around all of the annual activity centers within the territory. If Barred Owls were detected anywhere within the cumulative frame of reference in a given year, then that territory was considered to be occupied by Barred Owls in that year, and the annual study area covariate was the proportion of Spotted Owl territories occupied by Barred Owls (Appendix B). We felt that this approach was the best indicator of whether there was likely to be a Barred Owl effect on the Spotted Owls that occupied each territory. Preliminary results indicated that the relative abundance of Barred Owls varied considerably among years and study areas, and that the appearance of Barred Owls in any appreciable numbers on the study areas occurred in Washington in the mid-1980s, Oregon in the early 1990s, and California in the mid-1990s. Consequently, we predicted that any associations between demographic rates of Spotted Owl and Barred Owl detections would be variable among study areas.

Habitat Covariates

Another objective of our analysis was to determine if fecundity, survival, or recruitment were related to the annual percent cover of suitable owl habitat within or adjacent to individual study areas. The frame of reference for habitat covariates in the analysis of fecundity, apparent survival, and recruitment was the percent cover of suitable habitat within each study area. For this estimate, we used a 2.4-km radius around all historical owl activity centers to define each study area (Fig. 2, Appendix C). The acronym used for this environmental covariate was "HAB1." Choice of the 2.4-km radius as the criteria for defining study area boundaries was based on an approximation of the annual area used by resident pairs of Northern Spotted Owls (Forsman et al. 1984, 2005; Carey et al. 1992; Hamer et al. 2007). Although annual home ranges of Spotted Owls vary widely among geographic regions, we opted to simplify the analysis by using a constant radius to define all study areas.

Our definition of suitable habitat was based on Davis and Lint (2005), who created a base map of suitable Spotted Owl habitat for Washington and Oregon based on multiple covariates, including tree diameter, stand structure, canopy cover, and elevation. Accuracy assessments of these maps were conducted at both the physiographic province and territory scale. At the province scale, maps correlated well with locations of known owl territories, with Spearman rank coefficients ranging from $r_s = 0.83$ to 0.99 ($P < 0.001$; Appendix E in Lint 2005). At the territory scale, 19 sets of independent data from radio-marked Spotted Owls in Oregon indicated that average Spearman rank correlations between suitable habitat and locations of owls were 0.99 in the Coast Ranges, 0.93 in the western Cascades, and 0.94 in the southern Oregon Cascades (Appendix F in Lint 2005). Although there were exceptions, the majority of forests that fit the Davis and Lint (2005) definition of suitable habitat were characterized by large overstory conifers (dbh > 50 cm) and high (>70%) canopy cover (e.g., see Table 3-3 in Davis and Lint 2005:41). The Davis and Lint definition of "suitable owl habitat" does not perfectly define suitable habitat for Northern Spotted Owls throughout their geographic range, but was the best and most current habitat map that was available for our study areas in Oregon and Washington.

Because the base map created by Davis and Lint was based on a single snapshot in time (1996), we used time period-specific stand replacement/disturbance data (Cohen et al. 1998, Healey et al. 2008) to add or subtract habitat in the base map to create a time series of habitat maps for each study area in Oregon and Washington, with four-year time steps in 1984, 1988, 1992, 1996, 2000, and 2002. To create this time series, we assumed that "change" represented loss of habitat, and that the time scale was too short for regrowth of habitat. Therefore, the historical time step maps could be created by "adding back" habitat to the baseline map in years prior to 1996 and subtracting

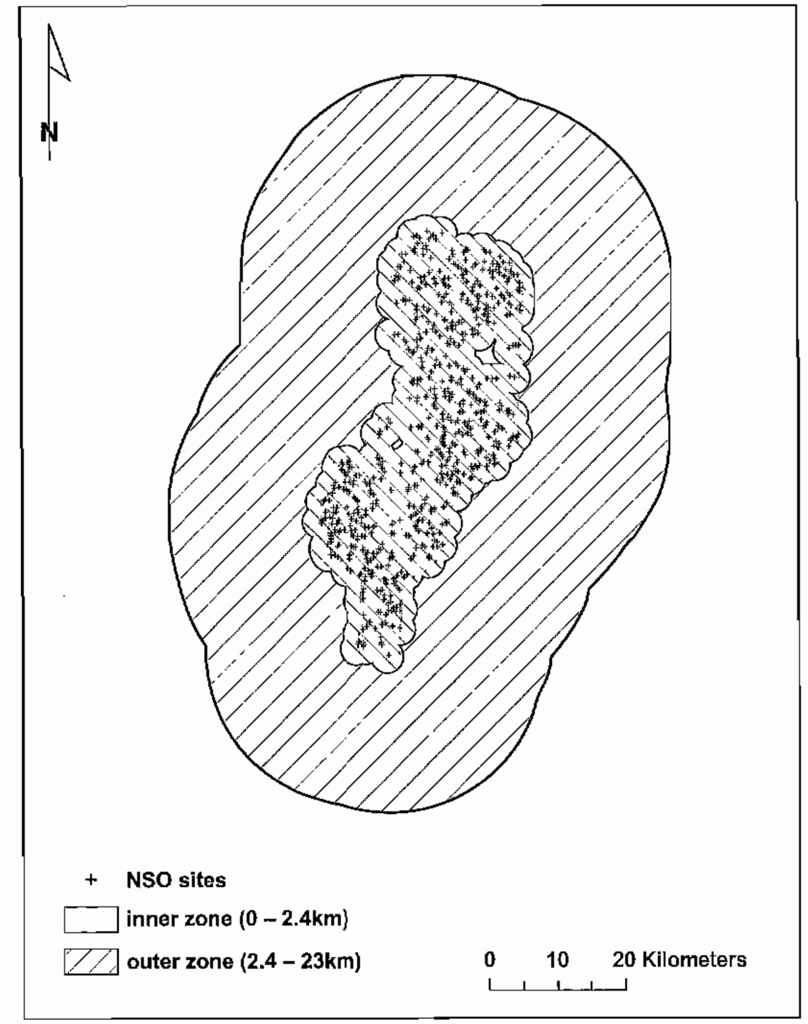

Figure 2. Example illustrating frames of reference used to evaluate the proportion of the landscape covered by suitable owl habitat on one of the Northern Spotted Owl demographic study areas (in gray). The small polygon indicates the area within 2.4-km-radius circles around all owl site centers, and the larger polygon indicates the area within 23-km-radius circles around all owl site centers, exclusive of the area of the inner polygon.

habitat from the base map in the years after 1996. To produce annual estimates of suitable habitat, we plotted the estimated percent cover of suitable owl habitat in each time step and then estimated the percent cover of habitat in the years between time steps by assuming a linear trend between the 4-year intervals (Appendix C). Consequently, the habitat covariate was a random effects variable that was time (year)-specific and was applied at the scale of each study area or owl population, comparable to the Barred Owl covariate. For the meta-analyses of survival and λ, the habitat covariate was a random effects variable that was applied at the meta-population level, with population data that were specific to each study area.

For the habitat covariate in the analysis of λ, we used the same definition of suitable habitat as in the analysis of survival, but developed two covariates based on different spatial scales. One covariate (HAB2) was the same as the HAB1 covariate in the analysis of survival (2.4-km-radius scale), with minor differences due to the fact that we truncated the time-series data to use fewer years in the meta-analysis than the analyses of survival and fecundity on some individual study areas. The second covariate (HAB3) was based on the percent cover of suitable habitat within a 23-km radius of all historical owl activity centers minus the area in HAB2 (Fig. 2, Appendix C). We used the 23-km radius to account for the possible influence of habitat on recruitment from the region immediately surrounding the study area out to a distance that approximated the median natal dispersal distances of Northern Spotted Owls, which were about 19 km for males and 27 km for females (Forsman et al. 2002:15).

After reviewing the habitat map for California, we decided not to develop habitat covariates for study areas from the state map of California because of inconsistencies with the map for Washington and Oregon (Davis and Lint 2005). Two primary problems with the California habitat data were that (1) the California map was based on different remote-sensed data than the combined map for Oregon and Washington (Davis and Lint 2005), and (2) complete evaluation of habitat change in California was not possible because the change detection information for California dated back to only 1994. Therefore, rather than confound our results with maps that were not comparable, we opted to limit our examination of the effects of habitat covariates to Oregon and Washington.

Weather and Climate Covariates

To determine if fecundity, apparent annual survival, or rate of population change were associated with variation in weather and climate, we used climate covariates that were associated with demographic performance of Spotted Owls in previous studies, including mean precipitation and temperature, Palmer Drought Severity Index (PDSI), Southern Oscillation Index (SOI), and Pacific Decadal Oscillation (PDO; Franklin et al. 2000, Seamans et al. 2002, LaHaye et al. 2004, Olson et al. 2004, Dugger et al. 2005, Glenn 2009). These climate variables included measures of seasonal and annual weather as well as longer-term measures of climatic conditions.

We obtained mean temperature and precipitation data for each study area from Parameter Elevated Regression on Independent Slope Models (PRISM) maps (Oregon Climate Service 2008). PRISM maps were developed using weather station data and a digital elevation model to generate raster-based digital maps with 4-km^2 resolution of mean monthly temperature (minimum and maximum) and precipitation on each study area (Daly 2006). We combined the monthly maps into seasonal and annual maps that corresponded with important life history stages of the owl, including winter (1 Nov to 28 Feb), early nesting season (1 Mar to 30 Apr), late nesting season (1 May to 30 Jun), and annual periods (1 Jul to 30 Jun). Temperature and precipitation values for each study area and time period were obtained by computing the average values of raster cells for each seasonal or annual map that fell within the study area boundaries.

We used the Palmer Drought Severity Index (PDSI) as an index of primary productivity that has the potential to influence abundance of Spotted Owl prey (NOAA 2008a). The PDSI is the deviation of moisture conditions from normal (30-yr mean = 1970 to 2000), standardized so comparisons can be made across regions and over time (Alley 1984). Values ranged from -6 (extreme drought) to +6 (extremely wet), with zero representing near-normal conditions. The index was calculated separately for climate regions within each state. Most study areas fell within one climate region. For study areas that included multiple climate regions, we used a weighted average of PDSI values based on the proportion of the study area that fell within each climate region.

We used monthly values of the Southern Oscillation/el Niño Index (SOI; NOAA 2008b) and the Pacific Decadal Oscillation (PDO; University of Washington 2008) to assess region-wide climate patterns. We averaged monthly values to obtain annual (Jul 1 to Jun 30) measures of SOI and PDO. Consequently, all of the weather and climate covariates were random effects variables that were time-specific and

were applied at the scale of owl populations in the analyses of individual study areas. For the meta-analyses of fecundity, survival, and λ, the weather covariates were random effects variables that were applied at the meta-population level, but with data that were specific to each study area.

Land Ownership, Ecoregion, and Latitude Covariates

To evaluate whether vital rates or rates of population change differed depending on land ownership, ecoregion, or latitude, we developed covariates for land ownership (OWN), ecoregion (ECO), and latitude (LAT). The ownership covariate was a categorical variable that divided study areas into three categories depending on whether they were privately owned, federally owned, or included an approximately equal mix of private and federal ownership (Appendix A). The ecoregion covariate categorized each study area into one of five ecoregions that incorporated geographic location (state) and the major forest type in each study area (Appendix A). Latitude was a continuous variable measured at the center of each study area. In the meta-analyses of fecundity, survival, and λ, all of these covariates were fixed effects variables that were applied at the scale of meta-populations.

Reproduction Covariate

To determine if there was evidence for a cost of reproduction on adult survival in the following year, we used the mean number of young fledged per female as a year- and study area–specific covariate in analyses of apparent survival. We also used the mean NYF covariate in recapture models to investigate the effect of reproduction on detection probabilities in the current year. The mean NYF covariate was time (year)-specific and used as a random effects variable at the scale of populations, comparable to the way we used the Barred Owl and habitat covariates. In the meta-analysis of survival, the NYF covariate was applied at the scale of meta-populations.

Fecundity

Individual Study Areas

We conducted all analyses of reproduction based on the annual number of young produced per territorial female (NYF), but to be consistent with previous reports (Forsman et al. 1996a, Franklin et al. 2004, Anthony et al. 2006), we present the data as "fecundity," where fecundity is the average annual number of female young produced per female owl. We estimated fecundity as NYF/2, based on genetic evidence from blood samples of juveniles that the sex ratio of Spotted Owls is 1:1 at hatching (Fleming et al. 1996). We assumed that the owls in our samples were representative of the population of territorial birds and that sampling was not biased toward birds that reproduced. We think these assumptions were reasonable because Spotted Owls typically occupy the same areas year after year and are reasonably easy to find even in years when they do not breed (Franklin et al. 1996, Reid et al. 1999).

For the analysis of individual study areas, we used PROC MIXED in SAS (SAS Institute, Inc. 2008) to fit a suite of *a priori* models for each study area that included: (1) the effects of age (A), (2) general time variation (t), (3) linear (T) or quadratic (TT) time trends, (4) the proportion of Spotted Owl territories where Barred Owls were detected each year on each study area (BO; see Appendix B), and (5) an even–odd year effect (EO). In addition, we included a simple autoregressive time effect model and the climate and habitat covariates described above (see also Appendix C). The autoregressive time effect model [AR(1)] fits a time trend but allows residuals to be non-independent where $Y_t = \beta_0 + \beta_1 t + \varepsilon_t$ and the correlation of ε_t and $\varepsilon_{t+k} = \rho^k$. Model ranking and selection of best models were based on minimum AIC_c (Burnham and Anderson 2002).

Plots of the annual variance-to-mean ratio for all study areas confirmed that the variance of NYF was nearly proportional to the mean of NYF, with some evidence of smaller variances at higher levels of reproduction. This pattern was consistent with a truncated Poisson distribution

(Evans et al. 1993) because Spotted Owls seldom raise more than two young. However, despite the integer nature of the underlying data (0, 1, 2, and rarely 3 young), the average annual number of young fledged per age class in each study area in each year was not distributed as Poisson (Franklin et al. 1999, 2000; Anthony et al. 2006). For this reason, we did not use a Poisson regression because it is not robust to departures from a Poisson distribution (White and Bennetts 1996). Instead, we used regression models based on the normal distribution, which are less biased when distributions depart from normal. Sample sizes were also sufficiently large to justify the assumption of a normal distribution for each average as long as an allowance was made for the dependence of the variation on the mean (see below; Anthony et al. 2006). The process of averaging NYF also clarified the definition of the sampling unit for this analysis, as the appropriate sample unit was not the individual owl, but the study area–age class combination, which responds to yearly effects that influence the entire study area. Autocorrelation issues in NYF over time for a particular territory were also avoided by treating study areas as the sampling unit. For all these reasons, we used the normal regression model on the annual averages for the analysis of NYF in each age class.

We also reduced the effect of the variance-to-mean relation by fitting models to the annual mean NYF by age class. Annual means for each study area were modeled as

PROC MIXED; MODEL MEAN_NYF = fixed effects.

Thus, residual variation was a combination of year-to-year variation in the actual mean and variation estimated around the actual mean and is approximately equal to

$$\text{var(residual)} = \text{var(yr effects)} + \text{var(NYF)}/n,$$

where n = number of territorial females checked in a particular year. Our approach was justified for several reasons. First, we performed a variance components analysis in which we looked at the individual fecundity records of adult females and estimated the resulting variance components after adjusting for the obvious even–odd year effects. Because Spotted Owls are highly territorial and long-lived, it is difficult to distinguish between spatial and individual effects, and such effects are termed "spatial" components in this report. Our variance components analysis showed that when comparing components of variance, spatial variance among territories tended to be small relative to temporal variance among years and other residual effects (see Results). Therefore, we concluded that ignoring spatial variance within study areas would not bias the results, which negated the need to include owl territory as a random effect. Second, we were able to support the key assumption that the var(residual) was relatively constant because (1) var(NYF)/n was small relative to var(yr effects); (2) the total number of females sampled was roughly constant over time for each study area so that var(NYF)/n was roughly constant; and (3) relatively few (<10%) territorial subadults were encountered, such that var(NYF)/n was also about constant even though var(NYF) may decline with increasing age class. The assumptions were verified by Levene's test for homogeneity of variances (Ramsey and Schafer 2002). Third, we assumed that residual effects were approximately normally distributed because, based on the central limit theorem, the average of the measurements will have an approximate normal distribution with large sample sizes even if the individual measurements are discrete. Finally, covariates included in the analysis of each study area (such as BO) were more easily modeled at the study area (population) level with the above approach.

The best model was not consistent among study areas, so we used a nonparametric approach to estimate mean NYF. First, we computed mean NYF for each year and age class. Then we averaged the means across years within each age class. The estimated standard error was computed as the standard error of the average of the averages among years. This method for estimating NYF gave equal weight to all years, regardless of the number of birds actually sampled in a year, and did not force a model for changes over time. It treated years as random effects with year effects being large relative to within-year-sampling variation. Estimates weighted by sample sizes in each year were not substantially different.

Meta-analysis of Fecundity

In the meta-analysis of fecundity, we restricted the analysis to adult females only because samples of 1- and 2-yr-old owls were small (<10%) in most data sets. In this analysis, we developed a set of *a priori* models similar to those developed for individual study areas, but in addition to the effects included in the models for individual study areas, we also investigated the effects of latitude (LAT), ecoregion (ECO), and land ownership (OWN; Appendix A) as fixed random variables. We did not have habitat covariates for study areas in California, so we conducted two separate meta-analyses of fecundity. The first analysis included all study areas without any habitat covariates, and the second included study areas from Washington and Oregon only, with habitat covariates included in the *a priori* models.

We used mixed models to perform meta-analyses on mean NYF per year for the same reasons specified above for the study area analysis. An ecoregion by year (ECO*yr) treatment combination was defined for each study area with owls within study areas as units of measure. Thus, sampling units were study areas within ECO*yr, which we treated as a random effect in the mixed models. Because ownership, latitude, and ecoregion apply at the study-area level rather than at the individual level, we conducted model selection based on average NYF by study area and year. Model rankings and selection of best models were based on minimum AIC_c or $QAIC_c$ (Burnham and Anderson 2002).

Apparent Survival

Individual Study Areas

We used capture–recapture (re-sighting) data to estimate recapture probabilities (p) and annual apparent survival probabilities (φ) of territorial owls. Recapture probabilities were defined as the probability that an owl alive in year $t+1$ is recaptured, given that it is alive and on the study area at the beginning of year t. Apparent survival was defined as the probability that an owl survives and stays on the study area from time t to $t+1$, given that it is alive at the beginning of year t. Our general approach for estimating apparent survival was to first develop a set of *a priori* models for analysis based on biological hypotheses that were discussed and agreed upon by all participants at the workshop. The *a priori* models were then represented by statistical models in program MARK (White and Burnham 1999). Then we evaluated goodness-of-fit and estimated an overdispersion parameter ($\hat{c}$) for each data set, and estimated recapture probabilities and apparent survival for each capture–recapture data set with the *a priori* models in program MARK. If needed, we adjusted the covariance matrices and AIC_c values with $\hat{c}$ to inflate variances of parameter estimates and obtain $QAIC_c$ values for model selection. Then, we selected the most parsimonious model for inference based on the $QAIC_c$ model selection procedure (Burnham and Anderson 2002). Additional details on methods of estimation of survival from capture–recapture data from Northern Spotted Owls are provided by Burnham et al. (1994, 1996) and Anthony et al. (2006).

We used Cormack–Jolly–Seber open population models (Cormack 1964, Jolly 1965, Seber 1965, Burnham et al. 1987, Pollock et al. 1990, Franklin et al. 1996) in program MARK (White and Burnham 1999) to estimate apparent survival of owls for each year. The yearly estimate of apparent survival was roughly from 15 June in year t to 14 June in year $t+1$, which corresponded with the approximate mid-point of the annual field season in the demographic studies (March or April to August). Owls first banded as subadults or adults were assigned to one of three non-juvenile age classes based on plumage attributes (Forsman 1981, Moen et al. 1991, Franklin et al. 1996). The three age classes were: 1-yr-old subadults (S1), 2-yr-old subadults (S2), and ≥3-yr-old adults (A). We did not estimate juvenile survival rates because estimates of juvenile survival were confounded by permanent emigration caused by natal dispersal (Burnham et al. 1996, Forsman et al. 2002). Although permanent emigration can also cause underestimates of survival for non-juvenile owls, we did not consider this a serious bias because site fidelity of adult Spotted Owls is high and because breeding dispersal is most commonly restricted to short movements between adjacent territories (Forsman et al. 2002).

The goal of the data analysis and model selection process was to find a model from an *a priori* list of models that was best in the sense of Kullback–Leibler information (Burnham and Anderson 2002). Prior to model fitting we used the global model φ(a*s*t), *p*(a*s*t) to evaluate each data set for goodness-of-fit to the assumptions of the Cormack–Jolly–Seber model using the combined χ^2 values and degrees of freedom for Test 2 and Test 3 from program RELEASE (Lebreton et al. 1992). The global model included estimates of age (a), sex (s) and time (t) effects, plus the interactions among age, sex, and time for both φ and *p*.

We computed estimates of overdispersion ($\hat{c}$) using the median-$\hat{c}$ procedure in program MARK to determine if there was evidence of overdispersion in the data. In cases where there was evidence of overdispersion, we used estimates of $\hat{c}$ to inflate standard errors and adjust the log-likelihood function for the effects of lack of independence in the data.

For the analysis of survival on the individual study areas, we fit models that included the effects of age, sex, time, time trends (linear, quadratic, autoregressive, change-point, cubic spline), and the annual covariates for reproduction (Appendix D) and Barred Owls (Appendix B). We used cubic spline models to fit flexible trends without specifying their form (Hastie and Tibshirani 1990, Green and Silverman 1994, Venables and Ripley 1999). Spline models provide this flexibility by estimating cubic polynomial trends between a series of four knots (two boundary, two interior) in such a way that the polynomials meet smoothly (i.e., are differentiable) at each knot. Boundary knots were placed at the starting and ending year for each study, while one interior knot was placed midway between the first year of each study and 2002, and the other interior knot was placed at 2002. Cubic spline models with two interior knots estimated six additional parameters each.

We conducted model selection in three stages. First, we identified the best *p* structure for the data in each study area by using AIC_c model selection (see below) to choose the best model from among a set of *a priori* recapture models developed during the protocol session. The *a priori* models included 11 models that were the same for all study areas (Appendix E) plus up to three optional "biologist's choice" models that could be included if group leaders wanted to evaluate the effects of unique conditions on their study areas. In this stage, we used the same global structure on φ for all models [φ(g*s*t)], where "g" indicates study area. Then, in stage two, we applied the best *p* structure from stage one to 64 *a priori* survival models developed during the protocol session (Appendix F) and used AIC_c model selection to identify the best survival model for each study area. Then, we used the φ structure from the best 2 to 3 models in stage two in combination with the *p* structure from the best 2 to 3 models in stage one to develop 4 to 9 additional models.

We used maximum likelihood estimation to fit models (Brownie et al. 1978, Burnham et al. 1987) and optimized parameter estimation using program MARK (White and Burnham 1999). We used $QAIC_c$ for model selection (Lebreton et al. 1992, Burnham and Anderson 2002), which is a version of Akaike's Information Criterion (Akaike 1973, 1985; Sakamoto et al. 1986) corrected for small sample bias (Hurvich and Tsai 1989) and overdispersion (Lebreton et al. 1992, Anderson et al. 1994). We computed $QAIC_c$ for each candidate model and selected the model with the lowest $QAIC_c$ value as the best model for inference. We used $\Delta QAIC_c$ values to compare models, where $\Delta QAIC_{ci} = QAIC_{ci} - \min QAIC_c$. We used Akaike weights (w_i) (i.e., model probabilities) to address model selection uncertainty and the degree to which ranked models were considered competitive. We also used Akaike weights to compute estimates of time-specific, model-averaged survival rates and their standard errors for each study area (Burnham and Anderson 2002:162). We used model averaging because there were usually several competitive ($\Delta QAIC_c < 2.0$) models for a given data set (Burnham and Anderson 2002).

For each study area, we used the variance components module of program MARK to estimate temporal process variation ($\sigma^2_{temporal}$; White et al. 2001, Burnham and White 2002). Use of variance components allowed us to separate sampling variation (variation attributable to estimating a parameter from a sample) in apparent survival estimates from total process variation. Process variation was decomposed into temporal (parameter variation over time) and spatial (individuals on territories) components.

Meta-analysis of Apparent Survival

The meta-analysis of apparent survival rates was based on capture histories of adult males and females from 11 study areas. Subadults were not included because samples of subadults were small in many study areas, and our objective was to reduce the complexity of the analysis to focus on the main variables of interest, including trends in adult survival and the effects of the Barred Owl, reproduction, weather, and habitat covariates. Apparent survival and recapture probabilities were estimated with the Cormack–Jolly–Seber model using program MARK (White and Burnham 1999). The global model for these analyses was φ(g*s*t) *p*(g*s*t), where g was study area, s was sex, and t was time (yr). Goodness-of-fit was assessed with the global model in program RELEASE (Burnham et al. 1987), and the estimate of overdispersion (c) was computed as the average of the $\hat{c}$ estimates from the median-$\hat{c}$ routine for each of the 11 study areas, weighted by the number of owls in each study area analysis. Estimates of overdispersion were used to adjust model selection to $QAIC_c$ and to inflate variance estimates. We initially evaluated eight models of recapture probability [*p*(g+t), *p*(R), *p*(g+s+t), *p*(R+s), *p*([g+t]*s), *p*(R*s), *p*(BO), *p*(BO+g)] with a general structure on apparent survival [φ(g*t+s)], where R indicates the effect of reproduction in the current year and BO indicates the potential effect of Barred Owls. Using the best model structure for *p* from the initial eight models, we evaluated 15 additional models for apparent survival to determine which combinations of area, sex, time, Barred Owl effects (BO), and reproductive effects (R) minimized the amount of Kullback–Leibler information loss (Appendix G). Sex was then removed from the best model to check for strength of this effect. Then we ran four more models in which the group effect of study area (g) was replaced with the group surrogates OWN, ECO, OWN*ECO, and Latitude (LAT). Next, we added six climate covariates for all study areas and a habitat covariate (HAB1) for study areas in Washington and Oregon. The habitat covariate was added to the base model of φ(g) as either an additive (+) or an interactive (*) effect. Comparable habitat data were not available for study areas in California, so the habitat covariate was applied only to study areas in Washington and Oregon. Time variation for California study areas was modeled with an additive time effect (t) instead of habitat. Climate data for the Southern Oscillation Index (SOI), Pacific Decadal Oscillation (PDO), mean amount of precipitation during the early nesting season (ENP), and mean temperature during the early nesting season (ENT) were added to the base model of φ(g) as either additive (+) or interactive (*) effects.

After reviewing the results of the above analyses, we concluded that the annual variability in apparent survival was too great for any of the covariates for Barred Owls, reproduction, habitat, or climate to have a measurable effect on the modeling or estimates. Consequently, we used the Method of Moments random effects module (White et al. 2001) in program MARK to do some additional *a posteriori* modeling of apparent survival with the above covariates in order to determine the amount of temporal variability explained by each covariate. We used the general model φ(g*t) *p*(g+s+t) in the random effects analysis. To estimate the temporal variation explained by each covariate, a random effects design matrix was used that included the study area effect (g) plus the temporal covariate.

Annual Rate of Population Change (λ)

Individual Study Areas

In the analysis of annual finite rate of population change (λ), we used estimates from the reparameterization of the Jolly–Seber capture–recapture model (λ_{RJS}), which was implemented in program MARK based on the *f*-parameterization of the temporal symmetry models of Pradel (1996; see also Franklin 2001). The rationale for using this parameterization instead of Leslie matrix models was discussed in detail in Franklin et al. (2004) and Anthony et al. (2006). Most importantly, estimates of survival rates for juvenile owls from capture–recapture data are biased low because of extensive emigration from the study areas; losses to natal dispersal lead to negatively biased estimates of λ from Leslie matrix models (Anthony et al. 2006). Since the Pradel (1996) method analyzes capture histories in both a forward and backward manner, it treats mortality, reproduction (recruitment), and movements into and out of the study areas equally, and therefore produces less-biased estimates of λ (see Anthony et al. 2006:11 to 13). The two primary assumptions of the Pradel (1996) method are that study area size is constant and that survey effort is relatively constant in each sampling interval. In other words, owls are not gained or lost because of changes in effort or survey area.

In addition to obtaining annual estimates of λ (λ_t) and trends over time in these estimates, the Pradel model allowed for the decomposition of λ_t into two components, apparent survival (φ) and recruitment (f), where:

$$\lambda_t = \varphi_t + f_t$$

Here, φ_t is local apparent survival and reflects both survival of territory holders within study areas and site fidelity of territory holders to study areas. Recruitment (f_t) is the number of new animals in the population at time $t + 1$ per animal in the population at time t and reflects both *in situ* recruitment (individuals born on the study area that become established territory holders) and immigration of recruits from outside the study area. Unfortunately, we were unable to further decompose φ_t and f_t. The complement of adult survival includes losses to death and permanent emigration, whereas recruitment includes immigration of new adults, as well as reproductive rate, survival of young, and ability of young birds to obtain territories. Consequently, the estimates of λ_t accounted for all of the losses and gains in the study area populations during each year. All estimates of λ were truncated at 2006, because parameter estimates for the last two years of study were not estimable. In addition, we removed 1 to 5 of the first years of surveys to eliminate any potential bias in estimates of λ that may have been associated with any artificial population growth associated with initial location and banding of owls that occurred during the first few years of each study (Anthony et al. 2006). Our procedure resulted in truncated data sets for each study area, which satisfied the second assumption of equal sampling effort for the Pradel (1996) method.

Estimates of Realized Population Change

We used the methods of Franklin et al. (2004) to convert estimates of λ_t to estimates of realized population change ($\hat{\Delta}_t$), which is the proportional change in estimated population size relative to population size in the initial year of analysis. We computed annual estimates of realized population change on each study area as

$$\hat{\Delta}_t = \prod_{i=x}^{t-1} \hat{\lambda}_i$$

where x was the year of the first estimated λ_t. To compute 95% confidence intervals for Δ_t, we used a parametric bootstrap algorithm (see Franklin et al. 2004:19) with 1,000 simulations. Under this approach, we used the estimates of annual survival, $\hat{\varphi}_t$, recruitment, $\hat{f}_t$, and recapture probabilities, $\hat{p}_t$, together with an estimate of initial abundance, $\hat{N}_x$, to stochastically generate individual capture histories. Each of the 1,000 generated data sets (sets of capture histories) was then analyzed as data and used to obtain estimates of λ_t and Δ_t, from which empirical confidence intervals were constructed. Specifically, we followed the basic approach of Anthony et al. (2006), where the 95% confidence intervals were based on the *i*th and *j*th values of Δ_t arranged in ascending order, where $i = (0.025)(1{,}000)$ and $j = (0.975)(1{,}000)$.

Meta-analysis of Annual Rate of Population Change

We used encounter histories from banded territorial owls (subadults and adults) in the meta-analysis of λ from the 11 study areas. In this analysis, we used the most general model [$\varphi(g^*t)$ $p(g^*t)$ $f(g^*t)$] as the basis of the random effects modeling. Our approach permitted inferences about the influence of the various covariates on λ_t, φ_t, and f_t and allowed us to investigate whether φ_t or f_t appeared to covary more closely with λ_t. Modeling results included models in two categories: 45 models in the original *a priori* model set and six additional models developed *a posteriori* after looking at the results of the initial model set (Appendix H). Basically, there was evidence from the ranking of the *a priori* models that two covariates (ecoregions, Barred Owls) were important sources of variation for φ_t and f_t, so we developed six models that included both covariates (see last six models in Appendix H). Thus, our inferences were based on the original members of the model set, but we believe that the two-covariate models that we explored should be considered for future modeling in the next cooperative meta-analysis. As in the analyses of individual study areas, estimates of λ from the meta-analysis were truncated at 2006, because parameters for the last two years of study were not estimable.

Statistical Conventions

We used estimates of regression coefficients (β) and their 95% confidence intervals as evidence of an effect on fecundity, apparent survival, or annual rates of population change by the different factors or covariates in models. The sign of the coefficient represented a positive (+) or negative (-) effect of a factor or covariate, and the 95% confidence intervals were used to evaluate the evidence for $\beta < 0.0$ (negative effect) or $\beta > 0.0$ (positive effect). We did not use 95% confidence intervals as strict tests of $\beta = 0.0$, but as measures of precision and general evidence of an effect. For example, if the 95% confidence intervals for a regression coefficient did not overlap 0 and the covariate was included in the best or a competitive model, we concluded that there was "strong evidence" for an effect of that factor or covariate. If the 95% confidence interval overlapped 0 broadly, regardless of the model it occurred in, we concluded that there was "no evidence" for an effect of that factor or covariate. Lastly, if a 95% confidence interval overlapped 0 only slightly, with <10% of the interval above or below 0, we concluded that there was "some evidence" of an effect of that factor or covariate. We attempted to use this approach consistently throughout all of the modeling of fecundity, apparent survival, and annual rate of population change (Anthony et al. 2006).

WORKSHOP PROTOCOLS

Data from the demographic studies of Northern Spotted Owls have been examined in four previous workshops, the results of which have been described in four published reports (Anderson and Burnham 1992, Burnham et al. 1994, Forsman et al. 1996a, Anthony et al. 2006) and one unpublished report (Franklin et al. 1999). Participants in these workshops knew that their data and methods would be subjected to considerable scrutiny, and they developed a transparent and consistent protocol for conducting the analyses (Anderson et al. 1999). We followed the same protocol in our workshop, which was held during 9 to 19 January, 2009. Our first step was to subject the data to a formal error-checking process prior to the workshop to make sure that all data were correctly prepared for analysis and that all participants followed the same field protocols for assessing fecundity and survival of owls. The error-checking process was accomplished by first having the lead biologist on each study area prepare their fecundity files and capture history files in a standardized format for analysis in programs SAS (SAS Institute, Inc. 2008) or MARK (White and Burnham 1999). Then we had each group leader submit the field data forms for a randomly selected sample of 10 records each from their fecundity files and capture history files. If the data were correctly formatted and the field data forms supported the data in the random sample, then the data were approved for analysis. If not, the study area leader was apprised of any problems and asked to review and correct their files before resubmitting another 10 randomly selected records for review. The resampling process was repeated until no errors were found in the random samples from each area. Upon arrival at the workshop, each study area leader signed a form stating that their data had passed the error-checking process and were ready for analysis.

Once at the workshop, the entire group of biologists and analysts met and discussed the plausible hypotheses and developed the protocols and *a priori* models that were used in the analysis (Anderson et al. 1999). The planning part of the workshop involved 2.5 days of discussion, including presentations and discussions regarding the covariates that were available for analysis. Once the protocol session was complete and everyone was in agreement regarding which hypotheses would be used and how they would be modeled, the analysis began, and all participants agreed that, regardless of the outcome, they would not withdraw their data once the analysis started.

RESULTS

Fecundity

Individual Study Areas

Estimates of fecundity (mean number of female young fledged per female per year) were based on 11,450 observations of the number of young produced by territorial females. Female age was an important factor affecting fecundity on all areas (Table 2), with mean fecundity generally lowest for 1-yr-olds (0.070 ± 0.015), intermediate for 2-yr-olds (0.202 ± 0.042), and highest for adults (0.330 ± 0.025; Table 3). Estimates of mean fecundity also varied among study areas (Table 3). The overall composition of the territorial female population across all areas and years was 3.8% 1-yr-olds, 6.1% 2-yr-olds, and 90.1% adults. Mean fecundity of adults and 2-yr-olds was markedly higher on the CLE study area than on all other study areas (Table 3).

In 9 of the 11 study areas, the best model or a competitive model included a biennial pattern of high reproduction in even years and low reproduction in odd years (EO effect; Table 2). However, this even–odd year effect was stronger in some areas than others and appeared to be less prominent in the later years of the study (Fig. 3). In addition, alternative models with other types of time effects on fecundity [T, TT, AR(1)] were competitive with the EO models (Table 2). Thus, no single model adequately explained the annual variation in fecundity across all areas.

Of the 11 study areas, seven (CLE, COA, HJA, TYE, KLA, NWC, GDR) had top models or competitive models that included linear (T) or quadratic (TT) time trends on fecundity (Table 2). The best model that included a linear or quadratic time trend on fecundity is listed for each study area in Table 4, along with the slope coefficients and 95% confidence intervals for each model. Based on 95% confidence intervals for β's that either did not overlap zero or barely overlapped zero (Table 4), we concluded that fecundity was declining in five areas (CLE, KLA, CAS, NWC, GDR), stable in three areas (OLY, TYE, HUP), and increasing in three areas (RAI, COA, HJA). Although the best trend model for CAS was not competitive (ΔAIC_c = 6.07), the 95% confidence interval for the slope coefficient from that model did not include zero, suggesting this was an important, if not the best, effect that we investigated for fecundity on CAS (Table 4). Annual variation in fecundity was high on the Washington study areas compared to study areas in Oregon

TABLE 2

Best model and competing models with $\Delta AIC_c < 2.0$, from the analysis of mean age-specific fecundity for female Northern Spotted Owls on 11 study areas in Washington, Oregon, and California.

[a] Model notation indicates structure for effects of owl age (A), even–odd years (EO), linear time (T), quadratic time (TT), autoregressive time [AR(1)], proportion of territories with Barred Owl detections (BO), percent cover of suitable owl habitat within 2.4 km of owl activity centers (HAB1), early nesting season precipitation (ENP), late nesting season precipitation (LNP), early nesting season temperature (ENT), and Pacific Decadal Oscillation (PDO). Habitat information was not available for California, so we did not fit models with habitat covariates for study areas in California.

and California, which may have made it more difficult to detect trends in Washington (Fig. 3). For example, there were a few years with zero reproduction on the RAI and OLY study areas in Washington, whereas years with no reproduction were rare on study areas in Oregon and were never observed in any of the California study areas (Fig. 3).

Models that included the Barred Owl covariate were part of the top model or competitive models for five study areas (COA, HJA, KLA, NWC, GDR; Table 2). Confidence intervals for the slope coefficients of the Barred Owl effect from the best linear or quadratic time-trend model that included the BO covariate indicated a negative relationship between Barred Owls and fecundity on four study areas (COA, KLA, CAS, GDR) and a positive relationship between Barred Owls and fecundity on one study area (HJA; Table 5). On the other six areas (CLE,

[a] Sample size indicates the number of cases in which we sampled owls in each age class. This is not a sample that was used to calculate means and standard errors. Those estimates were based on the number of years in the survey period. Estimates were determined using a nonparametric approach. Total number of samples by age class was: S1 = 432, S2 = 693, Adult = 10,325.

RAI, OLY, TYE, NWC, HUP), the 95% confidence intervals on the slope coefficients of the Barred Owl effect broadly overlapped zero, indicating little evidence of an effect of Barred Owls on fecundity (Table 5). In all study areas, the proportion of Spotted Owl territories with Barred Owl detections was increasing with time, but variable among study areas (Appendix B). As a result, temporal trends in fecundity and the Barred Owl covariate were negatively correlated and not easily separated. On some study areas, the temporal effect on fecundity may have been stronger, and this may explain, in part, the lack of effects of Barred Owls on fecundity in some areas. As a result, there was general uncertainty in selection of models with time trends versus Barred Owl effects for most study areas (Table 2).

The habitat covariate (HAB1) was in the top model for all study areas in Oregon, and in competitive models for two of the three study areas in Washington (Table 2). In Oregon, all 95% confidence intervals for regression coefficients for the habitat covariate excluded zero, and on four of the five areas (COA, HJA, TYE, CAS) the habitat effect was positive as predicted, with increased reproductive success associated with increased amounts of suitable habitat. The exception was the KLA study area, where there was evidence that reproductive success declined with increases in suitable habitat (Table 6). On all three study areas in Washington, 95% confidence intervals for the habitat covariate broadly overlapped zero, indicating that there was little evidence for a habitat effect on fecundity on those areas (Table 6).

[a] Model notation indicates structure for effects of owl age (A), even–odd years (EO), linear time (T), quadratic time (TT), autoregressive time [AR(1)], proportion of territories with Barred Owl detections (BO), percent cover of suitable owl habitat within 2.4 km of owl activity centers (HAB1), early nesting season precipitation (ENP), early nesting season temperature (ENT), and Pacific Decadal Oscillation (PDO). Habitat information was not available for California, so we did not fit models with habitat covariates for study areas in California.

[b] The first estimate is the linear term, and the second is the quadratic term.

Weather or climate covariates occurred in competitive models for RAI, COA, HJA, CAS, and HUP (Table 2), but the best covariate and the direction of the effect varied among areas (Table 7). In particular, the effect of temperature during the early nesting season (ENT) occurred in the top model or a competitive model for four study areas (RAI, COA, CAS, HUP; Table 2). In three of those areas (RAI, COA, CAS), fecundity was positively associated with ENT, as predicted, but the confidence intervals on the slope coefficient for COA included zero (Table 7). In contrast, fecundity was negatively associated with ENT on the HUP study area, which was contrary to what we predicted (Table 7). ENT was also the best climate covariate for GDR, but the model containing ENT was not competitive, and 95% confidence limits on the slope coefficients for the ENT effect included zero (Table 7).

Precipitation during the early nesting season (ENP) occurred in a competitive model for one study area (COA) and was the best weather/climate covariate for CLE and NWC as well (Table 7). The 95% confidence intervals on the slope coefficients for ENP excluded, or just barely included, zero for all three of these study areas, and the association was negative, as predicted (Table 7). There was weak evidence for a negative effect of precipitation on fecundity during the late nesting season (LNP) on the HJA study area, but the 95% confidence interval for

[a] Model notation indicates structure for effects of owl age (A), even–odd years (EO), linear time (T), quadratic time (TT), autoregressive time [AR(1)], proportion of territories with Barred Owl detections (BO), percent cover of suitable owl habitat within 2.4 km of owl activity centers (HAB1). Habitat information was not available for California, so we did not fit models with habitat covariates for study areas in California.

the beta coefficient overlapped zero (Table 7). The Southern Oscillation Index (SOI) was the best weather/climate covariate for OLY, but the model that included SOI was not competitive with the best model, and the 95% confidence interval on the slope coefficient overlapped zero (Table 7). The best weather/climate covariate for TYE indicated a negative effect of late nesting season temperature (LNT) on fecundity (Table 7). While this model was not competitive with the best model, the 95% confidence limits on the slope coefficient for the effect of LNT excluded zero, suggesting that temperature during the late nesting season was an important effect and possibly the best predictor of fecundity for TYE.

Estimation of spatial (site-to-site), temporal (year-to-year), and residual variance on the territory-specific data from the best models indicated that the proportion of variance in number of young fledged attributable to territories and/or individual owls (spatial) was generally <6% (Table 8). The proportion of variance attributable to fluctuations over time was usually in the range of 10 to 20%, while the proportion of unexplained (residual) variation was generally >80%. As a consequence, the explainable variation in fecundity by time and territory was overwhelmed by unexplained, residual variation.

Meta-analysis of Fecundity

The meta-analysis of fecundity for all study areas with no habitat covariates included produced three competitive models (ECO+t, LAT+t, ECO+t+BO), which accounted for 42%,

[a] Model notation indicates structure for effects of owl age (A), even–odd years (EO), linear time (T), autoregressive time [AR(1)], percent cover of suitable owl habitat within 2.4 km of owl activity centers (HAB1), early nesting season temperature (ENT), and forest habitat within 2.4 km radius of owl territory (HAB1). Habitat information was not available for California, so we did not fit models with habitat covariates for study areas in California.

34%, and 19% of the model weights, respectively (Table 9). These three models suggested that fecundity varied by time and was parallel across ecoregions or latitudinal gradients (Fig. 4), with some weak evidence for an additional Barred Owl effect. The estimate of the regression coefficient for the best model with the BO effect was negative, suggesting fecundity decreased as the proportion of territories where Barred Owls were detected increased. However, the 95% confidence interval for the beta coefficient for the BO effect overlapped zero ($\hat{\beta}$ = -0.12, SE = 0.10, 95% CI = -0.31 to 0.07). A linear time trend (T) in fecundity was not supported by the meta-analysis because of the high variation in fecundity over time and the breakdown of the even–odd year effect after about 1999 (Fig. 4). The ΔAIC_c estimates for the best models that included ownership (OWN+t) or climate (ECO+ENP) were 8.6 and 79.0, respectively, indicating that ownership and climate covariates explained little of the temporal variability in fecundity across the range of the Spotted Owl. Average fecundity over all years was similar among ecoregions except for the Washington Mixed-Conifer region, where mean fecundity was 1.7 to 2.0 times greater than in the other ecoregions (Table 10). Fecundity was lowest for the Oregon Coastal Douglas-fir ecoregion.

The meta-analysis of fecundity for Washington and Oregon, which included the habitat covariate, resulted in two competitive models (ECO+t, ECO+t+HAB1) and a third model that was only slightly less competitive (ECO+t+BO; Table 9). These three models accounted for 55%, 21%, and 17% of the model weights, respectively, and were similar to the most competitive models from the meta-analysis of all study areas, except for the competitive model that included the habitat covariate (Table 9). As in the meta-analysis of all areas, there was some evidence for a weak negative effect of Barred Owls on fecundity, although the 95% confidence

[a] Model notation indicates structure for effects of owl age (A), even–odd years (EO), percent cover of suitable owl habitat within 2.4 km of owl activity centers (HAB1), early nesting season precipitation (ENP), early nesting season temperature (ENT), late nesting season temperature (LNT), and Southern Oscillation Index (SOI). Habitat information was not available for California, so we did not fit models with habitat covariates for study areas in California.

interval for the beta coefficient for the effect of Barred Owls overlapped zero (β = -0.104, SE = 0.129, 95% CI = -0.369 to 0.151). There was no evidence for an effect of habitat on fecundity in the meta-analysis (β = -0.469, SE = 0.453, 95% CI = -1.363 to 0.426). Linear time trends (T) in fecundity had little support, and models that included ownership (OWN+t) or climate (ECO+ENP+HAB1) were not competitive with the top model (ΔAIC_c = 12.9 and 55.1, respectively).

Apparent Survival

Individual Study Areas

To estimate annual apparent survival we used a sample of 5,244 banded owls, including 796 (15.2%) 1-yr-old subadults, 903 (17.2%) 2-yr-old subadults, and 3,545 (67.6%) adults (Table 1). The total number of recaptures/resightings of banded owls (19,164) was approximately four times the number of initial captures. The overall χ^2 goodness-of-fit for the global model from program RELEASE summed across study areas was 1,543.2 with 972 degrees of freedom (χ^2 = 1.59, $P > 0.10$), indicating good fit of the data to the Cormack–Jolly–Seber open population mark-recapture model (Table 11). The range of χ^2 for the individual study areas was 0.86 to 2.79, with df ranging from 63 to 125 (Table 11), again indicating good fit to the model for most study areas. Examination of the data indicated that the small lack-of-fit to the Cormack–Jolly–Seber open population model was due primarily to temporary emigration, when owls moved off of the study area for one or more years and later returned or were temporarily displaced as a

[a] CJS indicates data sets used for Cormack–Jolly–Seber estimates of apparent survival. λ_{RJS} indicates data sets used for reparameterized Jolly–Seber estimates of annual finite rate of population growth. Values for χ^2 and df are from TEST 2 and TEST 3 in program RELEASE. Estimates of $\hat{c}$ are from median-$\hat{c}$ routine in program MARK. Estimates of $\hat{c} < 1.0$ were set to 1.00 for analysis.

[b] Weighted average across all study areas.

territorial owl. The overall estimate of overdispersion from the median-$\hat{c}$ routine in program MARK was 1.03, with estimates for individual study areas ranging from 0.97 to 1.11 (Table 11). Overall, results of GOF testing indicated there was little to no overdispersion (i.e., lack of independence) of recaptured owls.

Although there were exceptions, estimates of annual recapture probabilities (p) typically were high, ranging from 0.70 to 0.95 on most study areas. High rates of recaptures/resightings make the Spotted Owl an ideal species for mark–recapture studies. In the analyses of recapture probabilities, factors affecting p in the best models varied among study areas (Table 12). For seven of the 11 areas, there was an effect of sex on p; in all seven cases, p was higher for males. Other effects on p in the top models for one or more areas were a variable time effect (OLY, HJA, CAS areas), negative Barred Owl effect (RAI, COA, KLA areas), and/or a positive reproductive effect (RAI, CLE, TYE areas; Table 12). There was no evidence of time trends on p on any study areas. On two study areas, the "biologist's choice" models were the best models for p. The best p model for one of these areas (NWC) included the additive effects of sex and recapture method; in this case, owls were physically recaptured in 1986 to 1987 and then resighted or recaptured in subsequent years. The other case in which the biologist's choice model was the best p model included an east–west division of the HUP study area based on differences in Spotted Owl density, forest type, and ease of access (Table 12).

[a] Model notation indicates structure for additive (+) or interactive (*) effects of sex (s), time (t), linear time trend (T), quadratic time trend (TT), 2004 change point (CP), reproduction (R), proportion of territories with Barred Owl detections (BO), age class (S1, S2, A), east–west binomial subdivision of study area (EW), survey method (Meth), or differential survey effort in particular years (Effort). An "=" sign means that age classes were combined, and a "," indicates they were modeled separately.

[b] Age classes (S1, S2, A) indicate owls that were 1, 2, or ≥3 years old. Average survival is the arithmetic mean of model-averaged annual survival estimates. Standard errors were calculated using the delta method.

The best model structure for apparent survival (φ) varied among study areas, but several patterns emerged (Table 12). Most notably, apparent survival tended to be higher for adults than for subadults and was similar between the sexes, except on the OLY study area where males had higher survival than females (Table 12). Presence of Barred Owls, variable time (t), or time trends (T or TT) were important effects on apparent survival in one or more study areas. In the best models for each study area (Table 12), the Barred Owl covariate was included in the φ

[a] T = linear time trend, TT = quadratic time trend, CP = change point starting in 2004.

[b] Models that have a change point beyond which the function changes. The first row estimate is the linear time trend (T) and the second is a change point starting in 2004 (CP).

[c] For quadratic models (TT), the first row indicates the linear term and the second row indicates the quadratic term.

[d] Constant survival from start year to 2004, with negative time trend beginning in 2004.

structure for two study areas (RAI, GDR) and the p structure for three study areas (RAI, COA, KLA). The Barred Owl covariate also occurred in competitive models for φ on the OLY and NWC areas (see Effects of Barred Owls on Recapture and Survival below).

Based on the best survival models that included time trends, we concluded that apparent survival was declining on 10 of the 11 study areas (CLE, RAI, OLY, COA, HJA, TYE, CAS, NWC, HUP, GDR), as indicated by 95% confidence intervals on β that either did not overlap zero or narrowly overlapped zero (Table 13). Declines in apparent survival were most evident in Washington, where all β estimates were negative with 95% confidence intervals that did not overlap zero (Fig. 5A). In addition, the declines in apparent survival on the CLE and RAI study areas were most precipitous during the last five years of the study, as represented by the change-point (CP) time structure in the best models and steeper declines after 2004 (Fig. 5A). Annual estimates of apparent survival for owls on the CLE, RAI, and OLY areas

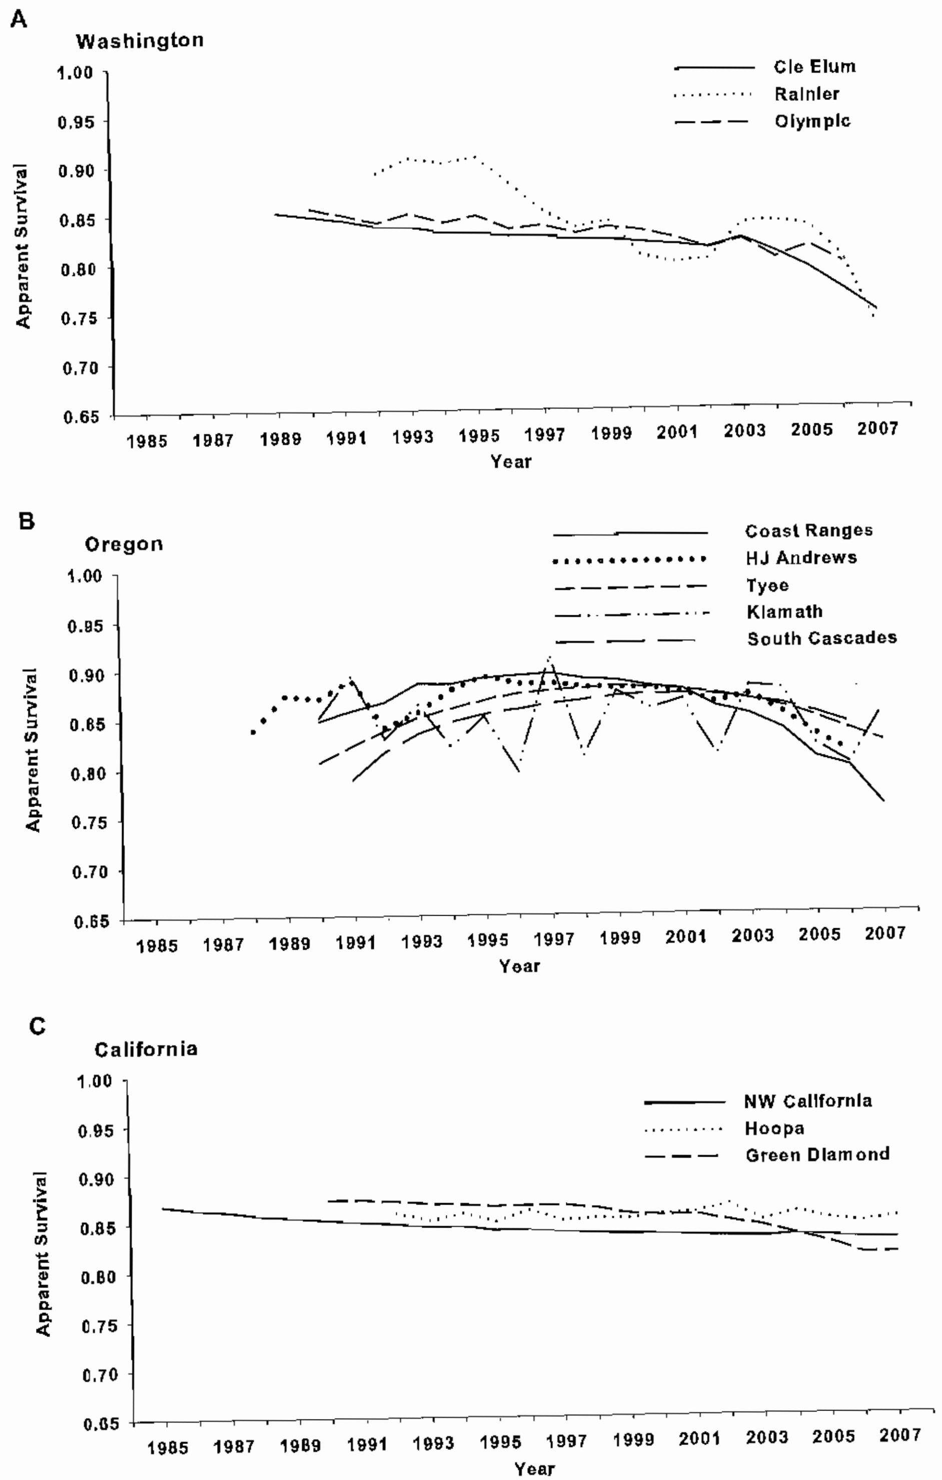

Figure 5. Model averaged estimates of apparent survival of adult female Northern Spotted Owls in three study areas in Washington (A), five study areas in Oregon (B), and three study areas in California (C).

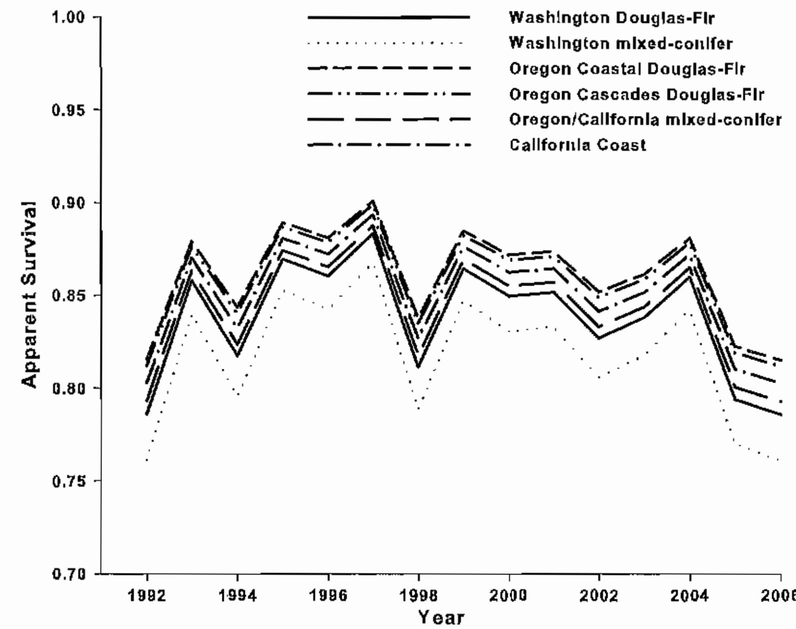

Figure 6. Estimates of apparent annual survival of adult female Northern Spotted Owls in six ecoregions, based on model φ(ECO+t) p(g+t+s) from the meta-analysis of 11 study areas, where ECO represents ecoregion, t represents annual time effects, g represents study area effects, and s represents sex effects.

were <0.80 during the latter years of the study, which were the lowest rates recorded. In Oregon, apparent survival declined on four (COA, HJA, TYE, CAS) of the five study areas, most noticeably during the last five years of study (Fig. 5B). Temporal changes in apparent survival for COA, TYE, and CAS were best described by a quadratic function, whereby survival increased during the early years of the study, then declined during later years. The owl population on the KLA study area was the only one in Oregon that did not have a declining survival rate, as the best model for KLA supported a variable time (t) effect (Table 12). In California, there was strong evidence for linear or change-point declines in apparent survival on all three study areas (NWD, HUP, GDR), as indicated by 95% confidence intervals for β's that either did not overlap zero or only narrowly overlapped zero (Table 13, Fig. 5C).

Meta-analysis of Apparent Survival on All Areas

We used encounter histories from 3,545 adults in the meta-analysis of apparent survival (Table 1). The estimate of goodness-of-fit from program RELEASE indicated good fit of the data to the Cormack–Jolly–Seber open population model (χ^2 = 1740.9, df = 1,012, P > 0.10). The weighted average estimate of median-$\hat{c}$ was 1.031, indicating little overdispersion (i.e., lack of independence) in capture histories. We used this estimate to adjust model selection from AIC_c to $QAIC_c$ and inflate variance estimates accordingly.

The best model from the meta-analysis of apparent survival was the random effects model φ(g*t) p(g+s+t): RE(g+R), which indicated that survival varied among study areas (g) and years (t) and that recapture rates varied among study areas, sexes, and years (Table 14). This model, which had a $QAIC_c$ weight of 0.18, also included the reproduction covariate (R). The effect of reproduction was negative with a 95% confidence interval that barely overlapped zero (Table 15). Several random effects models were competitive, including a second-best model that included the Barred Owl (BO) covariate. The regression coefficient for the BO covariate was negative, with a 95% confidence interval that did not overlap zero (Table 15). For more details on the effects of Barred Owls on apparent survival, see below. Other random effects models with ΔQAIC ≤ 2 from the best model were identical in structure

[a] Codes indicate effects of study area (g), time (t), sex (s), proportion of territories with Barred Owl detections (BO), reproduction (R), Pacific Decadal Oscillation (PDO), linear time trend (T), percent cover of suitable owl habitat within 2.4 km of owl activity centers (HAB1), land ownership (OWN), latitude (LAT), early nesting precipitation (ENP), early nesting temperature (ENT), or Southern Oscillation Index (SOI).

[b] WA Douglas-fir was the reference type.

[c] Non-federal ownership was the reference type.

to the best model, except that the reproduction covariate was replaced by other environmental covariates, including Pacific Decadal Oscillation (PDO), linear time effects (T), mean effects, early nesting season precipitation (ENP), early nesting season temperature (ENT), or Southern Oscillation Index (SOI; Table 14). The random effects models were based on the assumption that the years of our study were a sample of all possible years, whereas the fixed effects models pertained directly to the years sampled. Although none of the fixed effects models were competitive with the best random effects model (Table 14), it is important to describe the results for each analysis because they represent different interpretations of the data (see Methods).

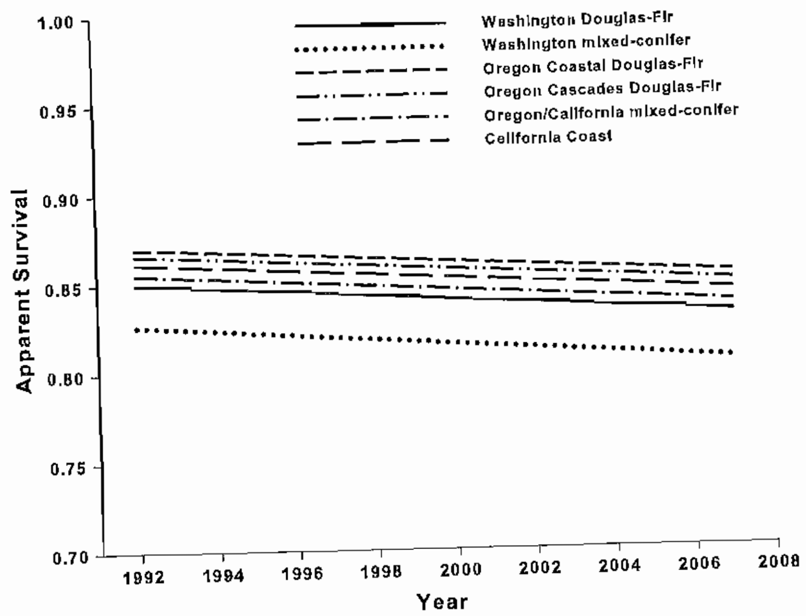

Figure 7. Estimates of apparent annual survival of adult female Northern Spotted Owls in six ecoregions (ECO), based on the linear time-trend model φ(ECO+T) *p*(g+t+s) from the meta-analysis of 11 study areas. Study area effects are represented by g, annual time effects by t, and sex effects by s.

In the meta-analysis of survival, the best or competing models indicated that there was considerable variation in survival rates among study areas, ecoregions, and years (t), and that the variation in survival among study areas and ecoregions was parallel over time (Fig. 6). Because the general trend in survival suggested a slight decline over the period of study (Fig. 6), we investigated the regression coefficients in the best random effects and fixed effects models that included time trends (T). The best random effects model with a time trend [φ(g*t) *p*(g+s+t): RE(g+T)] included a negative effect on survival (β = -0.0016), with a 95% confidence interval that barely overlapped zero (Table 15). The best fixed effects model with a time trend [φ(ECO+T) *p*(g+s+t)] also provided evidence for an overall decline in apparent survival for all study areas combined (Fig. 7).

Several other covariates were included in competitive models for the meta-analysis of apparent survival. There was no evidence from the random effects models that early nesting season temperature (ENT), Southern Oscillation Index (SOI), or percent cover of suitable owl habitat (HAB1) had an effect on survival because the 95% confidence intervals for these covariates included zero (Table 15). In contrast, there was some evidence that presence of Barred Owls (BO), early nesting season precipitation (ENP), and time trends (T) each had an effect on survival rates in the random effects models (Table 15). From the fixed effects models, there was evidence that survival rates differed among ecoregions, with the Oregon Cascades Douglas-fir, Oregon Coast Douglas-fir, and California Coast regions having higher survival rates than the Oregon/California Mixed-conifer and Washington Mixed-conifer regions (Table 15; Fig. 7). There was no evidence from the fixed effects models that ownership, Barred Owls, habitat, or latitude had an effect on survival, but there was evidence that annual survival was negatively related to the mean number of young produced in the previous breeding season (β = -0.200, 95% CI = -0.328 to -0.072). Although the evidence suggested that several of the above covariates influenced apparent survival, they explained little (0 to 5.7%, individually) of the variation among study areas and years. Thus, there was considerable annual variation in survival estimates (Fig. 6), and no covariate, including Barred Owls, percent cover of suitable habitat, climate, or time trends, explained a major portion of this variation. For example, the Barred Owl covariate and time trend explained only 5.7 and 2.3% of the variability in apparent survival, respectively.

[b] $\hat{c}$ values for individual study areas can be found in Table 11.

Meta-analysis of Apparent Survival on the Eight NWFP Monitoring Areas

The two best models in the meta-analysis of apparent survival for the eight NWFP study areas were the same as the analysis of all 11 study areas (Table 16). In the top model, the regression coefficient for the effect of reproduction was negative with a 95% confidence interval that barely overlapped zero. In the second best model, the regression coefficient for the effect of Barred Owls was negative with a 95% confidence interval that did not overlap zero. Six other random effects models that were competitive included mean effects, Pacific Decadal Oscillation (PDO), time trend (T), early nesting season precipitation (ENP), Southern Oscillation Index (SOI), or early nesting season temperature (ENT) in place of the BO covariate (Table 16). The rankings of the random effects and fixed effects models were similar between the analyses of all 11 study areas and the eight NWFP monitoring areas, and none of the fixed effects models were competitive with the best random effects models (Tables 14, 16). Because the results were similar regardless of

whether we examined the eight NWFP study areas or all 11 study areas combined, we emphasize only the results from all 11 areas in the following sections.

Potential Cost of Reproduction on Survival

In the analyses of apparent survival for individual study areas, there was no evidence of a negative effect of reproduction on survival rates in the following year at seven of the 11 study areas (COA, HJA, TYE, KLA, CAS, NWC, HUP, Table 17). Confidence intervals for the regression coefficients for reproduction at those seven areas all overlapped zero (Table 17). For two study areas in Washington (RAI, OLY), there was evidence of a negative effect of reproduction on survival in the following year. At RAI, the regression coefficient for the reproductive effect in the best model was negative with a 95% confidence interval that did not overlap zero. At OLY, the effect of reproduction was part of a competitive model in which the 95% confidence interval on $\hat{\beta}$ barely overlapped zero (Table 17). In contrast, there was evidence of a positive effect of reproduction on survival at CLE and GDR, as the regression coefficients for the reproduction covariates were positive, with 95% confidence intervals that did not overlap zero. However, the models for CLE and GDR that included the effect of reproduction were >2 QAICs from the best models, and these latter results were contrary to our original hypothesis.

In the meta-analysis of apparent survival for all 11 study areas, the best random effects model, $\varphi(g{*}t)$ $p(g{+}s{+}t)$: RE(g+R), included the effect of reproduction. The effect of reproduction was negative ($\hat{\beta} = -0.024$) and the 95% confidence interval barely included zero (-0.049 to 0.001). The best fixed effects models with an effect of reproduction were $\varphi(g{*}R)$ $p(g{+}s{+}t)$ and $\varphi(R{+}s)$ $p(g{+}s{+}t)$ (Table 14). Although there was little support for either of these models ($\Delta QAIC_c$'s > 168.0 and $QAIC_c$ weights = 0.000), the regression coefficient for the effect of reproduction in the second model was negative ($\hat{\beta} = -0.200$) with a 95% confidence interval (-0.328 to -0.072) that did not overlap zero (Table 15). Based on this outcome, we concluded that there was evidence for a negative effect of reproduction on survival in the following year in some, but not all, study areas.

Effects of Barred Owls on Recapture and Survival

The BO covariate was included in the best model structure for recapture probability in three (RAI, COA, KLA) of the 11 study areas (Table 12), and the best models that included a BO effect on recapture indicated a negative effect in seven study areas and a positive effect in four areas. However, the 95% confidence intervals on the regression coefficients for the BO effect overlapped zero in seven areas. In the four cases where the 95% confidence intervals did not overlap zero, two cases indicated a negative effect and two cases indicated a positive effect.

In the analysis of individual study areas, we found evidence for a negative effect of Barred Owl presence on apparent survival of Spotted Owls on the RAI, COA, HJA, and GDR study areas (Table 18). There also was some evidence that presence of Barred Owls had a negative effect on apparent survival of Spotted Owls on the OLY and NWC study areas; on those areas the Barred Owl effect was among the competitive models, but the 95% confidence intervals for the regression coefficient barely overlapped zero (Table 18). Inexplicably, there was one study area (CAS) that had weak evidence for a positive effect of Barred Owls on survival (Table 18). The evidence for an effect of Barred

TABLE 18

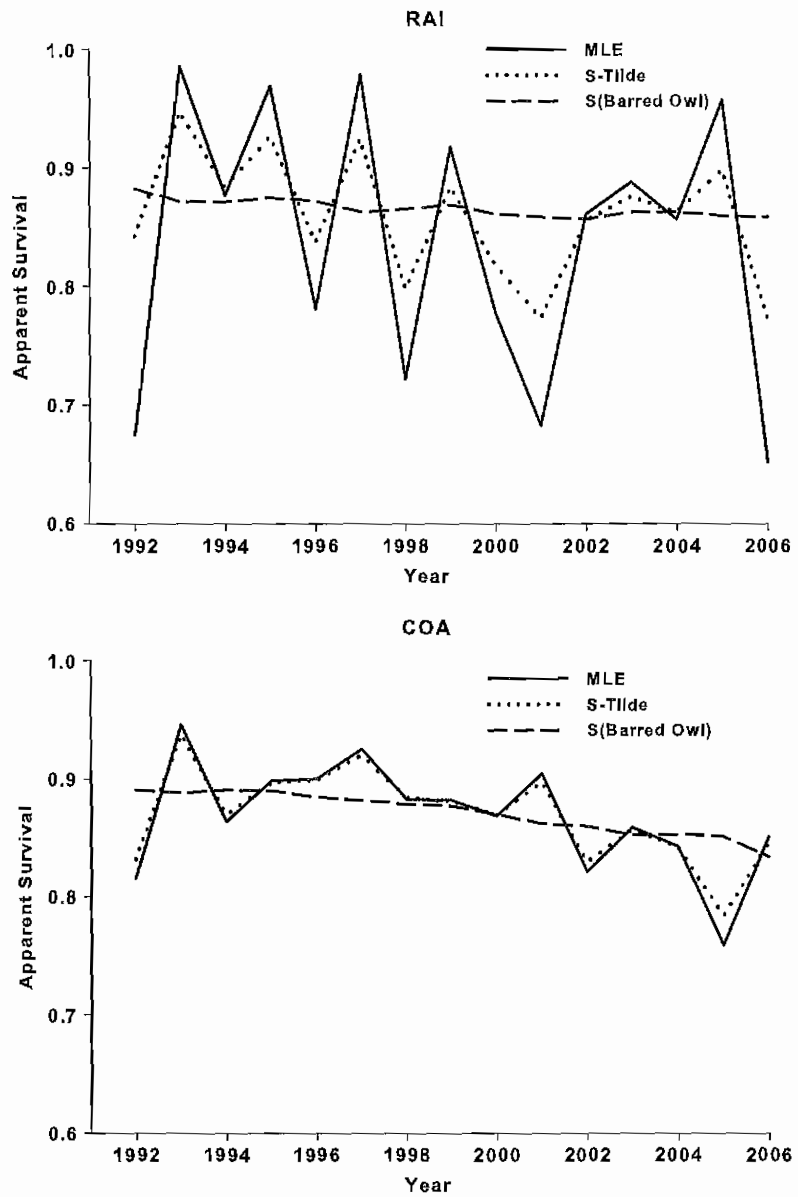

Figure 8. Estimates of the Barred Owl effect (BO) on apparent survival of Northern Spotted Owls. Estimates were generated from the best random effects model [φ(g+t+BO)], plotted with original apparent survival estimates (MLE) and shrinkage estimates (S-tilde) for one study area in Washington (RAI), two study areas in Oregon (CAS, COA), and one study area in California (NWC). Study area effects are represented by g and annual time effects by t.

Owls on survival of Spotted Owls was weak or negligible for CLE, TYE, KLA, and HUP because confidence intervals on regression coefficients overlapped zero (Table 18). With the exception of CLE, the latter areas were all in the southern portion of the range of the Northern Spotted Owl (Fig. 1).

In the meta-analysis of apparent survival, the second best model [φ(g*t) *p*(g+s+t): RE(g+BO)] provided strong evidence that the presence of Barred Owls had a negative effect on apparent survival, as the 95% confidence interval on $\hat{\beta}$ for the Barred Owl effect did not overlap zero (Table 15; Fig. 8). In addition, the g+BO model ranked higher than the g*BO model, indicating that the BO covariate was important across all study areas in explaining time variation in φ. Thus, there was strong evidence that Barred

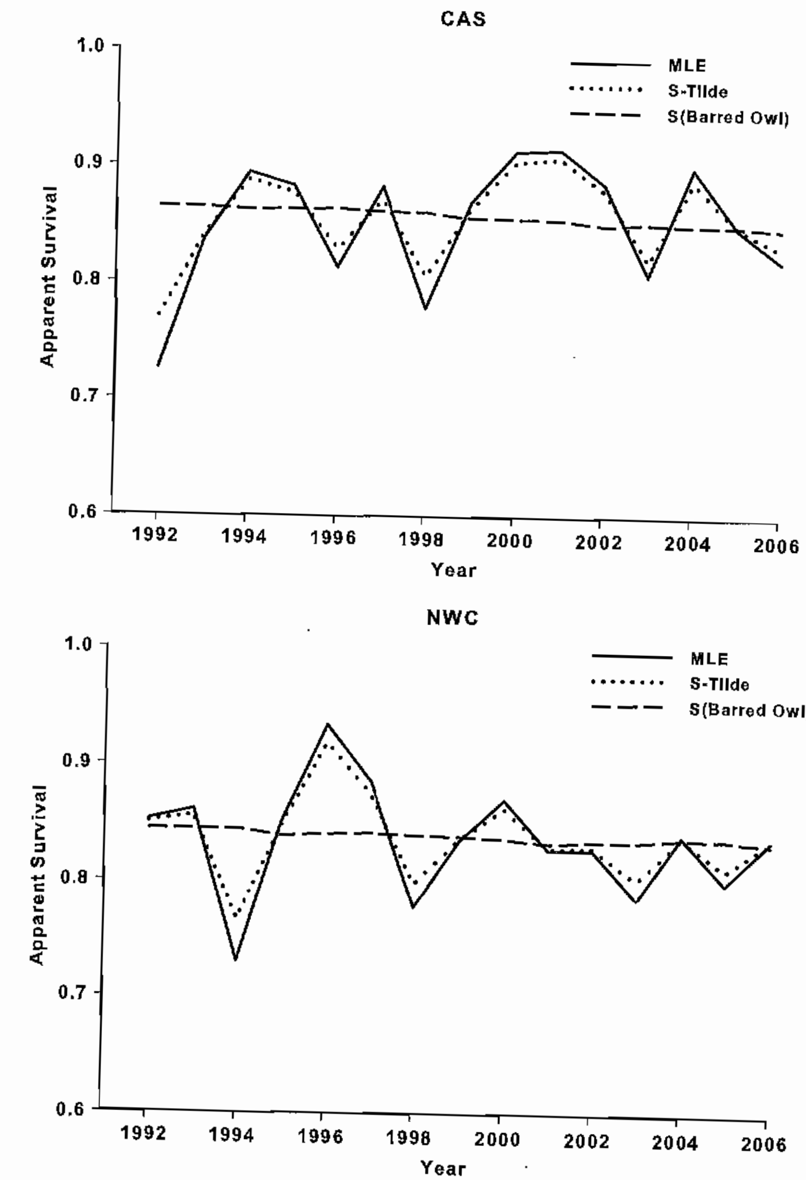

Figure 8. (*continued*)

Owls had a negative effect on apparent survival of Spotted Owls.

Annual Rate of Population Change

Individual Study Areas

We used capture histories of 5,244 banded territorial owls to estimate annual rates of population change (λ) at the 11 study areas. Estimates of goodness-of-fit (χ^2/df) of the capture–recapture data from program RELEASE ranged from 0.69 to 3.02 for individual study areas (Table 11), and the overall estimate of χ^2/df for all of the data combined was 1.61 ($P > 0.10$), indicating good fit of the data to the Cormack–Jolly–Seber model. Estimates of $\hat{c}$ from the median-$\hat{c}$ routine in program MARK ranged from 1.00 to 1.13, indicating little evidence for lack of independence in capture histories (Table 11).

The full sex- and time-specific model $\varphi(s^*t)$ $p(s^*t)$ $f(s^*t)$ for estimation of λ was not appropriate for most study areas based on model selection with $QAIC_c$. Therefore, we used the time-only model $\varphi(t)$ $p(t)$ $f(t)$ for estimating λ and temporal process variation for most study areas (Table 19). The only exception was the OLY study area, where there were differences in φ between males and females. Estimates of λ ranged from 0.929 to 0.996 for the 11 study areas and the time span of the estimates ranged from 12 to 16 years (Table 19). There was strong evidence that populations on the CLE, RAI, OLY, COA, HJA, NWC, and GDR study areas declined during the study, based on 95% confidence intervals for estimates of λ that did not include 1.0 (Table 19, Fig. 9). Estimates of λ for CLE and RAI were especially low, suggesting population declines of 6.3 and 7.1 % per year, respectively (Table 19). Point estimates of λ for the TYE, KLA, CAS, and HUP study areas all indicated declining populations, but had 95% confidence intervals that included 1.0 (Table 19). The weighted mean estimate of λ for all study areas combined was 0.971 (SE = 0.007, 95% CI = 0.960 to 0.983), indicating that the average rate of population decline was 2.9% per year during the study.

TABLE 19

Estimates of λ and temporal process standard deviation ($\hat{\sigma}_{temporal}$) for Northern Spotted Owls on 11 study areas in Washington, Oregon, and California.

Estimates of λ were generated using the best random effects model; estimates of temporal variance are based on random effects models (Means, T, or TT), using time-specific estimates of φ, *p*, and λ, except where noted.

[a] Best capture–recapture model structure from analysis of the *a priori* model set. Model notation indicates structure for effects of time (t), linear time trend (T), quadratic time trend (TT), or constant (.), or random effects (RE). For linear and quadratic time trend models, λ was computed using a mean-centered model.

[b] Random effects model using the survival–recruitment parameterization would not run on derived lambdas for CLE. Therefore, we used the survival–lambda *f*-parameterization instead.

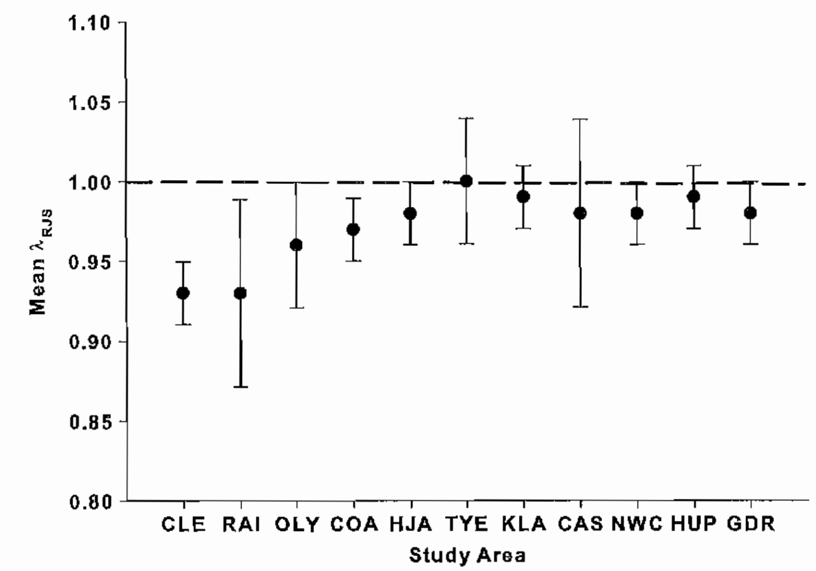

Figure 9. Estimates of mean annual rate of population change ($\hat{\lambda}_{RJS}$), with 95% confidence intervals for Northern Spotted Owls in 11 study areas in Washington, Oregon, and California. Estimates of λ were derived parameters from the recruitment and survival parameterization and the best random effects models based on the best global model [either $f(t)$ $\varphi(t)$ $p(t)$ or $f(s^*t)$ $\varphi(s^*t)$ $p(s^*t)$], where s and t represent sex and annual time changes, respectively.

Results of the variance components analyses for each study area provided little evidence of temporal process variation in λ for most study areas, relative to the magnitude of sampling variation in estimates (Table 19). Estimates of temporal process variation in λ were highest for the RAI, OLY, CAS, and NWC study areas, but the only study area for which the 95% confidence interval on temporal variation did not include zero was CAS (Table 19).

There was evidence that populations were declining on five of the eight monitoring areas (CLE, OLY, COA, HJA, NWC) based on 95% confidence intervals for λ that did not overlap 1.0. Point estimates of λ for the remainder of the study areas (TYE, KLA, CAS) were less than one, but had confidence intervals that overlapped 1.0, so the evidence for declines on those areas was weak. The weighted mean estimate of λ for the eight monitoring areas was 0.972 (SE = 0.006, 95% CI = 0.958 to 0.985), indicating an estimated decline of 2.8% per year on federal lands within the range of the owl. The weighted mean estimate of λ for the other three study areas (RAI, GDR, HUP) was 0.969 (SE = 0.016, 95% CI = 0.938 to 1.000), indicating an estimated decline of 3.1% per year on those areas.

Estimates of Realized Population Change

Estimates of realized population change indicated that populations in Washington and northern Oregon (OLY, RAI, CLE, COA) declined by 40 to 60% during our study (Fig. 10A, B). There was also evidence that populations on HJA,GDR, and NWC declined during the same period, but the 95% confidence intervals around the estimates of Δ_t on the latter three areas slightly overlapped 1.0 (Fig. 10B, C). Estimates of realized population change for the rest of the study areas (CAS, TYE, KLA, HUP) were all <1.0, but the 95% confidence intervals around the estimates of Δ_t substantially overlapped 1.0. Trends in populations for each of the study areas were variable, and declines, if any, occurred at different times on different areas. For example, the decline on HJA occurred primarily during 1992 to 1993 after a year of high reproductive success in 1992, then the population declined about 10% during

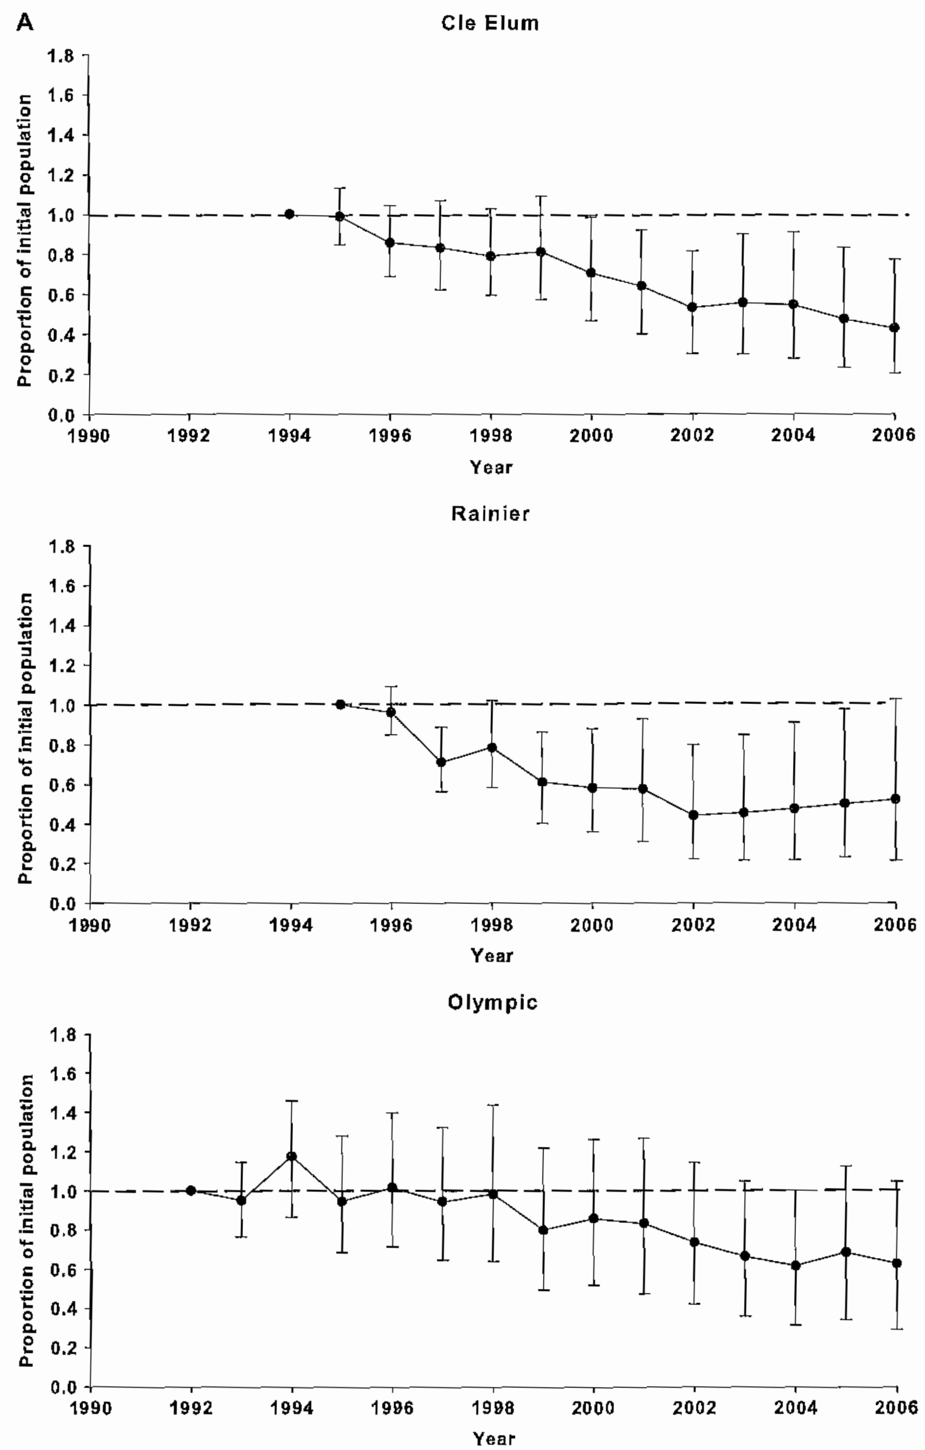

Figure 10. Estimates of realized population change, Δ_t, with 95% confidence intervals for Northern Spotted Owls at three study areas in Washington (A), five study areas in Oregon (B), and three study areas in California (C).

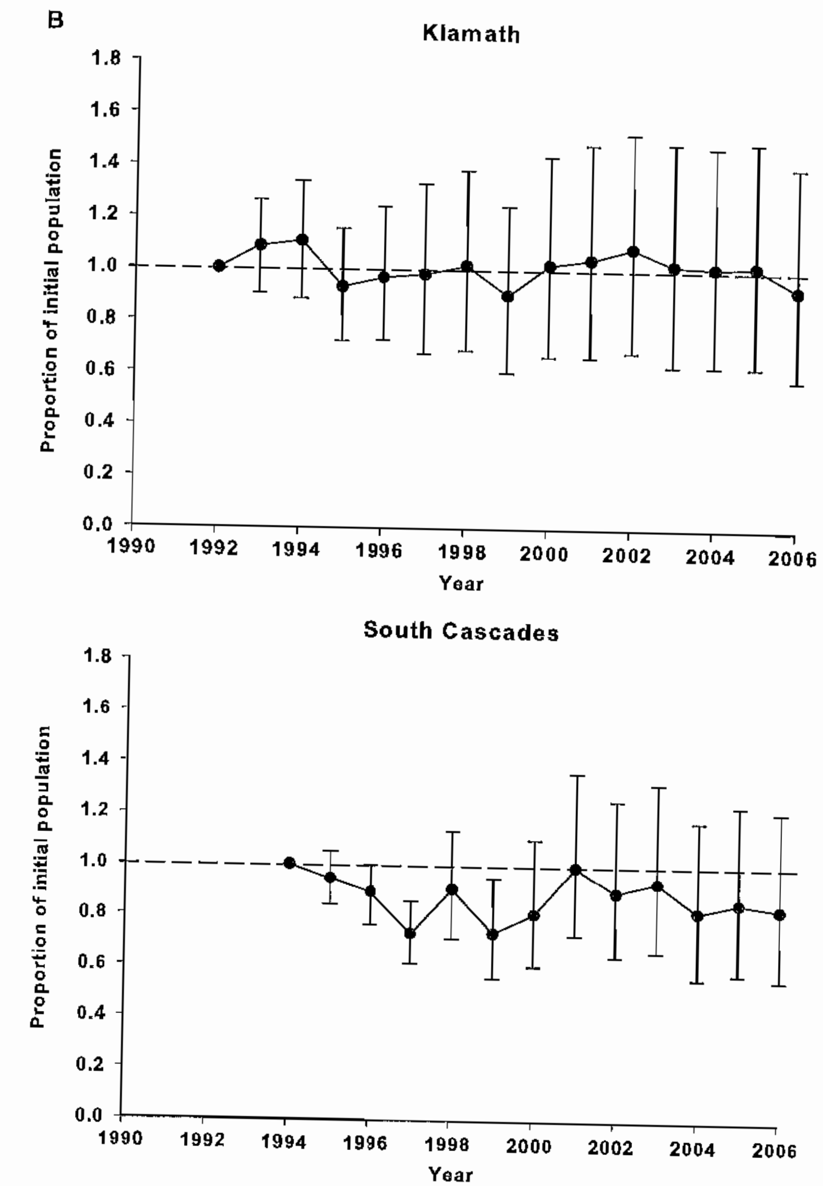

Figure 10. (*continued, for Northern Spotted Owls in Oregon*)

the ensuing decade. In contrast, the decline on COA occurred after 2001 and continued through 2006 (Fig. 10B). Populations in Washington (CLE, RAI, OLY) exhibited a long, gradual decline after the mid-1990s, except that the population on RAI actually increased slightly after 2002 (Fig. 10A). Consequently, there was no evidence for synchrony in timing of population declines among the 11 study areas.

Meta-analysis of Annual Rate of Population Change

Estimates of goodness-of-fit from program RELEASE for individual study areas (Table 11) indicated good fit of the data to the Cormack–Jolly–Seber model for all study areas. In addition, the mean estimate of median-$\hat{c}$ from program MARK was 1.06 with a range of 1.0 to 1.17,

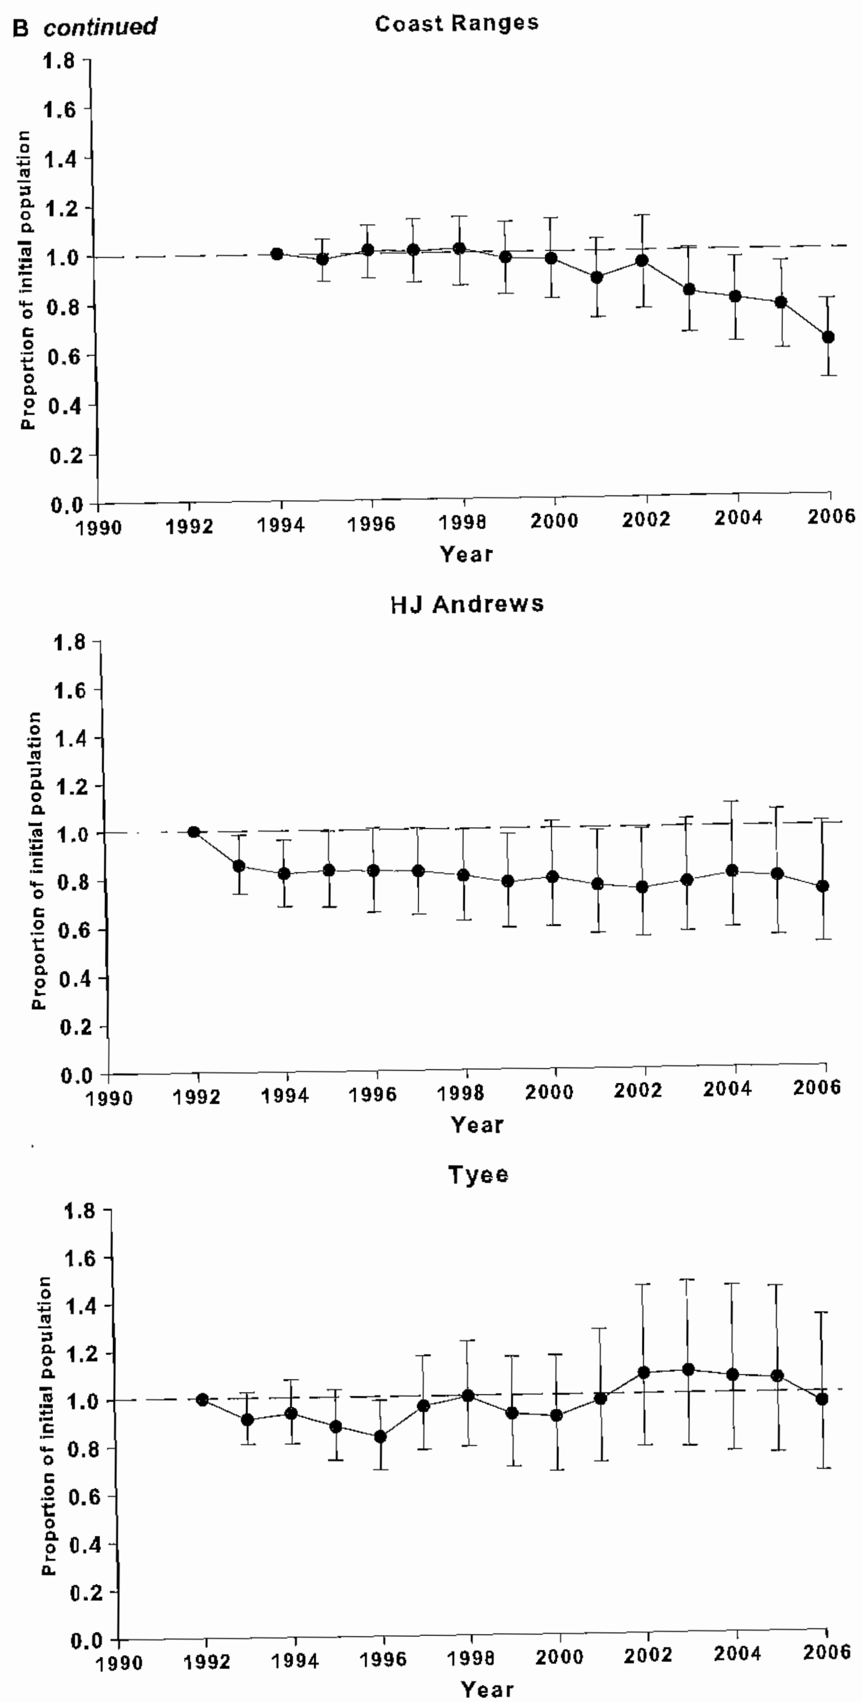

Figure 10. *(continued, for Northern Spotted Owls in Oregon)*

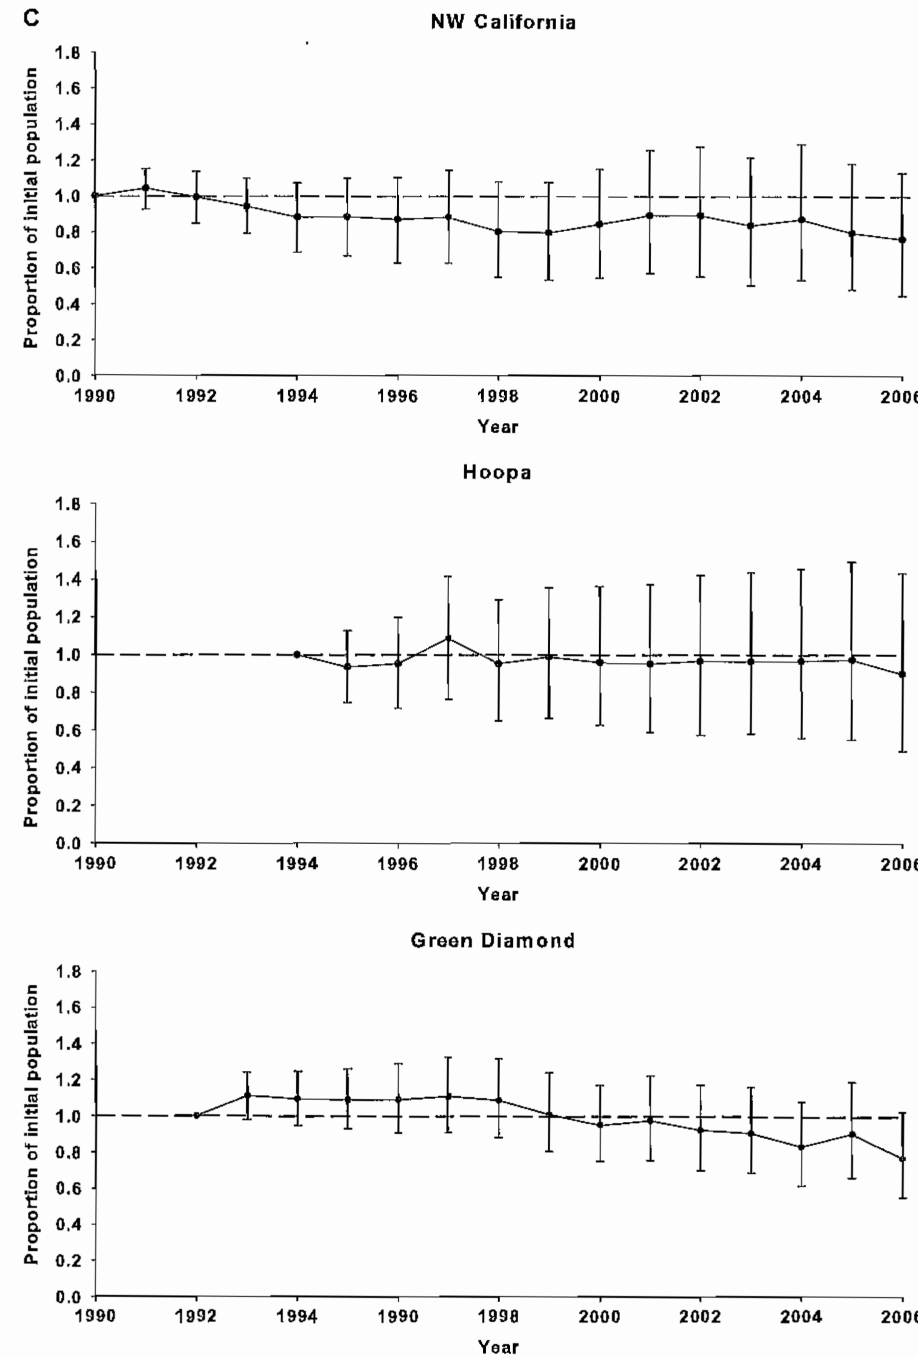

Figure 10. *(continued, for Northern Spotted Owls in California)*

indicating little evidence for overdispersion (i.e., lack of independence) in the capture–recapture data. As a result, we did not use $\hat{c}$ to adjust model selection to $QAIC_c$ or inflate variance estimates of parameters.

The best *a priori* model in the meta-analysis of λ was RE (random effects) model $\varphi(ECO)$ $f(ECO)$, which indicated evidence of an effect of ecoregion on φ and f (Table 20). Two competing random effects models had ΔAIC_c values

TABLE 20 (*continued*)

TABLE 20 (CONTINUED)

NOTE: Model form was the survival and recruitment parameterization. Notation for random effects (RE) models includes the general model on which the random effects model is based (g = study area, t = time varying). Models ending with asterisks were developed *a posteriori* after seeing the results of the original modeling. Inferences were based on the models in the original *a priori* model set.

[a] Model notation indicates structure for study area (g), time (t), linear time trend (T), quadratic time trend (TT), ecoregion (ECO), land ownership (OWN), proportion of territories with Barred Owl detections (BO), early nesting season precipitation (ENP), early nesting season temperature (ENT), late nesting season precipitation (LNP), late nesting season temperature (LNT), Palmer Drought Severity Index (PDSI), percent cover of suitable owl habitat within a 2.4 km radius of owl activity centers (HAB2), percent cover of suitable owl habitat within 23 km of owl activity centers, minus the area within 2.4 km of owl activity centers (HAB3), latitude (LAT), Southern Oscillation Index (SOI), and Pacific Decadal Oscillation (PDO).

<2.0, one of which indicated evidence of a Barred Owl effect on φ and *f* [φ(g+BO) *f*(BO)], and one [φ(ECO) *f*(ECO+OWN)] that indicated differences in recruitment among different land ownership categories (Table 20). The 95% confidence interval for the effects of ownership on *f* in the latter model included zero, indicating little evidence of an effect of ownership on recruitment (Table 21). Therefore, model selection results for the top two models [φ(ECO) *f*(ECO) and φ(g+BO) *f*(BO)] indicated the most support for models that included Barred Owls (BO) and ecoregions (ECO). Estimates of apparent survival from the best *a priori* model were highest for the Oregon Coast Douglas-fir ecoregion and lowest for the Washington Mixed-conifer ecoregion (Fig. 11). Recruitment was highest in the Oregon/California Mixed-conifer ecoregion ($\hat{f}$ = 0.145, SE = 0.020), but similar among the other ecoregions (Fig. 11). The low estimates of λ for the Washington Douglas-fir and Washington Mixed-conifer ecoregions were a result of both low apparent survival and low recruitment. In contrast, the Oregon/California Mixed-conifer region had the highest estimate of λ, which was a result of high recruitment and intermediate survival rates. Values of φ, *f*, and λ were intermediate for the other ecoregions.

Slope coefficients for the Barred Owl effect in the random effects (RE) model φ(g+BO) *p*(g*t) *f*(BO) were negatively associated with apparent survival and recruitment, although the 95% confidence interval for the effect of Barred Owls on recruitment included zero (Table 21). There was some evidence for differences in apparent survival among different land ownership categories

[a] Covariates included proportion of territories with Barred Owl detections (BO), early nesting season precipitation (ENP), early nesting season temperature (ENT), late nesting season precipitation (LNP), Palmer Drought Severity Index (PDSI), Southern Oscillation Index(SOI), Pacific Decadal Oscillation (PDO), percent cover of suitable owl habitat within a 2.4-km radius of owl activity centers (HAB2), forest habitat in the ring between HAB2 and a circle defined by the median natal dispersal distance (23 km) (HAB3), and latitude (LAT).

but the differences were minor, and the best model that included the ownership covariate ranked far below the top model ($\Delta AIC_c = 38.72$; Table 20). There was no evidence that latitude or habitat within the study area (HAB2) had an effect on apparent survival, but there was evidence that apparent survival was positively related to the Pacific Decadal Oscillation ($\hat{\beta}$ = 0.017, 95% CI = 0.0002 to 0.033; Table 21), which was consistent with our prediction. Other

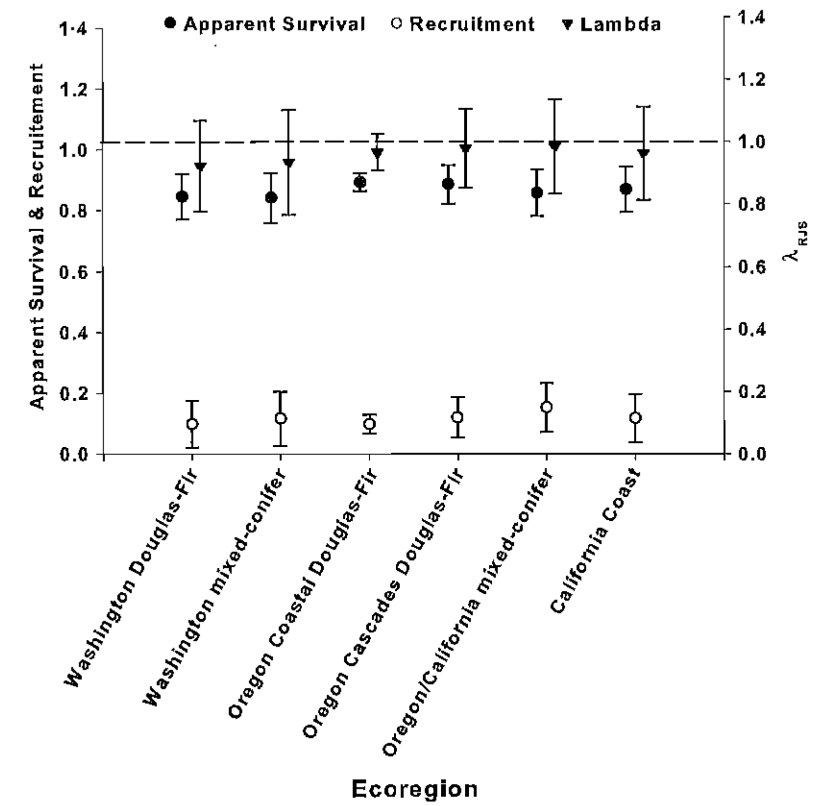

Figure 11. Point estimates and 95% confidence limits of apparent survival, recruitment, and λ of Northern Spotted Owls in different ecoregions based on the best *a priori* model from the meta-analysis of 11 study areas [RE φ(ECO) *f*(ECO)].

climate covariates explained little of the variation in apparent survival rates (Table 21). Lack of evidence of an effect of habitat and weather on apparent survival may represent a true absence of an effect, but we cannot rule out the possibility that the lack of an effect resulted from the covariates being computed at too coarse a scale, or because the definitions we used to map habitat did not accurately reflect suitable habitat.

Examination of the relationship between recruitment and ownership indicated a weak effect, with slightly higher recruitment on federal lands ($\hat{\beta}$ = 0.098, 95% CI = 0.058 to 0.137) than on mixed federal–private and private lands (Table 21). Although habitat covariates did not appear in any of the top models in the meta-analysis of λ, examination of the best models that included habitat covariates provided evidence that the percent of the study area covered by suitable owl habitat had a positive effect on recruitment (covariate HAB2 in Table 21). In contrast, recruitment was negatively related to the percent of the area surrounding the study area that was covered by suitable owl habitat (covariate HAB3 in Table 21). Our results may reflect an interaction or synergistic relationship between recruitment and the percent cover of suitable owl habitat within versus surrounding the study areas on federal lands compared to other land ownerships. We did not include such models in our *a priori* model set, so these relationships should be investigated in more detail in future analyses. There was no evidence that recruitment was influenced by any of our weather or climate covariates as all 95% confidence intervals for these covariates included zero (Table 21).

Plots of year-specific estimates of φ_t and f_t indicated considerable temporal and spatial variation, which produced high temporal and spatial variation in λ (Fig. 12). For example, all

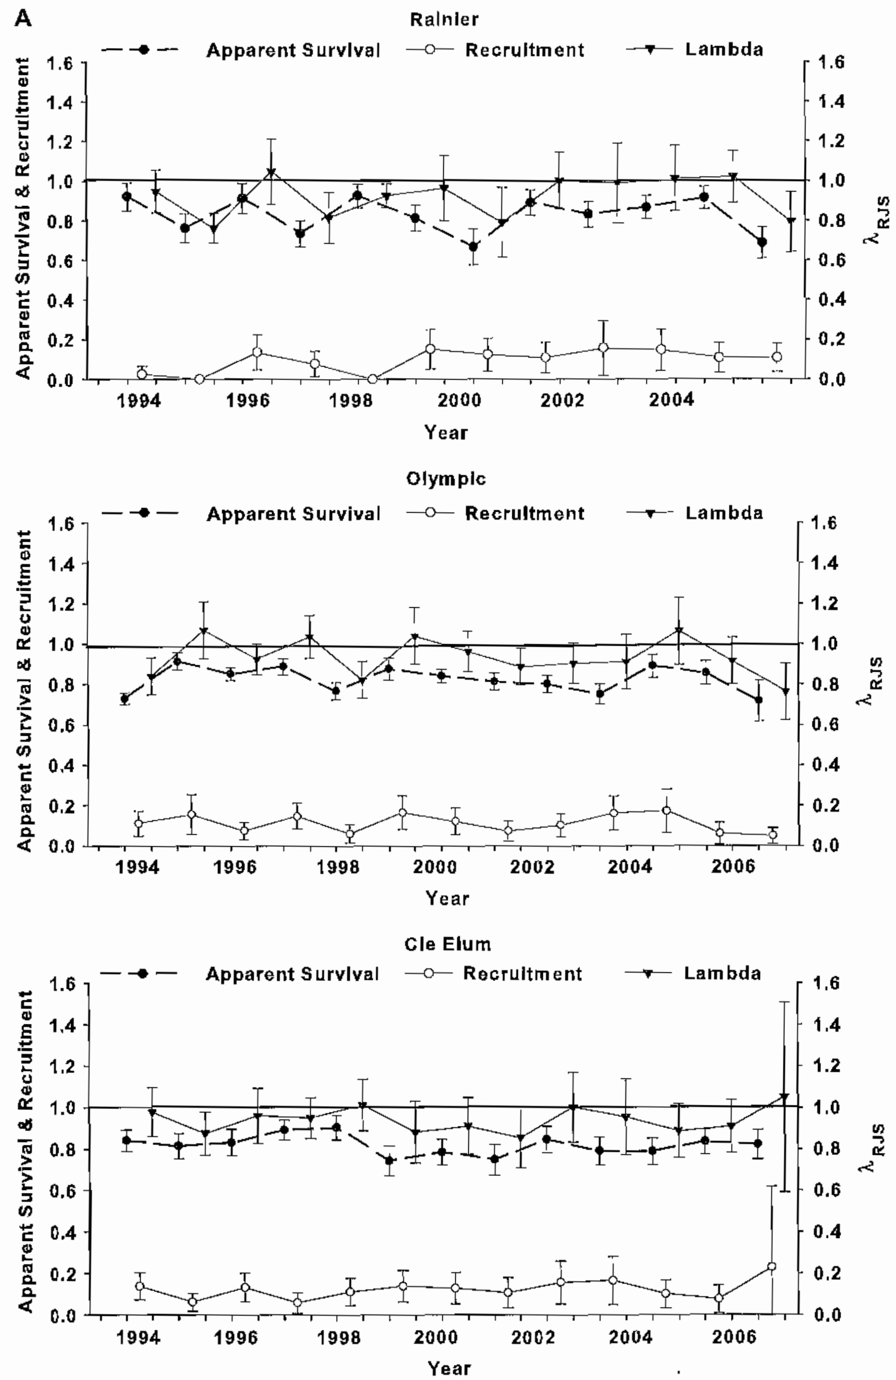

Figure 12. Estimates of apparent survival, recruitment, and λ of Northern Spotted Owls based on the most general model [(g*t) f(g*t)] from the meta-analysis of three study areas in Washington (A), five study areas in Oregon (B), and three study areas in California (C). Vertical bars indicate 95% confidence limits, and g and t represent study area and annual time effects, respectively.

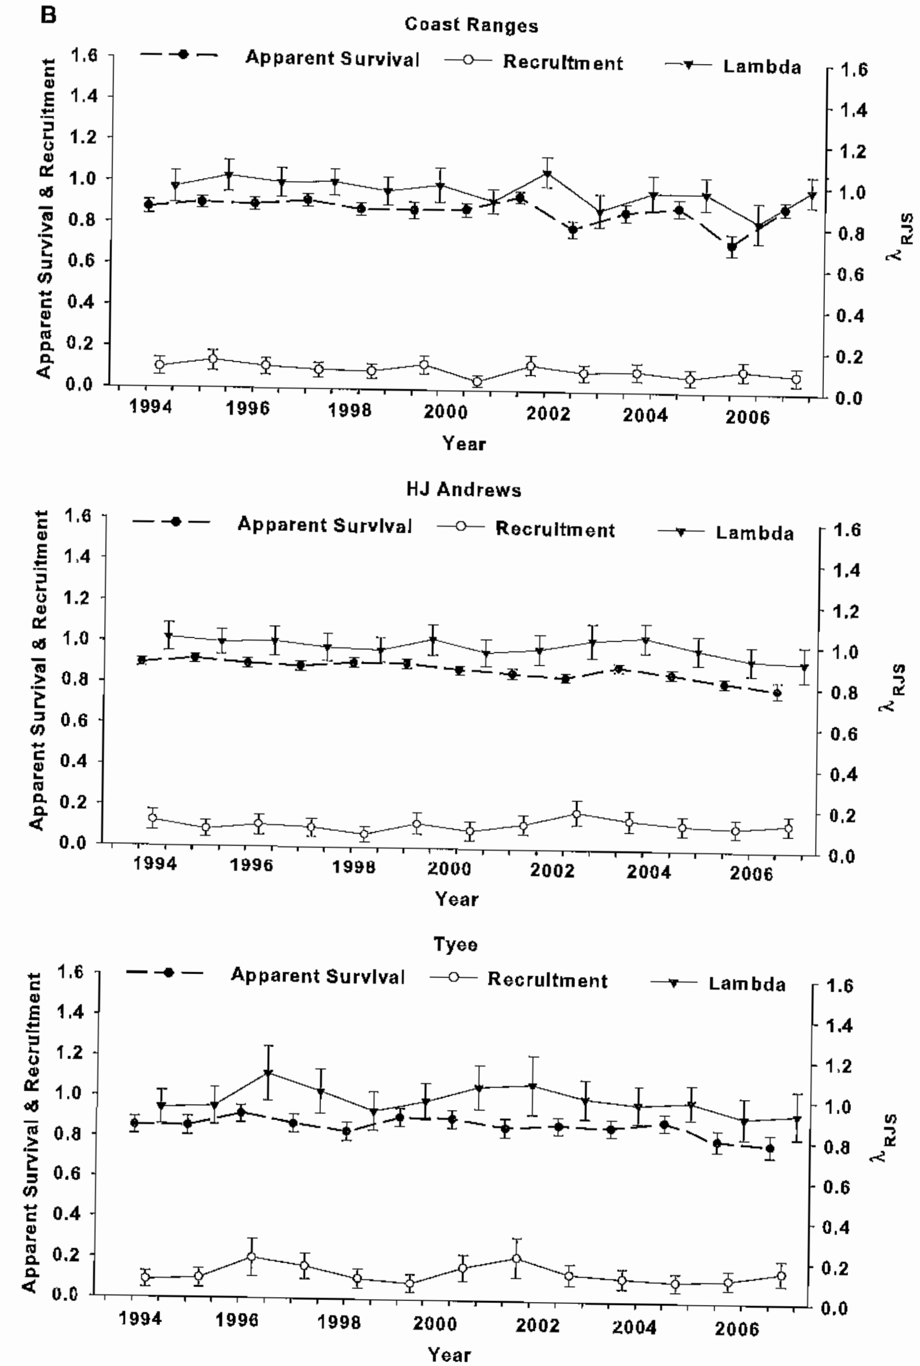

Figure 12. (*continued, for study areas in Oregon*)

B ***continued***

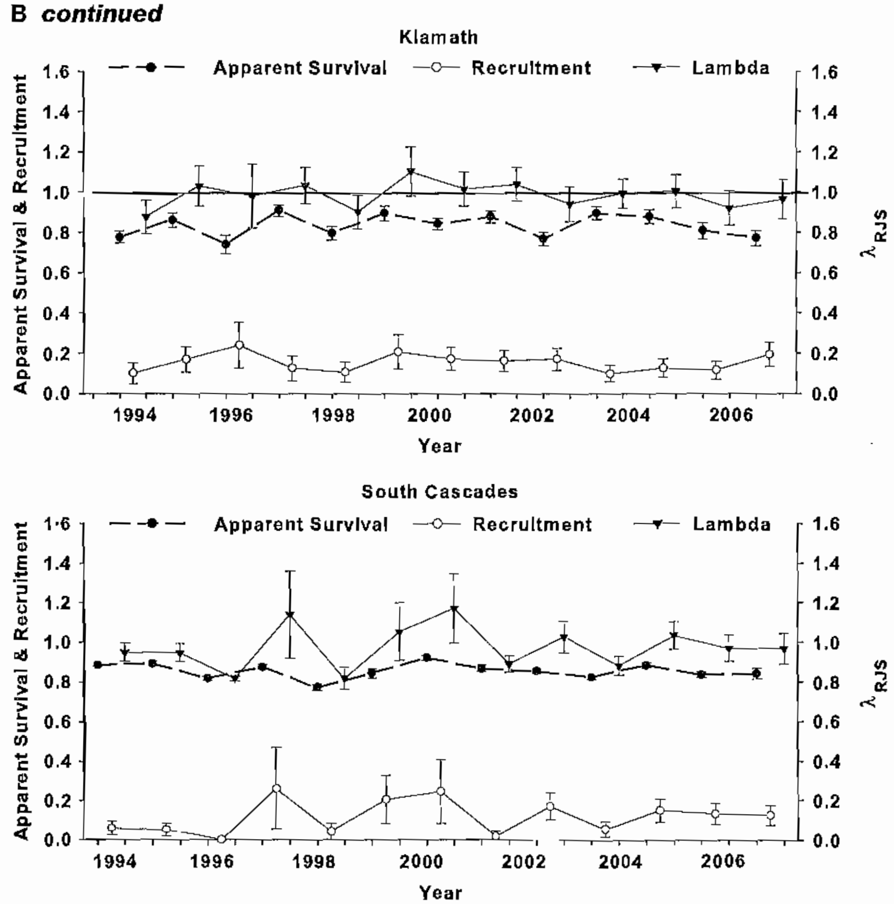

Figure 12. (*continued, for study areas in Oregon*)

three parameters (φ_t, f_t, λ) exhibited considerable variation in Washington where owl populations were declining the most (Fig. 12A), but less variation in most of the other study areas. Temporal variation in φ_t was paralleled by temporal variation in λ_t for most study areas (OLY, CLE, COA, HJA, TYE, KLA, NWC, HUP, GDR), suggesting that changes in λ_t were influenced primarily by changes in survival. However, this pattern was not as evident for RAI and CAS during all years, and there was evidence that recruitment had a substantial influence on λ_t in those two areas, particularly during years when λ_t increased noticeably. In addition, estimated recruitment was essentially zero in some years on the RAI, OLY, and CAS study areas, which resulted in noticeable declines in λ_t, since φ was always <1.0. Overall, the high temporal variation in the annual rate of population change of Spotted Owls was closely associated with apparent survival rates in most cases and with recruitment in a few cases.

DISCUSSION

The Northern Spotted Owl has been the "poster child" for conservation of old-growth and mature forests on federal lands in the Pacific Northwest and has served as an "umbrella species" (Roberge and Angelstam 2004) for conservation of other species associated with old forests (USDA Forest Service and USDI Bureau of Land Management 1994). As a result, numerous conservation plans have addressed the habitat needs of Spotted Owls on federal lands. In conjunction with the listing of the subspecies as threatened in 1990, the Interagency Scientific Committee (ISC) developed and published the first comprehensive conservation

C

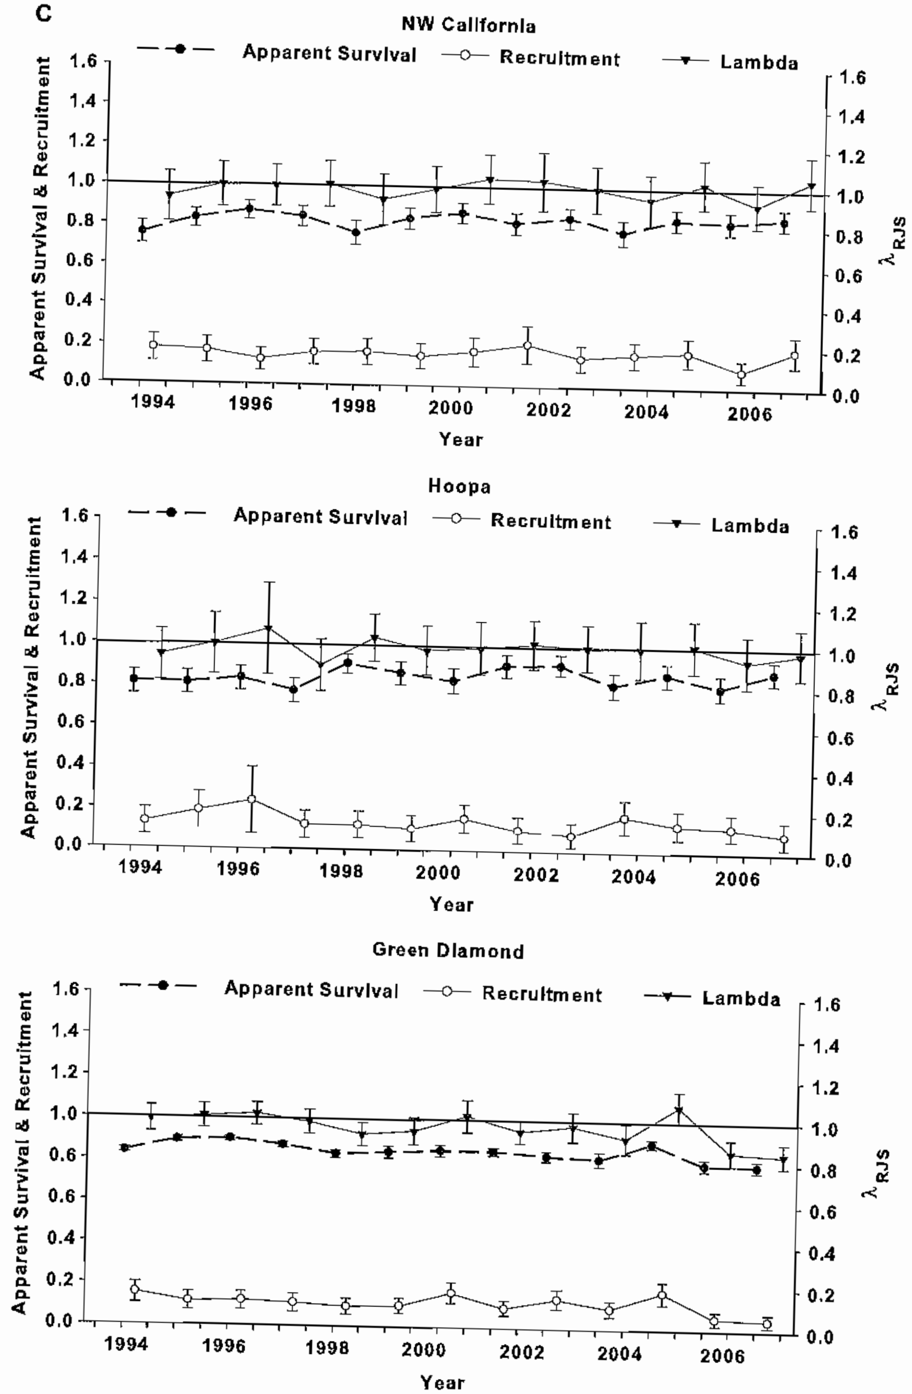

Figure 12. (*continued, for study areas in California*)

plan for the Northern Spotted Owl (Thomas et al. 1990). The ISC plan called for the conservation of an unprecedented amount of old forest in large reserves that were spaced within 19.2 km of each other and large enough to support 20 to 25 pairs of territorial owls. The ISC conservation strategy was the framework, with minor modifications, for the first draft final recovery plan for the Northern Spotted Owl (USDI Fish and Wildlife Service 1992), and also served as a model for the network of old forest reserves that eventually became the Northwest Forest Plan for management of all federal lands within the geographic range of the subspecies (USDA Forest Service and USDI Bureau of Land Management 1994).

The Northwest Forest Plan served as the *de facto* recovery plan for the Northern Spotted Owl for approximately 14 years during which time there was no approved recovery plan for the owl. The situation changed in 2008, when the U.S. Fish and Wildlife Service published a final recovery plan for the Northern Spotted Owl (USDI Fish and Wildlife Service 2008). The 2008 recovery plan included a much-reduced network of old forest reserves compared to the Northwest Forest Plan, and the approach laid out in the recovery plan was criticized by three professional societies concerned about the recovery of the owl (e.g., Wildlife Society 2008). The U.S. Department of Justice subsequently declined to defend the 2008 recovery plan, and it was remanded to the Fish and Wildlife Service with instructions that they address the deficiencies noted by their critics. At this writing, the Fish and Wildlife Service is working on a revision of the 2008 plan, but the situation is still unresolved.

Because the Northern Spotted Owl is federally listed as "Threatened" under the Endangered Species Act (USDI Fish and Wildlife Service 1990), and is the focus of many forest management practices that have been implemented in recent years in the Pacific Northwest, results of our study will be of interest to a number of stakeholders, including state and federal government agencies, conservation groups, private industry, and the public. Consequently, it is important to ask: What is our frame of reference and what kind of inferences can we make from the results of our study? From a statistical standpoint, a formal inference can be made from the sample of marked and recaptured owls to the population of owls in the study areas in which the marked owls were located. Our 11 study areas covered a large portion of the subspecies' geographic range and included substantial variation in latitude, elevation, and land ownership (Appendix A), but they were not selected randomly. Consequently, the results of our analyses cannot be considered representative of demographic trends of Northern Spotted Owls throughout their entire range. For example, there were no study areas in the extensive areas of state and private lands in northwestern Oregon and southwestern Washington or in the California Cascades. However, we believe that our results are representative of most populations of Northern Spotted Owls in the Pacific Northwest that are on federal lands or in areas of mixed federal and private ownership. We do not think that our results can be used to assess demographic trends of Spotted Owls on non-federal lands because the two study areas in our sample that were entirely on non-federal lands (GDR, HUP) were atypical. Both the Green Diamond Resource Company and the Hoopa Tribe managed their lands to protect known Spotted Owl nest areas and to maintain at least part of their lands in suitable foraging habitat for Spotted Owls. Such practices are not universal on private and state lands. If anything, our results probably depict an optimistic view of the overall population status of the Northern Spotted Owl.

This study is the fifth meta-analysis of demographic data from Northern Spotted Owls (Anderson and Burnham 1992, Burnham et al. 1996, Franklin et al. 1999, Anthony et al. 2006); however, only two of these efforts were published as refereed journal articles (Burnham et al. 1996, Anthony et al. 2006). The other articles are not readily available, so we will concentrate our discussion on the two published articles. The second meta-analysis of demographic rates of Northern Spotted Owls was conducted in 1993 and included 11 study areas (Burnham et al. 1996, Forsman et al. 1996a). The three major findings of the second analysis were: (1) Fecundity rates varied among years and ages of owls, with no increasing or decreasing trend over time; (2) survival rates were dependent on age and there was a decreasing trend in adult female survival; (3) the annual rate of population change (λ_{PM}) was <1.0 for 10 of 11 areas examined, and the estimated average rate of population decline was 4.5% per year (Burnham et al. 1996). Results of the first three meta-analyses of demography of Northern Spotted Owls were critiqued by Raphael et al. (1996) and Boyce et al. (2005), who questioned the estimates of annual rate of population change from Leslie matrix models (λ_{PM}), primarily because estimates of juvenile survival from capture–recapture methods were biased by permanent emigration during natal dispersal. Anthony et al. (2006) avoided this problem by using the Pradel (1996) model, which estimates the annual finite rate of population change (λ_{RJS}) of territorial owls without inclusion of juvenile survival rates. In addition, the Pradel (1996) model treats losses due to emigration and mortality and gains due to recruitment and survival in a symmetric way, so it is less subject to biases in the estimate of λ. For more information on this topic, see Anthony et al. (2006), and for a review of the differences between λ_{PM} and λ_{RJS}, see Sandercock and Beissinger (2002).

The most important findings in the Anthony et al. (2006) report were: (1) Fecundity was relatively stable among the 14 study areas examined, (2) survival rates were declining on 5 of the 14 areas, and (3) populations were declining on 9 of 13 study areas for which there was adequate data to estimate λ. The mean λ for the 13 areas was 0.963, which indicated that populations were declining 3.7% annually during the study (Anthony et al. 2006:34). The reasons for declines in Spotted Owl populations in their study were not readily apparent. Therefore, Anthony et al. (2006) recommended the use of additional covariates in future analyses to evaluate the possible influence of Barred Owls, weather, habitat, and reproduction on vital rates and population trends of Spotted Owls.

Fecundity

The results from our analysis of fecundity were consistent with previous analyses in that we found substantial annual variation in fecundity on individual study areas and a biennial cycle of high fecundity in even-numbered years and low fecundity in odd-numbered years (Burnham et al. 1996, Anthony et al. 2006). The cause of this synchronization remains unknown. One hypothesis for alternate year breeding in long-lived species that require many months to produce a single brood is that reproduction every year is physically impossible because of the large investment of time and energy required to produce a single brood. A hypothesis of intermittent breeding makes sense for some long-lived alternate year breeders such as Albatross (*Diomedea exulans, Phoebetria fusca, P. palpebrata*), which have to travel huge distances for many months in order to provision a single young (Tickell 1968, Weimerskirch et al. 1987). Although Spotted Owls also invest many months to produce a single brood (Mar–Aug), there is considerable variation among individuals regarding the alternate year pattern of breeding. In some of our study areas, the majority of owls nested every other year, but there were a few pairs that nested in nearly all years, and there were many that did not follow a predictable pattern. We conclude that breeding in the Spotted Owl is a complex interaction between age, prey abundance, weather, individual variation, and territory quality. However, none of these factors are known to fluctuate on a two-year cycle on our study areas, and prey cycles observed in other studies generally suggest cycles of three years or longer (Korpimaki 1992). Another hypothesis is that the likelihood of breeding is somehow influenced by the molt, which in Spotted Owls is characterized by an alternate year molt of the remiges and rectrices (Forsman 1981). The molt hypothesis seems unlikely, however, as no evidence indicates that the molt was synchronized within the owl populations. The molt hypothesis also does not explain the fact that the even–odd year effect became less evident in the last five years of our study.

Another consistent effect across study areas was variation in fecundity by age class. Fecundity was higher for adults than for 1-yr-olds, and 2-yr-olds were intermediate. A pattern of increasing fecundity with age is typical in birds (Clutton-Brock 1988, Saether 1990), and, in the case of territorial predators like Spotted Owls, probably reflects increased experience and familiarity with a territory and a long-term mate. Spotted Owls in the 1- and 2-yr-old age classes typically comprised <10% of the territorial population, so they contributed little to annual reproduction compared to adults. Age effects were not unexpected and have been well documented in previous studies of Northern Spotted Owls (Burnham et al. 1996, Anthony et al. 2006), California Spotted Owls (*S. o. occidentalis*; Blakesley et al. 2001), and Mexican Spotted Owls (*S. o. lucida*; Seamans et al. 1999, 2001), and are typical of long-lived birds in general (Newton 1989). Compared to the previous meta-analysis of Northern Spotted Owls (Anthony et al. 2006), the addition of five years of data resulted in slightly lower mean fecundity across study areas for adults ($\bar{x}$ = 0.340 vs. 0.372) and 2-yr-olds ($\bar{x}$ = 0.195 vs. 0.208), but slightly higher fecundity for 1-yr-olds ($\bar{x}$ = 0.103 vs. 0.074). However, our fecundity estimates were still well within the range of values reported on the same study areas during 1985 to 1994 (Burnham et al. 1996). Our results suggested that fecundity was declining in five areas (CLE, KLA, CAS, NWC, GDR), stable in three areas (OLY, TYE, HUP), and increasing in three areas (RAI, COA, HJA). Given the variation in trends among study areas, it was not surprising that the best or competitive models in the meta-analyses of fecundity did not include time trends in fecundity. Our results also were in contrast to a previous analysis in which fecundity appeared to be declining in only two study areas in Washington (Anthony et al. 2006).

In our analysis of individual study areas, there was evidence that the proportion of Spotted Owl territories with detections of Barred Owls had a negative effect on fecundity in four study areas (COA, KLA, CAS, GDR) and an unexpected positive effect on fecundity in one area (HJA). The high frequency of study areas with little evidence of effects of Barred Owls on fecundity did not support our hypothesis of competitive interactions, but findings of negative effects of Barred Owls on some study areas were in contrast to Anthony et al. (2006), who found little evidence of a Barred Owl effect on fecundity. In addition, there was weak evidence for a negative effect of Barred Owls on fecundity in both of our meta-analyses of fecundity. One explanation for the relatively weak effect of Barred Owls on fecundity in studies such as ours is that Barred Owls may simply displace Spotted Owls from their territories. When this happens, Spotted Owls enter the non-territorial population, where they are non-breeders and less detectable using the calling surveys used to sample territorial owls (Kelly 2001). Under this scenario, Spotted Owls that are not displaced may continue to breed at levels similar to historic levels, but the net effect of Barred Owls on fecundity is to reduce the total number of young Spotted Owls produced. Displacement of territorial Spotted Owls by Barred Owls may explain seemingly counterintuitive results such as the positive beta associated with the BO covariate in the analysis of fecundity on the HJA study area. In this situation, the Spotted Owls that are monitored are mostly the ones not displaced by Barred Owls, and are likely to be the oldest and most experienced owls. In addition, detections of Barred Owls were more frequent in our study areas in Washington and Oregon, so we did not expect the effects of Barred Owls to be as strong in California.

While climate and weather covariates explained little of the variation in fecundity in the meta-analysis, there was some support for climate or weather effects in the analyses of individual study areas. For example, there was evidence that low temperatures during the early nesting season had negative effects on fecundity in three study areas (RAI, COA, CAS) and had a positive effect on fecundity in one area (HUP). There was also evidence that high precipitation during the early nesting season had negative effects on fecundity in three study areas (CLE, KLA, NWC). Based on a territory-specific study of Spotted Owls on the TYE study area, Olson et al. (2004) also found evidence for a negative effect of precipitation during the early nesting season on fecundity in 1988 to 1999. Cold, wet weather during the incubation, brooding, and early fledgling stages has been reported to be a direct cause of egg and chick mortality through chilling and exposure in Peregrine Falcons (*Falco peregrinus*; Olsen and Olsen 1989, Bradley et al. 1997) and Australian Brown Falcons (*F. berigora*; McDonald et al. 2004). We also observed mortality in cases where recently fledged owlets died from exposure during unseasonal periods of cold, snowy weather in late May or early June. However, it is unclear if the effect of precipitation on fecundity is due primarily to direct loss of eggs or juveniles from exposure, effects on prey abundance or availability, or reduced foraging efficiency of adults (Franklin et al. 2000). Most likely, the effect is due to a combination of all of these factors. Studies of corticosterone levels show that inclement weather can lead to increased stress among adult birds in Dark-eyed Juncos (*Junco hyemalis*; Rogers et al. 1983), Storm Petrels (*Pelecanoides urinatrix*; Smith et al. 1994), Lapland Longspurs (*Calcarius lapponicus*; Astheimer et al. 1995), White-crowned Sparrows (*Zonotrichia leucophrys*; Wingfield et al. 1983), and male Song Sparrows (*Melospiza melodia*; Wingfield 1985). However, some studies also suggest that only unusually severe weather actually results in stress levels high enough to cause birds to forego nesting or to fail after starting to nest (Romero et al. 2000).

Dugger et al. (2005) suggested that a negative relationship between fecundity of Spotted Owls and mean precipitation in the previous winter could reflect climate effects on prey abundance and/or availability. Few studies have linked abundance or availability of Spotted Owl prey to weather conditions, but Lehmkuhl et al. (2006b) reported that annual survival of northern flying squirrels (*Glaucomys sabrinus*) was negatively associated with snow depth. Fecundity of Spotted Owls could also be influenced by prey abundance. Rosenberg et al. (2003) reported a positive correlation between fecundity of Northern Spotted Owls and abundance of deer mice (*Peromyscus maniculatus*) during the nesting season over an eight-year period on the HJA study area. However, deer mice were not the most important prey in the diet on the HJA study area (<10% of prey numbers), so it was unclear if the correlation between owl fecundity and deer mouse numbers was a causal relationship. Similarly, Ward and Block (1995) documented a year of high reproduction by Mexican Spotted Owls (*S. o. lucida*) that occurred in conjunction with an eruption of white-footed mice (*P. leucopus*) in southern New Mexico. Although the data are limited for Spotted Owls, annual variation in prey abundance has strong effects on fecundity of most raptors in northern latitudes, including such diverse species as Tengmalm's Owl (*Aegolius funereus*; Korpimäki 1992, Hakkarainen et al. 1997), Golden Eagle (*Aquila chrysaetos*; Steenhof et al. 1997), Great-horned Owl (*Bubo virginianus*; Rohner 1996), and Northern Goshawk (*Accipiter gentilis*; Salafsky et al. 2005). We suspect, therefore, that we will continue to have difficulty modeling annual variation in fecundity of Northern Spotted Owls without long-term information on the abundance of prey that make up the majority of their diet, especially flying squirrels, woodrats (*Neotoma* spp.), red-backed voles (*Myodes* spp.), deer mice, tree voles (*Arborimus* spp.), and lagomorphs (*Lepus americanus*, *Sylvilagus* spp.).

In Washington and Oregon, the habitat covariate was included in either a top fecundity model or a competitive model in seven of the eight study areas. There was strong evidence for a positive effect of the amount of habitat on fecundity in four study areas (COA, HJA, TYE, CAS), and a negative effect of habitat on fecundity in one area (KLA). We cannot discount the possibility that the absence of a strong effect of habitat on fecundity in all study areas was because our habitat covariate was too simplistic. Other habitat features such as the amount of edge, mean patch size, or amount of interior forest habitat may be important to Spotted Owls (Franklin et al. 2000, Olson et al. 2004, Dugger et al. 2005), and these variables were not readily available for all of our study areas. Also, in a previous territory-specific study on the NWC study area, Franklin et al. (2000) found that fecundity of Spotted Owls was negatively associated with the amount of interior forest and positively associated with the amount of edge, whereas adult survival was positively associated with the amount of interior old-growth forest and with the amount of edge. Based on these findings, Franklin et al. (2000) postulated that "habitat fitness" for Spotted Owls was greatest in areas that included large amounts of interior mature and old-growth forest, but with considerable amounts of edge as well. However, evidence for a positive effect of edge on fecundity of Spotted Owls is not consistent across the range of the subspecies. For example, Dugger et al. (2005) found a positive relationship between fecundity and the percent cover of old forest within a 730-m-radius circle of Spotted Owl activity centers in southern Oregon but found no evidence that fecundity was positively associated with the amount of edge. Whether spatially explicit covariates such as the amount of edge or amount of interior old forest could be useful or meaningful in a study-area–specific analysis or in a meta-analysis of multiple study areas is questionable but should be explored.

The meta-analysis of adult fecundity also indicated differences among ecoregions and substantial annual variability with no apparent time trend. Our results were virtually identical to those reported by Anthony et al. (2006), including the high fecundity of Spotted Owls in the Washington Mixed-conifer ecoregion compared to all other regions. There was also some evidence for an effect of habitat and presence of Barred Owls on fecundity, but in both cases the confidence intervals for the regression coefficients overlapped zero. The lack of a strong signal regarding the effects of habitat and Barred Owls on fecundity in the meta-analysis was not surprising considering the high variation among study areas regarding the importance of the habitat and the highly variable number of detections of Barred Owls among study areas (Appendix B). The meta-analysis also provided little evidence that ownership, climate, or weather had strong effects on fecundity.

We did not monitor prey abundance on all our study areas, but some lines of evidence suggest that the high fecundity of Spotted Owls on the east slope of the Cascades in Washington could be due to particularly high abundance or availability of preferred prey such as flying squirrels and woodrats (Lehmkuhl et al. 2006a, b). In addition, the understory shrub layer in forests on the east slope of the Cascades tends to be less dense than in forests in western Washington and Oregon, which may make it easier for Spotted Owls to capture prey in forests on the east slope. Tests of the prey abundance and availability hypotheses will likely prove difficult, but one obvious need is to initiate studies to better evaluate annual variation in the total biomass of prey available to Spotted Owls in different study areas.

We identified three major difficulties in the approach we used to model fecundity in the present analysis and previous meta-analyses. First, it was difficult to establish the effects of other variables in the presence of the strong even–odd year fluctuations in fecundity during the 1990s. If no adjustment is made for these even–odd year effects, the residual variation is large and negatively auto-correlated over time, which overwhelms the effects of any other covariate. In addition, because the even–odd year effect started to dissipate after about 2000, models that included the even–odd year effect had large residuals, which in turn made it difficult to detect the effects of other covariates.

Second, some of our covariates were highly correlated and in many cases also reflected time variation. For example, the BO covariate was negatively correlated with temporal trends because the proportion of territories on which Barred Owls were detected increased on most study areas over time (Appendix B). The habitat covariate was also somewhat correlated with time because it mainly reflected habitat loss over time.

Finally, some of the covariates we investigated were likely influential at the level of the individual territory, but in this analysis we modeled average effect across populations (study areas). For example, habitat and Barred Owls may have a strong effect on fecundity of individuals, but this could be masked by using yearly averages, particularly in conjunction with the strong annual variation in fecundity observed in our study. The above problems are likely to be present in any study of a species with a cyclic pattern of fecundity or with highly correlated covariates. There is no easy solution to these problems, except to recognize that they occur, and to avoid the inclusion of highly correlated covariates in the same models.

Apparent Survival

Annual recapture probabilities of territorial Spotted Owls in our study areas generally ranged from 0.70 to 0.90, within the range of estimates reported in previous studies of Spotted Owls (Burnham et al. 1996, Anthony et al. 2006). With the exception of one study area (OLY), our results indicated that male and female Spotted Owls had similar survival rates. Studies of Ural Owls (*Strix uralensis*; Saurola 2003) and Tawny Owls (*S. aluco*; Karell et al. 2009) also indicated no gender differences in survival of these species as well (but see Millon et al. 2009). Gender differences in survival of birds have been attributed to many factors, including sexual differences in dispersal (Croxall et al. 1990), plumage attributes (Møller and Szép 2002), territorial defense (Clobert et al. 1988), and feeding behavior (Clobert et al. 1988). Because male Spotted Owls play the dominant role in territorial defense and feeding of the young, we predicted that, if anything, they would have lower survival than females. The pattern on the OLY study area was opposite to this expected result, which supported the alternative hypothesis that egg production, incubation, brooding, and nest defense had higher costs on the survival and site fidelity of females than did territorial defense and foraging by the male.

Results from our study areas also indicated that apparent survival was influenced by a number of other factors including age, time, Barred Owls, reproduction, and weather, depending on the study area in question. The age-specific pattern that we observed (lower survival in young birds) is typical of many, if not most, species of birds (Clobert et al. 1988; Newton 1989; Saurola 1987, 2003; Martin 1995; Karell et al. 2009). In long-lived, territorial birds like Spotted Owls, higher adult survival is probably attributable to the acquisition of a territory, foraging experience, and familiarity with the foraging area (Newton 1989, Martin 1995), but tests of these hypotheses have not been conducted.

Our estimates of survival were generally comparable to those reported by Burnham et al. (1996) and Anthony et al. (2006) except that the range of estimates for each age group in our study was slightly narrower than in the earlier studies. Our results were also comparable to those for adult California Spotted Owls (Blakesley et al. 2001, Seamans et al. 2001, Franklin et al. 2004) and adult Mexican Spotted Owls in Arizona (Seamans et al. 1999). Results from all three subspecies of Spotted Owls throughout their geographic range indicated that survival rates were high, with relatively low annual variability, while fecundity was highly variable from year to year. This life history strategy has been referred to as "bet hedging" (Stearns 1976, Franklin et al. 2000, Gaillard et al. 2000), where natural selection favors adult survival at the expense of producing fewer young during years with unfavorable conditions. Selection for high and comparatively stable adult survival is important because sensitivity analyses on population dynamics of Northern Spotted Owls (Noon and Biles 1990, Lande 1991) and California Spotted Owls (Blakesley et al. 2001) indicated that annual rates of population change were most influenced by changes in adult survival.

One disturbing finding in our analysis was that estimates of apparent survival were declining on 10 of the 11 study areas (CLE, RAI, OLY, COA, HJA, TYE, CAS, NWC, HUP, GDR, Fig. 5, Table 22). In addition, fecundity was declining in 5 of the 11 areas (Table 22). Declines in apparent survival of Northern Spotted Owls on some study areas have been reported previously (Burnham et al. 1996, Anthony et al. 2006), but, in contrast to those studies, our results indicated that recent declines were occurring across the entire range of the subspecies, including the

TABLE 22

Summary of trends in demographic parameters for Northern Spotted Owls from 11 study areas in Washington, Oregon, and California, 1985–2008.

Study area	No. of territorial owls in 2008[a]	Fecundity	Apparent survival (Model-averaged)	$\hat{\lambda}$	$\Delta\lambda$[b]
Washington					
CLE	18	Declining	Declining	0.937	Declining
RAI	36	Increasing	Declining	0.929	Declining
OLY	54	Stable	Declining	0.957	Declining
Oregon					
COA	105	Increasing	Declining since 1998	0.966	Declining
HJA	152	Increasing	Declining since 1997	0.977	Declining
TYE	123	Stable	Declining since 2000	0.996	Stationary
KLA	136	Declining	Stable	0.990	Stationary
CAS	83	Declining	Declining since 2000	0.982	Stationary
California					
NWC	84	Declining	Declining	0.983	Declining
HUP	51	Stable	Declining since 2004	0.989	Stationary
GDR	125	Declining	Declining	0.972	Declining

[a] Counts are based on banded territorial owls used in the analysis of $\hat{\lambda}$ and do not include owls that were not banded or whose bands were not confirmed.

[b] Population trends are based on estimates of realized population change (Δ_t).

southern portion. Estimated declines in adult survival were most precipitous in Washington, where annual apparent survival rates were <0.80 in recent years (Fig. 5A), a rate that may not allow for sustainable populations with current rates of fecundity and recruitment (Noon and Biles 1990, Lande 1991). In addition, the declines in adult survival and fecundity in Oregon have occurred predominantly within the last five years (Fig. 5B) and were not observed in the previous analysis of data from Oregon (Anthony et al. 2006). Compared to study areas farther north, declines in survival on the GDR and NWC study areas in California were more gradual and over a longer period of years. Collectively, the declines in apparent survival of Northern Spotted Owls across much of the subspecies' range are cause for concern because Spotted Owl populations are most sensitive to changes in adult survival rates (Noon and Biles 1990, Lande 1991).

Anthony et al. (2006) found evidence of a negative Barred Owl effect on apparent survival of Spotted Owls in only 2 of the 14 study areas they examined. In our analysis of data from individual study areas, the percent of Spotted Owl territories with Barred Owl detections had a negative effect on apparent survival of Spotted Owls on 6 of 11 areas examined (RAI, OLY, COA, HJA, GDR, NWC), with a weak or negligible effect on the other five areas (CLE, TYE, KLA, CAS, HUP). Thus, our results suggest that the negative effect of Barred Owls on survival of Spotted Owls may be increasing as Barred Owls continue to invade and increase in numbers in our study areas (Appendix B).

In the meta-analysis of apparent survival, we found differences among study areas and ecoregions, and considerable annual variation in adult survival. Apparent survival rates were higher in the Oregon Cascades Douglas-fir, Oregon Coastal Douglas-fir, and California Coast ecoregions compared to the Mixed-conifer ecoregions in Washington and Oregon/California. The meta-analysis also provided evidence of a downward trend in survival for all study areas, which was expected given that our analyses of the individual study areas indicated declining survival rates on 10 of 11 areas. The overall decline in survival suggests a further deterioration of the situation reported by Anthony et al. (2006), who found that declines in survival were limited primarily to study areas in Washington.

The best random effects models in the meta-analysis suggested that reproduction in the previous year and the proportion of territories with Barred Owl detections both had negative effects on survival. We found some evidence that early nesting season precipitation had a negative effect on apparent survival but there was little to no evidence that the Pacific Decadal Oscillation, Southern Oscillation Index, nesting season temperature, percent cover of habitat, ownership, or latitude were associated with survival. It was not surprising that we did not find much evidence for an effect of weather in the meta-analysis because a previous analysis of demographic data and weather variables from six of our study areas indicated that the association of apparent survival with weather and climate covariates was quite variable among areas (Glenn 2009, Glenn et al. 2010, 2011). The lack of association between survival and most weather covariates suggests that Spotted Owls are able to cope physiologically with a fairly broad range of adverse weather conditions before their survival is affected. Romero et al. (2000) proposed a similar hypothesis regarding the effects of weather on reproduction of three species of Arctic passerines. If survival is affected only by the most extreme weather events, which occur at unpredictable times, detection of these effects will likely require hierarchical analyses to evaluate the influence of within-year or within-season weather events (Rotenberry and Wiens 1991).

Annual Rate of Population Change and Realized Rates of Population Change

Individual Study Areas

Our estimates of λ were <1.0 for all study areas (range = 0.929 to 0.996), and there was strong evidence that populations declined on 7 of the 11 areas that we examined (RAI, OLY, CLE, COA, HJA, NWC, GDR). On the other four areas (TYE, KLA, CAS, HUP), either populations were stable or the precision of the estimates was not sufficient to detect declines. The number of territorial owls detected on all 11 areas was lower at the end of the study than at the beginning, and few territorial owls could be found on some of the study areas in 2008 (Table 22). Estimated rates of decline were highest for study areas in Washington (RAI, OLY, CLE) and the COA study area in Oregon. The weighted mean estimate of λ for all 11 study areas was 0.971, indicating an average population decline of 2.9% per year during the years 1990 to 2006. An average annual decline of 2.9% is lower than the 3.7% reported by Anthony et al. (2006), but the rates are not directly comparable because Anthony et al. (2006) examined a different series of years and because two of the study areas in their analysis were discontinued (WEN, WSR) and not included in our analysis. In our analysis, rates of population decline for individual study areas were slightly higher than those reported by Anthony et al., who found that populations on 9 of 13 study areas were declining. In California, Franklin et al. (2004) found that estimates of λ_{RJS} for California Spotted Owls were negative on four of five study areas examined, but in all five cases the 95% confidence intervals on λ overlapped 1.0. Franklin et al. (2004:33) concluded that either ". . . the populations were stationary or the estimates of λ_t were not sufficiently precise to detect declines if they occurred."

Our estimates of λ apply only to the years from which the data were analyzed, which spanned the 16-year period from 1990 to 2006 (Table 19). Any predictions about past or future trajectories of Spotted Owl populations on our study areas are risky. Also, the estimates of λ are mean estimates of the annual rate of population change in the number of territorial Spotted Owls on the study areas, and the estimates of λ_t for each study area varied considerably. Consequently, we attempted to illustrate how annual changes in λ_t influenced trends in population numbers by estimating realized population changes, Δ_t, for each study area. Based on these estimates, populations on the CLE, RAI, OLY, and COA study areas declined 40 to 60% during the last 15+ years, and populations on HJA, NWC, and GDR declined by 20 to 30%. Populations of territorial owls on the TYE, KLA, CAS, and HUP study areas declined 5 to 15%, but confidence intervals for these estimates substantially overlapped 1.0, and precision of the estimates was not sufficient to detect such small declines. Both the timing of the population declines and the rates of decline differed among study areas (Fig. 10). Thus, there was no evidence that population declines were synchronized among study areas, even though some of the study areas were relatively close together (e.g., COA, TYE, KLA), and marked individuals from one study area were occasionally re-sighted in another study area. The number of populations that declined and the rate of decline on study areas in Washington and northern Oregon were noteworthy and should be cause for concern for the long-term sustainability of Northern Spotted Owl populations throughout the range of the subspecies.

Meta-analysis of Annual Rate of Population Change

In the meta-analysis of λ, we found differences among ecoregions and a negative effect of Barred Owls on survival. Apparent survival was highest in the Oregon Coast Douglas-fir ecoregion, which was expected given that the Oregon Coast Range study area also had higher survival in the meta-analysis of survival. Apparent survival and λ were lowest in the Douglas-fir and Mixed-conifer ecoregion in Washington, and recruitment was highest for the Oregon/California Mixed-conifer region. There was weak evidence that apparent survival was related to the percent cover of suitable owl habitat on four of eight study areas, but there was no evidence that weather or land ownership influenced apparent survival in the meta-analyses of λ. In contrast, there was evidence that the amount of suitable habitat within study areas had a positive influence on recruitment, and recruitment was highest for study areas on federally owned lands that had the highest proportions of suitable owl habitat. Positive associations between the percent cover of suitable owl habitat and survival and recruitment were expected because previous studies (Franklin et al. 2000, Olson et al. 2004, Dugger et al. 2005) have also found positive associations between apparent survival or fecundity and the amount of older forests surrounding Spotted Owl nest sites. However, given the importance of habitat in most previous studies of Spotted Owls, we were surprised that the percent cover of suitable habitat was not included in the top models for all study areas. Weak effects of habitat in our analysis could be the result of using habitat as a study area covariate as opposed to a site-specific covariate. The area-specific habitat covariate may have obscured relationships that could only be detected with finer-scale analyses of survival and fecundity at the scale of the owl home range.

In the meta-analysis of λ, we asked: Is temporal variation in λ_t determined primarily by variation in φ_t, f_t, or both? This general question is relevant to management because the answer may provide guidance regarding which population parameter(s) managers should focus on most when designing habitat management plans. In addition, there is some basis for prediction regarding the most important population parameters for species like Spotted Owls based on previous research on evolution of life history strategies in animals. In mammals and birds with long life spans, such as Spotted Owls, population dynamics are typically characterized by (1) rates of population change that are most sensitive to changes in adult survival, and (2) adult survival that exhibits a relatively small amount of temporal variation compared to temporal variation in recruitment (Pfister 1998; Gaillard et al. 1998, 2000; Gaillard and Yoccoz 2003). The degree to which annual variation in population change reflects variation in one parameter or another is a function of both the sensitivity of λ to that parameter and temporal variation in the parameter. Based on these patterns, we predicted there would be small temporal variability in adult survival compared to recruitment. The plots of year-specific estimates of λ_t, φ_t, and f_t provided illustrations of the temporal variation in annual population changes and its two primary components (φ_t and f_t; Fig. 12).

Although it was not our objective to draw inferences about whether survival or recruitment was more "important" to population change (see Hines and Nichols 2002 for discussion of this topic), we were interested in whether survival of territorial adults varied so little over time that most temporal variation in λ_t was produced by temporal variation in recruitment. This prediction did not hold true for Northern Spotted Owls because survival of adults varied considerably among years (range ≈ 0.70 to 0.90). Because of the importance of adult survival to annual population change (Lande 1988, Noon and Biles 1990), the observed variation in adult survival often corresponded closely to annual variation in λ and was most noticeable where populations were declining the most, especially study areas in Washington. However, the annual variation in apparent survival in our study was not nearly as great as annual variation in reproduction, so our results do fit the pattern usually observed in long-lived vertebrates, where survival is relatively constant compared to fecundity (Stearns 1976, Franklin et al. 2000, Gaillard et al. 2000).

Status of Owl Populations in the Eight NWFP Monitoring Areas

Eight of the study areas in our analysis (CLE, OLY, COA, HJA, TYE, KLA, CAS, NWC) are part of the effectiveness monitoring program for the Northern Spotted Owl in the Northwest Forest Plan (NWFP; Lint et al. 1999). As such, these areas are of special interest to the federal agencies charged with management of the owl. Our analysis indicated that populations on five of these study areas (CLE, OLY, COA, HJA, NWC) were declining during our study. Point estimates of λ on the other three areas (TYE, KLA, CAS) were <1.0, but the 95% confidence intervals on the estimates of λ broadly overlapped 1.0, so we could not reject the hypothesis that those populations were stationary. The weighted mean λ for the eight monitoring areas was 0.972 (SE = 0.006), which indicated that populations on those areas declined on average 2.8% per year during the 16-year study period.

Our results from the meta-analyses of fecundity and apparent survival were similar regardless of whether we used the entire sample of 11 study areas or limited the analysis to the eight NWFP monitoring areas. Therefore, we suggest that future analyses of the data from Northern Spotted Owl demography study areas be conducted only on the entire sample. Conducting a single analysis of all the data will greatly simplify the cooperative approach without losing any important information.

Associations Between Demographic Parameters and Covariates

Determination of cause–effect relationships is not possible with observational studies like ours. Rather, we attempted to assess the relative strength of associations between vital rates of owls and various environmental parameters such as habitat, weather, and presence of Barred Owls. It is implicit in this type of analysis that strong associations between vital rates and environmental factors are likely indicative of cause–effect relationships. Testing for associations is a common approach in ecology, where experimental tests of cause–effect relationships are difficult or impossible to conduct. Previous meta-analyses of demography of Northern Spotted Owls lacked the ability to assess potential processes responsible for causes of population declines. As a result, Anthony et al. (2006) recommended the development and use of biological covariates to help explain the variability in demographic rates and better understand the possible reasons for population changes. Consequently, we devoted considerable time to the development and refinement of covariates for evaluating the potential effects of reproduction, Barred Owls, climate, and percent cover of suitable owl habitat on fecundity, apparent survival, and recruitment at the population (study area) scale. Reproduction and Barred Owl covariates were previously investigated in the Anthony et al. (2006) analysis, but the climate and habitat covariates were new to our analysis. We also spent considerable time trying to develop a covariate for Barred Owls that was both time- and territory- or individual-specific, but inclusion of such a covariate proved infeasible in our analysis. Use of territory-specific covariates has proven feasible only in studies such as those conducted by Olson et al. (2004, 2005), Bailey et al. (2009), and Dugger et al. (2005), where the frame of reference is the individual territory as opposed to the study area or region. The area-specific Barred Owl covariate that we used differed from the covariate used by Anthony et al. (2006) in that our metric was based on Barred Owl detections anywhere within a 1-km radius of any of the historic activity centers in each Spotted Owl territory (see Methods for more details), as opposed to just the most recently occupied activity center. We used the new Barred Owl covariate because it may be a better indicator of the potential influence of Barred Owls on Spotted Owls in each territory.

Cost of Reproduction on Survival

There have been a number of correlative studies in which researchers found evidence that reproduction had negative effects on survival of breeding birds, including Western Gulls (*Larus occidentalis*; Pyle et al. 1997), Greater Flamingos (*Phoenicopterus ruber*; Tavecchia et al. 2001), Great Tits (*Parus major*; McCleery et al. 1996), and Lesser Scaup (*Aythya affinis*; Rotella et al. 2003). Anthony et al. (2006) found that apparent survival of Northern Spotted Owls was negatively related to the mean number of young produced in the previous summer on some study areas in Washington and higher-elevation areas in Oregon. They hypothesized that negative correlations between survival and reproduction suggested a cost of reproduction, with the ultimate factor being weather-related. Although the reproduction covariate was not included in the top or competitive models for most individual study areas in our analysis, it was a factor in the best random effects model in the meta-analysis of survival. Based on this result, we concluded that there was evidence of a negative effect of reproduction on survival, even though the reproduction covariate did not explain a large amount of the annual variation in adult survival. The potential effect of reproduction on apparent survival did not appear to be related to the recent and widespread declines in Spotted Owl populations; however, it may be a contributing factor to some of the population declines, and this relationship needs further investigation. If a cost of reproduction is important in Spotted Owls, the proximate causes could include increased exposure to predation or increased energy expenditure while foraging, feeding young, and defending the territory. These factors have all been proposed as potential costs associated with reproduction in other birds (Newton 1989), but have been experimentally tested in only a few cases, with mixed results (Cichoń et al. 1998).

Weather and Climate

Several studies have documented associations between fecundity or apparent survival of Northern Spotted Owls and seasonal weather patterns (Wagner et al. 1996, Franklin et al. 2000, Olson et al. 2004, Glenn 2009, Glenn et al. 2010, 2011). Our results indicated that associations between fecundity, apparent survival, or recruitment and weather covariates varied among study areas. Fecundity was positively associated with mean temperature during the early nesting season on four of our study areas (RAI, COA, CAS, GDR). The positive association between fecundity and warm weather during the early nesting season has also been noted in several previous studies in which researchers used territory-based analyses to examine the effects of weather on fecundity of Spotted Owls (Wagner et al. 1996, Franklin et al. 2000, Olson et al. 2004, Glenn et al. *In press*). In addition, there was some evidence that fecundity was negatively associated with mean precipitation during the early nesting season on the KLA, CLE, and NWC study areas, and mean temperature during the late nesting season had a negative association with fecundity on TYE. Our results, and those of others (Franklin et al. 2000, Olson et al. 2004, Glenn et al. *In press*), suggest that years of high precipitation and low temperatures during the early nesting season can have a negative effect on fecundity of Northern Spotted Owls.

In our meta-analysis of survival, we detected a positive association between apparent survival and the Pacific Decadal Oscillation, and a negative association between apparent survival and early nesting season precipitation, but these associations were not strong. Similarly, the meta-analysis of λ indicated a positive association of apparent survival with the Pacific Decadal Oscillation, but no evidence for an association between recruitment and any of the climate covariates. (Glenn et al. 2010) reported a similar association between λ and the Pacific Decadal Oscillation on a subset of the study areas in our analysis. Positive values of the Pacific Decadal Oscillation are associated with lower than average rainfall and higher than average temperatures (Parson et al. 2001). We did not find evidence for any other associations between survival or recruitment of Northern Spotted Owls and weather or climate covariates in the meta-analyses. Lack of effects was not surprising because weather and climate varied considerably across the range of the Northern Spotted Owl, even within the same year (Glenn et al. 2010). Thus, analyses of potential associations between demographic rates and weather and climate covariates on individual study areas may reveal patterns that were obscured in our meta-analysis of multiple study areas.

In summary, our analysis of climate covariates indicated the most evidence for a positive association between fecundity and mean temperature during the early nesting season, and a negative association between fecundity and mean precipitation during the early nesting season. We found little evidence for effects of weather on apparent survival and recruitment, and the only climate variable for which we found a positive association with apparent survival was the Pacific Decadal Oscillation. We concluded that weather and climate may contribute to lower demographic rates for some areas in some years, but the effects were not sufficient to explain the major population declines that have occurred during the last 15 to 20 years.

Barred Owls

The number of Barred Owl detections in our study areas has increased dramatically during the last two decades (Appendix B). The increase in Barred Owls has been most noticeable in Washington and Oregon, but has become apparent in northern California as well (Dark et al. 1998, Kelly 2001, Kelly et al. 2003). Invasion and rapid population growth of this congeneric species throughout the range of the Northern Spotted Owl has led to concerns of high potential for competition between the two species. Recent studies have also documented a negative association between occupancy of nesting territories (Kelly et al. 2003, Olson et al. 2005), fecundity (Olson et al. 2004), and apparent survival (Anthony et al. 2006) in some areas in relation to the presence of Barred Owls near nesting areas of Spotted Owls. Consequently, we hypothesized that demographic rates would be negatively associated with the presence of Barred Owls within 1 km of activity centers of Spotted Owls.

We found evidence that fecundity was negatively associated with the presence of Barred

Owls on the CAS, COA, KLA, and GDR study areas. Moreover, apparent survival was negatively associated with the presence of Barred Owls on the RAI, OLY, COA, HJA, GDR, and NWC study areas in both analyses of individual study areas and the meta-analysis. The meta-analysis of λ also indicated a negative association of apparent survival and recruitment with the proportion of territories with Barred Owl detections, but the evidence for a relationship with recruitment was weak. We also found evidence for a negative association of re-sighting probabilities of Spotted Owls when Barred Owls were detected near Spotted Owl nest areas on some of the individual study areas. In summary, we found evidence of negative relationships between demographic rates of Spotted Owls and the presence of Barred Owls on most study areas; therefore, our initial hypothesis was confirmed at least on some study areas. We suspect that the variable relationships between vital rates of Spotted Owls and the presence of Barred Owls were primarily due to the variable detection rates and arrival dates of Barred Owls invading the study areas (Appendix B). Another explanation for the inconsistent, and in some cases weak, associations between vital rates of Spotted Owls and detections of Barred Owls is that our BO covariate was coarse in scale (year-specific only) and was applied at the population scale and not the individual territory scale. Consequently, we believe the influence of Barred Owls on demography of Spotted Owls is likely stronger than was indicated by our analyses. There is a need to develop a covariate for Barred Owls that is both year- and territory-specific (Anthony et al. 2006). Our results support the findings of previous studies that have also reported evidence for negative associations of demographic performance of Spotted Owls when Barred Owls were detected near their nest areas (Kelly et al. 2003; Olson et al. 2004, 2005; Anthony et al. 2006). In addition, Olson et al. (2005) found evidence that occupancy and colonization rates of Spotted Owl territories were negatively associated with detections of Barred Owls. In another territory-specific study, K. Dugger et al. (In press) found evidence that extinction rates of Spotted Owl territories were higher on territories with Barred Owl detections, and this effect was stronger as the amount of habitat decreased. The latter results suggested an additive effect of decreasing habitat and presence of Barred Owls on demographic performance of Spotted Owls.

Taken together, results of our current study and previous studies do not prove a causal effect of Barred Owls on the demography of Northern Spotted Owls. However, the consistency of the negative associations between Spotted Owl demographic rates and presence of Barred Owls in multiple studies lends support to the conclusion that Barred Owls are having a negative effect on spotted owl populations. Of the various factors we investigated to ascertain potential effects on demographic rates of Northern Spotted Owls, the mostly negative associations with the presence of Barred Owls were the strongest and most consistent factor among study areas. The negative associations with Barred Owls were more numerous and stronger in our analysis than those reported by Anthony et al. (2006), and corresponded with the increase in detections of Barred Owls in the last five years on our study areas. The increasing evidence for a Barred Owl effect suggests that recent declines in fecundity, apparent survival, and populations of Spotted Owls on our study areas are at least partly due to interactions with Barred Owls. However, we cannot rule out the potential influence of continued declines in habitat as another factor contributing to population declines (see below).

Habitat

Our investigation of the potential influence of habitat on demographic rates of Northern Spotted Owls was both challenging and problematic for a number of reasons. First, comparable vegetation maps from satellite imagery for the entire range of the subspecies were not available, and it was clear during the workshop that the imagery for California was developed with different criteria and was different from the vegetation map of Washington and Oregon. As a result, we excluded the California study areas in the meta-analysis of demographic rates with the habitat covariate. Second, the available map for Oregon and Washington did not span the entire length of time that the demographic studies were conducted, so we had to estimate the amount of suitable owl habitat that was present on the study areas both prior to and after 1996, when the best map was available. We estimated the amount of habitat that was lost due to harvest and wildfires during the time of the studies with a change detection algorithm (see Methods section). Third, there may have been some small amount of forest that became suitable owl habitat as a result of forest re-growth during our studies, but we could not readily identify these forests to be able to adjust our estimates accordingly. Fourth, the maps that we used characterized forest vegetation at landscape scales and did not characterize the understory structure, which has been shown to be important for Spotted Owls and their primary prey (Carey et al. 1992, Rosenberg and Anthony 1992, Buchanan et al. 1995, LaHaye and Gutiérrez 1999, Lehmkuhl et al. 2006b).

While the amount of suitable habitat on some study areas in Oregon had a positive effect on reproduction, there was little evidence for a consistent effect of habitat on fecundity for all areas in Washington and Oregon from the meta-analysis. The absence of a strong association between the amount of habitat and fecundity was not entirely surprising considering that two previous studies found evidence that "habitat fitness" for Spotted Owls increased in landscape configurations that included a mixture of old forests and edge (Franklin et al. 2000, Olson et al. 2005, but see Dugger et al. 2005). Whether inclusion of a forest edge covariate in our analysis would have made a difference in the outcome is unclear, but inclusion of such a covariate should be considered in future analyses.

In the meta-analysis of survival, apparent survival was positively related to the percent cover of suitable owl habitat within the study area boundaries, but the 95% confidence intervals overlapped zero, indicating that the evidence for an association was weak. The habitat covariate was not included in the analysis of survival rates for individual study areas, which was an oversight during the development of the protocol (see below). Such analyses should be considered in the next major analysis of demographic data from Spotted Owls. In the meta-analysis of λ, apparent survival was related positively to the percent cover of suitable habitat in the CLE, COA, HJA, and TYE study areas, as 95% confidence intervals for the regression coefficients for the habitat covariate barely overlapped zero. More importantly, we found a positive relationship between recruitment and the percent cover of suitable owl habitat within the study areas in the meta-analysis of λ. Recruitment was also highest on federally owned lands where the amount of suitable habitat was highest (Davis and Lint 2005). One possible explanation for the latter result is that more habitat within the study areas provided areas where non-territorial owls could occupy and survive until they were able to recruit into the territorial population.

A number of territory-specific studies of Spotted Owls have reported fairly strong associations between the amount of suitable habitat and demographic rates of Spotted Owls. The fact that we found relatively weak associations between the amount of habitat and demographic rates suggests that our area-specific covariate was too coarse to reveal actual relationships that were acting at the scale of the individual owl territory. Our conclusion should not be used to infer that the amount of old forest (suitable owl habitat) is not important to the demography of the Spotted Owl, because other studies have documented positive associations between demography and the amount of old forest surrounding nest sites of Spotted

Owls. For example, apparent survival was positively related to the amount of old forest surrounding nest sites in territory-specific studies of Spotted Owls in northwestern California (Franklin et al. 2000) and southern Oregon (Dugger et al. 2005). In the territory-specific studies conducted by Franklin et al. (2000) and Olson et al. (2004), large areas of mature and old forest interspersed with openings provided the best habitat for Northern Spotted Owls in northwestern California and the Oregon Coast Ranges. In southern Oregon, Dugger et al. (2005) found that reproductive rates of Spotted Owls were positively related to the proportion of old-growth forest within a 730-m-radius circle around nest sites. In the Sierra Nevada of California, Seamans and Gutiérrez (2007) observed higher colonization and lower extinction rates for California Spotted Owls on territories with more mature conifer forest. In the above studies, analyses were conducted at the scale of owl territories within study areas and with a smaller scale of habitat mapping from aerial photographs; the results of those studies were more definitive than our study, which was at the scale of entire study areas (populations). Also, recent analyses of occupancy dynamics of Northern Spotted Owls in the southern Cascades of Oregon indicated that there was an additive and negative effect of Barred Owls and decreased amounts of habitat on occupancy and colonization, and a positive effect on extinction of nesting territories (Dugger et al. In press). The latter results suggest that it may be necessary to conserve even more old forest habitat than is currently protected, if the objective is to increase the likelihood that Spotted Owls will be able to persist in the face of potential competition with Barred Owls for space, habitat, or prey. Competition theory predicts that more habitat is necessary if two species are to persist when they are in direct competition (Levins and Culver 1971, Horn and MacArthur 1972), an important consideration in the conservation of Northern Spotted Owls. Carrete et al. (2005) recommended an increase in suitable habitat for two potentially competing raptors, the Golden Eagle (*Aquila chrysaetos*) and Bonelli's Eagle (*A. fasciata*) in southern Spain. Last, it is well documented that Northern Spotted Owls select older forests for nesting (Hershey et al. 1998, Swindle et al. 1999), and roosting and foraging (Forsman et al. 1984, Thomas et al. 1990, Bart and Forsman 1992, Herter et al. 2002, Glenn et al. 2004, Forsman et al. 2005) throughout most of their range, so these forests are important to their survival and population persistence. Selection for the oldest available forest is consistent even within managed forests on private lands in northwestern California, where Diller and Thome (1999) and Thome et al. (2000) found that Spotted Owls usually occurred in the oldest available forests. Researchers studying California Spotted Owls have also reported strong associations with older forests for nesting, roosting, and foraging (LaHaye et al. 1997, LaHaye and Gutiérrez 1999). Consequently, despite the weak associations between demographic rates and habitat in our analysis, it would be incorrect to conclude from our results that old forest vegetation is not important to Northern Spotted Owls.

Potential Biases in Estimates of Demographic Parameters

Numerous authors have discussed possible biases associated with estimates of fecundity or survival from long-term demography studies of Northern Spotted Owls (Raphael et al. 1996, Van Deusen et al. 1998, Manly et al. 1999, Boyce et al. 2005, Loehle et al. 2005). In some cases, these critiques resulted in rigorous rebuttals (Franklin et al. 2006). Because parameter bias could have important effects on development of effective conservation and management strategies, we discuss potential sources of bias in our estimates of fecundity and apparent survival below.

Fecundity

Estimates of fecundity can be biased if territorial females are present on the study area but are not detected in any given year. If the undetected territorial females nest successfully, fecundity could be underestimated. If undetected birds do not nest, or nest and fail, fecundity is overestimated. These two sources of bias may cancel each other out because both scenarios can happen in the same year, but we suspect that the positive bias is slightly more prevalent than the negative bias because non-nesting females and females that nest and fail tend to be more difficult to detect than nesting females. However, re-sighting probabilities of owls in our study were typically >0.75, so the frequency of missing data on reproduction in most years was small. Even if there was a bias in our estimates of fecundity, this bias should have been consistent among years and study areas. Therefore, any small positive or negative bias in our estimates of fecundity should not have confounded any analyses in which we examined the effects of time, age, study area, geographic region, latitude, Barred Owls, climate, or habitat on fecundity.

Apparent Survival

Temporary or permanent emigration, heterogeneity in recapture probabilities, and band loss are the primary factors that may create biases or lack of precision in estimates of apparent survival from analysis of capture-recapture data. Two of these potential biases were investigated by Manly et al. (1999), who used computer simulations with data from Northern Spotted Owls in the eastern Cascades of Washington. Variation in recapture probabilities for nesting and non-nesting owls, temporary emigration, and dependent captures of both members of a breeding pair had little effect on estimates of apparent survival, although temporary emigration can cause lower apparent survival estimates for the last few years of a study. In addition, the combination of high recapture and survival probabilities in our study likely reduced any bias associated with heterogeneity of recapture probabilities (Pollock et al. 1990, Hwang and Chao 1995). As for permanent emigration, Forsman et al. (2002) studied dispersal of territorial Spotted Owls on a subset of our study areas and estimated that only about 6.6% of resident owls dispersed from their territories each year, and most of those individuals were relocated on adjacent territories within the boundaries of our survey areas. Nevertheless, there were undoubtedly some individuals that dispersed and went undetected at the edges of our study areas, and to this extent, our estimates of apparent survival may have been biased low as an index of true survival.

Annual Rate of Population Change

Our use of the reparameterized Jolly–Seber method (RJS; Pradel 1996) to estimate the annual finite rate of population change (λ_{RJS}) was a departure from earlier analyses of Spotted Owls, in which researchers used Leslie projection matrices (PM; Caswell 2001) to estimate λ_{PM} (Anderson and Burnham 1992; LaHaye et al. 1992; Burnham et al. 1996; Seamans et al. 1999, 2002; Blakesley et al. 2001). Estimates of λ_{PM} were thought to be biased low in these studies because of permanent emigration of juveniles from study areas (Raphael et al. 1996, Boyce et al. 2005). In contrast, the Pradel (1996) method of estimating λ_{RJS} uses survival estimates from territorial owls only, so it is subject to less bias than the Leslie projection matrix models (λ_{PM}) for use in capture–recapture studies of Spotted Owls (Hines and Nichols 2002, Franklin et al. 2004, Anthony et al. 2006). Estimation of λ_{RJS} assumes that study area boundaries are fixed throughout the study and that surveys of territorial owls are conducted on the same areas with similar effort each year. In other words, new owls are not recruited into, or previously sampled owls are not lost from the sample because of changes in survey area or methods. We used established protocols for surveying and identifying marked Spotted Owls (Franklin et al. 1996, Lint et al. 1999) to ensure that study areas were surveyed with approximately equal effort each year. In addition, the study areas had fixed geographical boundaries for inclusion of data from individual owls, and any expansion or contraction of study areas (Appendix A) was corrected for by modeling in program MARK (see Methods section). Thus, the primary assumptions for estimating λ_{RJS} from capture–recapture data from Spotted Owls were met. The Pradel method for estimating λ accounts for movement into and out of the study area and is less subject to bias caused by permanent emigration of marked owls, which is why the Pradel models may improve on the Leslie matrix model for estimating the annual rate of population change for Spotted Owls. If movements in and out of the study area are truly asymmetric, then the Pradel method should produce a high or low λ to reflect this (it is not a bias, but an accurate reflection of reality).

Last, band loss in our studies was near zero. Franklin et al. (1996) examined records from over 6,000 Northern Spotted Owls double-banded with a colored band and a numbered metal band, and found only two cases where colored bands were lost and no cases where the numbered metal band was lost. Based on the above assessments, we believe that any biases in our estimates of λ were small.

Estimating Goodness-of-Fit and Overdispersion

There are potential biases in the estimation of overdispersion (c) when the estimate is based on the global goodness-of-fit statistic from program RELEASE. The overall goodness-of-fit chi-square (χ^2) is comprised of three additive components: identifiable outliers, structural lack-of-fit, and lack of independence in capture histories (overdispersion). These three potential components of lack-of-fit have differing effects on bias and precision of parameter estimates.

Outliers and structural lack-of-fit can result in biased estimators of φ and λ_{RJS}, but do not result in inflated variances of these estimators. Moreover, these components of lack-of-fit do not result in, and hence are not part of, overdispersion. In contrast, overdispersion does not cause bias in the estimates of φ, p, or λ_{RJS}, but it does result in estimated sampling variances that are too small. Thus, one needs an estimate of overdispersion (c) to adjust (inflate) the estimated theoretical sampling variances and adjust model selection to $QAIC_c$. Estimates of overdispersion and the variance inflation factor from program RELEASE in previous analyses of capture–recapture data from Spotted Owls were biased high (e.g., Franklin et al. 2004, Anthony et al. 2006). As a result, sampling standard errors from those analyses were conservative in assessing the status of populations from the estimation of λ_{RJS} and corresponding 95% confidence intervals. We corrected for this overestimation of overdispersion in our analysis by using the median-$\hat{c}$ routine in program MARK to estimate overdispersion in addition to using program RELEASE to estimate overall goodness-of-fit. Estimates from the median-$\hat{c}$ routine of program MARK in our analyses ranged from $\hat{c} = 0.97$ to 1.17 compared to the range of estimates for overall goodness-of-fit (χ^2/df) from program RELEASE ($\hat{c} = 0.86$ to 3.02). Our results indicated that there was little overdispersion (lack of independence) in our capture–recapture data sets, and any overall lack-of-fit was due to outliers caused by temporary emigration and perhaps some structural lack-of-fit. Consequently, inflation of our estimates of SE(φ) and SE(λ) was minimal, and the true precision of our estimates was higher than those in previous analyses given equal sample sizes (Franklin et al. 2004, Anthony et al. 2006). Use of the median-$\hat{c}$ routine in program MARK to estimate overdispersion in our analyses was an important improvement over previous analyses. Estimates of goodness-of-fit from program RELEASE also indicated that our data fit the Cormack–Jolly–Seber open population model well, so we did not expect unacceptable biases due to lack-of-fit of the data to the model.

The covariates that we used to assess the effects of Barred Owls, habitat, weather, and climate on demographic parameters of Spotted Owls were all study-area-specific variables, and in some cases they were not measured with the same degree of accuracy on all study areas. Use of area-specific covariates could explain why we sometimes found inconsistent or counterintuitive relationships between the covariates and demographic performance of Spotted Owls. Variable effort was a problem with the Barred Owl covariate because the amount of nocturnal survey varied among years and study areas, depending on whether it was a good nesting year for Spotted Owls. Surveyors sometimes did less night calling for Spotted Owls in good nesting years because many pairs of nesting Spotted Owls were easy to find by simply walking into their traditional nest areas and calling during the day. Variation in the amount of nocturnal calling surveys probably introduced methodological variation into the Barred Owl covariate, and lack of a species-specific survey for Barred Owls undoubtedly caused an underestimate of the number of Barred Owls present in all years. A recent study in which observers conducted a species-specific survey of Barred Owls in a Spotted Owl study area resulted in a ≈40% increase in the estimated number of territorial Barred Owls (Wiens et at. In press). An obvious solution to our problems with the Barred Owl covariate is to do a better job of measuring and standardizing all covariates in the future. For Barred Owls, improved procedures would require initiating species-specific surveys in which Barred Owl surveys are conducted independently of Spotted Owl surveys.

SUMMARY, CONCLUSIONS, AND RECOMMENDATIONS

The primary objectives of our investigation were to determine if survival rates and populations of Northern Spotted Owls were still declining, assess the influence of biological and meteorological covariates on demographic rates at the population scale, and provide estimates of recruitment rates. Our analyses indicated that fecundity and populations of Northern Spotted Owls have continued to decline in most parts of the range of the subspecies. Estimates of the annual rate of population change were <1.0 for all 11 study areas. Our finding that apparent survival rates were declining on 10 of the 11 study areas was of special concern because Spotted Owl populations are most sensitive to changes in adult survival (Noon and Biles 1990). We had some success in relating demographic rates to reproduction, weather, habitat, or Barred Owls on some study areas. In the analysis of fecundity, however, the amount of temporal variation explained by any one of these covariates was small due to the large temporal variation in fecundity. Temporal variation was not as problematic in the analyses of apparent survival and λ, because these parameters had much less temporal variation than fecundity. For the first time, we provided estimates of recruitment rates into the territorial population, which indicated that low recruitment in conjunction with low survival resulted in population declines. We also found a negative relationship between recruitment rates and the presence of Barred Owls and a positive relationship between recruitment and the amount of suitable owl habitat in the study areas. Recruitment was higher on federal lands where the amount of suitable owl habitat was generally highest. We concluded that there were several factors that contributed to declines in demographic rates of Northern Spotted Owls in any given year on any particular study area, and that these factors were spatially and temporally variable. Of these factors, the presence of Barred Owls appeared to be the strongest and most consistent factor. However, the reproduction covariate, weather/climate covariates, and percent cover of suitable habitat were also associated with demographic parameters on some study areas. Declining rates of apparent survival were the most likely proximate cause of population declines, but the ultimate factor(s) responsible for the declines in survival remained unclear and warrant further investigation. In addition, recruitment of new owls into the populations was often low on some study areas in some years and contributed to population declines. Future analyses should investigate the factors that affect survival of juvenile owls and their recruitment into the territorial population. All of these demographic parameters and the covariates that may affect them interact in a complex way in influencing annual rates of population change of Northern Spotted Owls. Our overall assessment is that reproduction and recruitment have not been sufficient to balance losses due to mortality and emigration, so many of the populations on our study areas have declined over the last two decades. The continuing decline of the Northern Spotted Owl on federal lands could be at least partly due to lag effects from the extensive harvest of old forest that occurred prior to 1990. However, the lag-effect hypothesis was not supported by ongoing declines among owl populations in national parks, where there was no habitat loss due to harvest at any time in the years before or during our study. Thus, we do not think the lag-effect hypothesis has much explanatory power for the continuing declines of Northern Spotted Owls.

Although the pattern was not consistent in all areas, there was strong evidence for a negative effect of Barred Owls on fecundity or survival of Spotted Owls in many of our study areas. This result was even more significant given that the actual effect of Barred Owls on fecundity of Spotted Owls was underestimated by our data. While our observational results do not demonstrate cause–effect relationships, they provide support for the hypothesis that the invasion of the range of the Spotted Owl by Barred Owls is at least partly the cause for the continued decline of Spotted Owls on federal lands. Our results also suggest that Barred Owl encroachment into western forests may make it difficult to insure the continued persistence of Northern Spotted Owls (see also Olson et al. 2004). The fact that Barred Owls are increasing and becoming an escalating threat to the persistence of Spotted Owls does not diminish the importance of habitat conservation for Spotted Owls and their prey. In fact, the existence of a new and potential competitor like the Barred Owl makes the protection of habitat even more important, since any loss of habitat will likely increase competitive pressure and result in further reductions in Spotted Owl populations (Horn and MacArthur 1972, Olson et al. 2004, Carrete et al. 2005). Manipulative experiments could provide future insights, and some authorities have suggested that removal experiments should be conducted on one or more study areas to better document the potential effects of competition between Barred and Spotted Owls (Courtney et al. 2004, Buchanan et al. 2007, Johnson et al. 2008). If conducted, manipulative experiments will almost certainly shed new light on relationships between Barred Owls and Spotted Owls.

The fact that the amount of spatial and process variation explained by all of the covariates in our analysis was small should not be interpreted to mean that habitat and climate are not important for Spotted Owls. To the contrary, several lines of evidence in our study and in studies conducted by others (Franklin et al. 2000, Olson et al. 2004, Dugger et al. 2005) show that habitat does influence demographic rates of Northern Spotted Owls. However, the poor performance of fixed effects models, which model temporal variation solely as a function of temporal covariates, should be discouraged in future analyses and replaced with improved random effects models that incorporate both environmental covariate(s) and temporal variation. In addition, we suggest that researchers need to consider the use of other covariates in future analyses. For example, there is considerable evidence that vital rates and population size of northern owls are strongly influenced by prey abundance (Korpimäki 1992, Rohner 1996, Hakkarainen et al. 1997). Unfortunately, we did not have long-term data on annual variation in prey abundance on any of our study areas, so we could not address the possible influence of trophic dynamics on owl demographic rates. We suggest, therefore, that studies of annual variation in numbers of small mammals be implemented on one or more of the demographic study areas in the future, so that the possible influence of prey abundance on owl demographic rates can be evaluated.

So, what can we glean from our results that can be translated into management recommendations? Our results and those of others referenced above consistently identify loss of habitat and Barred Owls as important stressors on populations of Northern Spotted Owls. In view of the continued decline of Spotted Owls in most study areas, it would be wise to preserve as much high quality habitat in late-successional forests for Spotted Owls as possible, distributed over as large an area as possible. This recommendation is comparable to one of the recovery goals in the final recovery plan for the Northern Spotted Owl (USDI Fish and Wildlife Service 2008), but we believe that a more inclusive definition of high-quality habitat is needed than the rather vague definition provided in the 2008 recovery plan. Much of the habitat occupied by Northern Spotted Owls and their prey does not fit the classical definition of "old-growth" as defined by Franklin and Spies (1991), and a narrow definition of habitat based on the Franklin and Spies criteria would exclude many areas currently occupied by Northern Spotted Owls. Second, we believe more information on competitive interactions between Spotted Owls and Barred Owls is needed. A recent study by D. Wiens at Oregon State University (pers. comm.) will provide some of this information for western Oregon, but similar information is needed for other parts of the range of the Spotted Owl. In addition, we support experimental removal of Barred Owls on at least one study area as a research project to test the hypothesis that competition is occurring between the two species. In theory, a Barred Owl removal experiment should result in competitive release of Spotted Owls, with subsequent increases in vital rates and density. Experimental removal of Barred Owls as part of a research program would also address one of the main recovery goals in the final recovery plan for Northern Spotted Owls (USDI Fish and Wildlife Service 2008). Finally, it is important that monitoring of Northern Spotted Owls be continued on study areas throughout the range of the subspecies, so that population status can be assessed periodically for the purposes of recovery planning and monitoring the effectiveness of the Northwest Forest Plan.

Appendices

APPENDIX A

Study areas included in the January 2009 analysis of demographic trends of Northern Spotted Owls.

Study area	Start year[a]	λ Start year	Expansion year[b]	Landowner[c]	Ecoregion	Latitude (°N)
Washington						
CLE	1989	1992	none	Mixed	Washington Mixed-conifer	46.996
RAI	1992	1993	1998	Mixed	Washington Douglas-fir	47.195
OLY	1990	1990	1994	Federal	Washington Douglas-fir	47.800
Oregon						
COA	1990	1992	none	Mixed	Oregon Coastal Douglas-fir	44.381
HJA	1988	1990	2000	Federal	Oregon Cascades Douglas-fir	44.213
TYE	1990	1990	none	Mixed	Oregon Coastal Douglas-fir	43.468
KLA	1990	1990	1998	Mixed	Oregon/California Mixed-conifer	42.736
CAS	1991	1992	2001	Federal	Oregon Cascades Douglas-fir	42.695
California						
NWC	1985	1988	none	Federal	Oregon/California Mixed-conifer	40.848
HUP	1992	1992	none	Tribal	Oregon/California Mixed-conifer	41.051
GDR	1990	1990	1998	Private	California Coast	41.122

[a] The Start year column indicates the first year in which we calculated estimates of fecundity and survival. The λ Start year column indicates the first year in which we calculated estimates of λ.

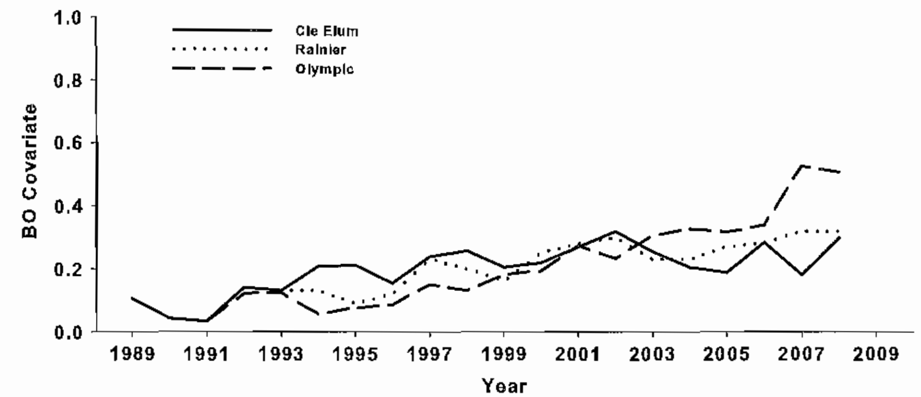
[b] Indicates year that study area was expanded, if any.

[c] Mixed = a mixture of Federal and private or state lands

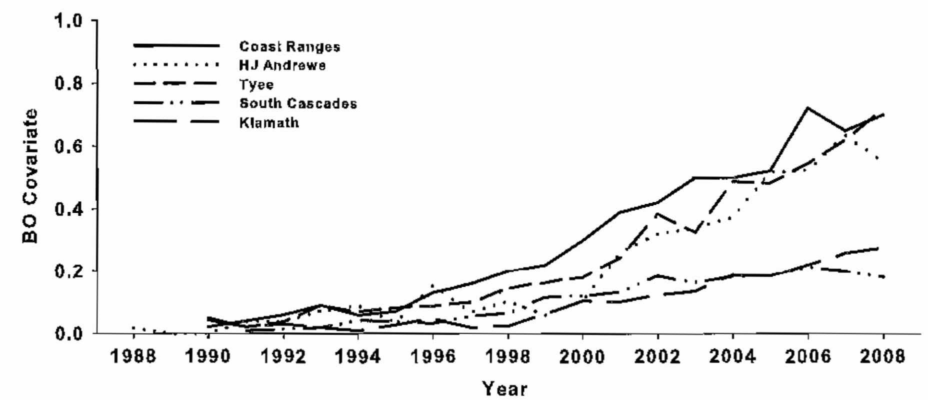
APPENDIX B

Annual proportion of Spotted Owl territories with Barred Owls detections (BO covariate) on study areas in Washington, Oregon, and California.

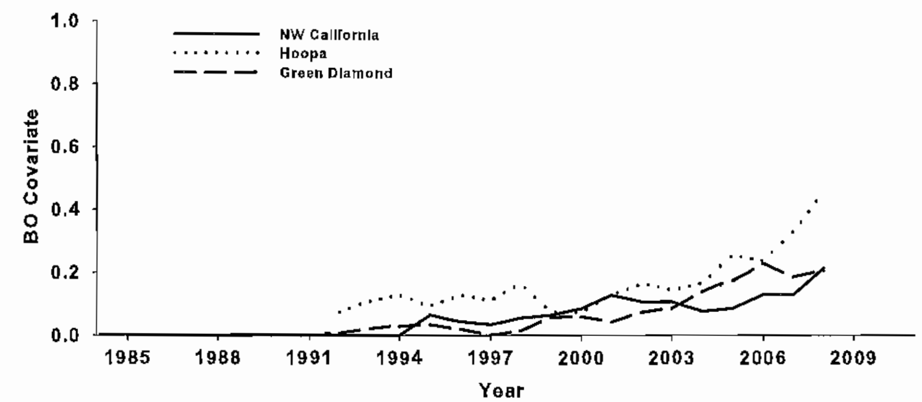
Washington



Oregon



California



APPENDIX C

Habitat covariates used in analyses of Northern Spotted Owl vital rates and population growth rates.

Graph A illustrates the percent cover of suitable Spotted Owl habitat within 2.4 km of the annual activity centers of Spotted Owls used in meta-analyses of fecundity and survival (covariate HAB1). Graph B illustrates the percent cover of suitable Spotted Owl habitat within 2.4 km of the annual activity centers of Spotted Owls that were included in the meta-analysis of λ (HAB2). Graph C illustrates the percent cover of suitable Spotted Owl habitat within a 23-km radius of the annual activity centers of Spotted Owls that were included in the meta-analysis of λ, minus the area in HAB2 (HAB3). Abrupt changes in some lines represent one-time study area expansions or reductions included in the meta-analysis of λ.

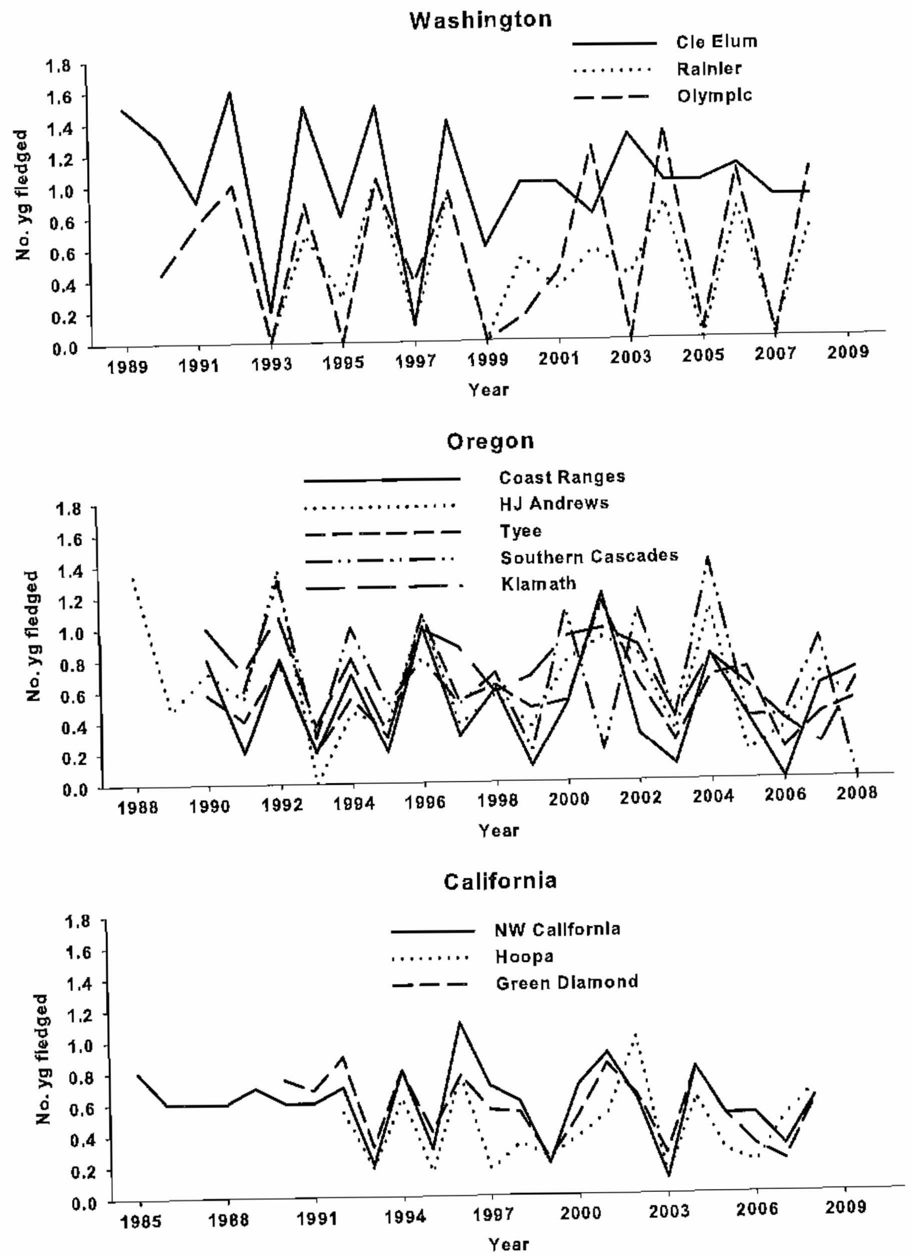
APPENDIX D

Reproductive covariate (number of young fledged/pair/yr) used to model survival, and recapture probabilities of Northern Spotted Owls on 11 study areas in Washington, Oregon, and California.



APPENDIX E

A priori models used in analysis of recapture probabilities (p) of Northern Spotted Owls on 11 demographic study areas in Washington, Oregon, and California.

Model[a]	Description of *p* structure
p(A + s*t)	Additive age, sex, and time effects with interactions between sex and time
p(.)	Constant model (no effects)
p(s)	Sex effect
p(R)	Effect of annual reproduction in year t on *p* in year *t*
p(R + s)	Additive reproduction and sex effects
p(t)	Annual time effect
p(s + t)	Additive sex and time effects
p(T)	Linear time trend effect
p(s + T)	Additive sex and linear time trend effects
p(BO)	Barred Owl effect
p(s + BO)	Additive sex and Barred Owl effects
p(R + s + BO)	Additive sex, Barred Owl, and reproduction effects
p(choice)	Biologist's choice

[a] Model notation indicates structure for effects of age (A), sex (s), reproduction (R), time (t), linear time (T), percent of Spotted Owl territories with Barred Owl detections (BO), and biologist's choice (choice). Biologist's choice models included study-area–specific effects such as changes in methodology or subdivisions of study areas based on forest type or ease of access. Additive and interactive effects are indicated by a + sign or asterisk, respectively.

APPENDIX F

A priori models used for analysis of apparent survival (φ) of Northern Spotted Owls on 11 demographic study areas in Washington, Oregon, and California.

Analyses used the best *p* structure from the initial analysis for each area.

Model	Description of φ structure
φ(.)	Constant survival, no age, sex, or time effects
φ[(S1 = S2 = A) + s]	Sex effect only
φ(S1,S2 = A)	Age effect (S2 = A, S1 different)
φ[(S1,S2 = A) + s]	Age effect (S2 = A, S1 different), additive sex effect
φ(S1 = S2, A)	Age effect (S1 = S2, A different)
φ[(S1 = S2, A) + s]	Age effect (S1 = S2, A different), additive sex effect
φ(S1, S2, A)	Age effect (all classes different)
φ[(S1, S2, A) + s]	Age effect (all classes different), additive sex effect
φ[(models 1–8) + t]	Models from 1–8 above with additive time effect (t)
φ[(models 1–8) + T]	Models from 1–8 above with additive linear time trend (T)
φ[(models 1–8) + TT]	Models from 1–8 above with additive quadratic time trend (TT)
φ[(models 1–8) + R]	Models from 1–8 above with additive effect of reproduction in year t on survival in year *t* + 1 (R)
φ[(models 1–8) + BO]	Models from 1–8 above with Barred Owl effect (BO)
φ[(models 1–8) + change-point]	Models from 1–8 above with change-point at 2002 (CP)[a]
φ[(models 1–8) + cubic spline]	Models from 1–8 above with cubic spline (spline)[b]

[a] Change-point in 2004 using best model structure of (.), (T), or (TT).

[b] Cubic spline with knot midway between start year and 2002 and second knot at 2002.

APPENDIX G

A priori models used for meta-analysis of apparent survival (φ) and recapture probabilities (p) of adult Northern Spotted Owls on 11 demographic study areas in Washington, Oregon, and California.

Area effects (g) refer to study areas.

Model	Description of Model Structure
Global model	
1. φ(g*t*s) *p*(g*t*s)	Area, time, and sex with all interactions (global model)
Recapture	
2. φ(g*t + s) *p*(g + t)	φ(Area, time, and sex with area and time interactions) *p*(additive area and time)
3. φ(g*t + s) *p*(R)[a]	φ(Area, time, and sex with area and time interactions) *p*(reproduction)
4. φ(g*t + s) *p*(g + s + t)	φ(Area, time, and sex with area and time interactions) *p*(additive area, time, and sex)
5. φ(g*t + s) *p*(R + s)	φ(Area, time, and sex with area and time interactions) *p*(additive reproduction and sex)
6. φ(g*t + s) *p*[(g + t)*s]	φ(Area, time, and sex with area and time interactions) *p*(additive area and time with different sex effects)
7. φ(g*t + s) *p*(R*s)	φ(Area, time, and sex with area and time interactions) *p*(interactive reproduction and sex)
8. φ(g*t + s) *p*(BO)	φ(Area, time, and sex with area and time interactions) *p*(BO)
9. φ(g*t + s) *p*(BO + g)	φ(Area, time, and sex with area and time interactions) *p*(BO + area)
Survival	
10. φ(g + s) *p*(best)	φ(additive area and sex) *p*(best structure from 2–9 above)

29. φ(CP) *p*(best)	φ(change-point in 2004 using best of (.), (t) or (T) models) *p*(best structure from 2–9 above)
30. φ(spline) *p*(best)	φ(cubic spline with knot midway between start year and 2002 and second knot at 2002) *p*(best structure from 2–9 above)
Study area surrogates	
31. φ(OWN) *p*(best)	Replace area effect in lowest $QAIC_c$ model from 9–29 with ownership effect
32. φ(ECO) *p*(best)	Replace area effect in lowest $QAIC_c$ model from 9–29 with ecoregion effect
33. φ(OWN*ECO) *p*(best)	Replace area effect in lowest $QAIC_c$ model from 9–29 with ownership and ecological region effects with interactions
34. φ(LAT) *p*(best)	Replace area effect in lowest $QAIC_c$ model from 9–29 with latitude effect
Habitat	
35. φ(s + g + [WA = OR + CA] *HAB1) *p*(best)	Sex included only if important in 1–34. Additive effects of area and habitat in WA and OR with minimum $QAIC_c$ model replacing habitat for CA. *p*(best structure from 2–9 above
36. φ(s + g HAB1) *p*(best)	Sex included only if important in 1–34. Interaction between area and HAB1. *p*(best structure from 2–9 above)
Climate	
37. φ(s + g + SOI + PDO) *p*(best)	φ(additive sex, area, Southern Oscillation Index, and Pacific Decadal Oscillation. *p*(best structure from 2–9 above)
38. φ[s + (g*SOI) + (g*PDO)] *p*(best)	φ(interaction between area and Southern Oscillation Index and area and Pacific Decadal Oscillation, with additive sex effects) *p*(best structure from 2–9 above)
39. φ(s + g + ENP) *p*(best)	φ(additive sex, area, and precipitation during early nesting season) *p*(best structure from 2–9 above)
40. φ(s + g*ENP) *p*(best)	φ(interaction between area and precipitation during early nesting season with additive sex effect) *p*(best structure from 2–9 above)
41. φ(s + g + ENT) *p*(best)	φ(additive sex, area, and temperature during early nesting season) *p*(best structure from 2–9 above)
42. φ(s + g*ENT) *p*(best)	φ(interaction between area and temperature during early nesting season with additive sex effect) *p*(best structure from 2–9 above)
Habitat-climate interactions	
43. φ(best babitat + best climate) *p*(best structure from 2–9 above)	φ(combine best habitat model from 35–36 with best climate model form 37–42 in additive model) *p*(best structure from 2–9 above)
44. φ(best habitat*best climate) *p*(best structure from 2–9 above)	φ(combine best habitat model from 35–36 with best climate model form 37–42 in interactive model) *p*(best structure from 2–9 above)

APPENDIX G (*continued*)

APPENDIX G (CONTINUED)

[a] When reproduction (R) appears as a covariate on recapture, it refers to the effect of reproduction in year *t* on recapture in year *t*. When R appears as a covariate on survival, it refers to the effect of reproduction in year *t* on survival in year *t* + 1.

APPENDIX H

Models used in the meta-analysis of λ of Northern Spotted Owls in Washington, Oregon, and California.

Model form was the apparent survival and recruitment parameterization. Model notation for random effects (RE) models includes the general model on which the random effects model is based. The last six models at the bottom of the list were developed *a posteriori* after looking at the ranking of the *a priori* models.

Model structure[a]

5-YEAR REVIEW

Short Form Summary

Species Reviewed: Northern Spotted Owl (*Strix occidentalis caurina)*

Current Classification: Threatened

FR Notice announcing initiation of this review:
The U.S. Fish and Wildlife Service published in the *Federal Register* on November 24, 2010, a Notice initiating the 5-year status review for this species (75 FR 71726), and reopened the public comment period for this 5-year review on April 20, 2011 (76 FR 22139).

Lead Region/Field Office:
Pacific Region
Sarah Hall, Chief, Division of Recovery – (503) 231-6868

Name of Reviewer(s):
Betsy Glenn, Oregon Fish and Wildlife Office, Northern Spotted Owl Specialist - (503) 231-6970.
Rollie White, Oregon Fish and Wildlife Office, Acting Assistant Project Leader – (503) 231-6179.

Methodology used to complete this 5-year review:
Review of science assessing the current status of the northern spotted owl (NSO) was conducted in conjunction with development of the 2011 Revised Recovery Plan for the Northern Spotted Owl. Development of the Revised Recovery Plan involved over 20 Fish and Wildlife Office staff reviewing NSO science, consultation with spotted owl experts, input from working groups, scientific peer-review, and 2 public comment periods. The Revised Recovery Plan addresses current status, population trends, threats (including the five listing factors), recovery objectives, recovery criteria, and recovery actions needed for this species.

Application of the 1996 Distinct Population Segment (DPS) Policy:
Not applicable. Not listed as a DPS.

Review Analysis:
Please refer to the 2011 Revised Recovery Plan for the northern spotted owl for a complete review of the species status (including biology, population trends, and habitat), threats, and recovery actions. The following is a summary of findings and recommendations from the 2011 Revised Recovery Plan.

Reasons for Listing and Assessment of Threats

The Endangered Species Act identifies five listing factors for determining whether a species merits Federal listing as threatened or endangered:

*This short form is to be used ONLY when there is no new information, or when the 5-year review is being done concurrent with another range-wide status review (such as a 12-month finding on a delisting petition) that completely addresses all the questions outlined in the standard 5-year review template. Attach a copy of the final 12-month finding or other status review to this form.

A. The present or threatened destruction, modification, or curtailment of its habitat or range;
B. Overutilization for commercial, recreational, scientific, or educational purposes;
C. Disease or predation;
D. The inadequacy of existing regulatory mechanisms;
E. Other natural or manmade factors affecting its continued existence.

The northern spotted owl was listed as threatened throughout its range "due to loss and adverse modification of spotted owl habitat as a result of timber harvesting and exacerbated by catastrophic events such as fire, volcanic eruption, and wind storms" (USFWS 1990). More specifically, threats to the spotted owl included low populations, declining populations, limited habitat, declining habitat, inadequate distribution of habitat or populations, isolation of populations within physiographic provinces, predation and competition, lack of coordinated conservation measures, inadequacy of regulatory mechanisms and vulnerability to natural disturbance (USFWS 1992). These threats were characterized for each province as severe, moderate, low or unknown (USFWS 1992). The range of the spotted owl is divided into 12 physiographic provinces from Canada to northern California and from the Pacific Coast to the eastern Cascades. Declining habitat was recognized as a severe or moderate threat to the spotted owl throughout its range, isolation of populations was identified as a severe or moderate threat in 11 provinces, and a decline in population was a severe or moderate threat in 10 provinces. Together, these three factors represented the greatest concerns about range-wide conservation of the spotted owl. Limited habitat was considered a severe or moderate threat in nine provinces, and low populations was a severe or moderate concern in eight provinces, suggesting that these factors were also a concern throughout the majority of the spotted owl's range. Vulnerability to natural disturbances was rated as low in five provinces.

The Service conducted a 5-year review of the spotted owl in 2004 (USFWS 2004), based in part on the content of an independent scientific evaluation of the status of the spotted owl (Courtney *et al.* 2004) performed under contract with the Service. For that evaluation, an assessment was conducted of how the threats described in 1990 might have changed by 2004. Some of the key ideas relative to threats identified in 2004 were: (1) "Although we are certain that current harvest effects are reduced, and that past harvest is also probably having a reduced effect now as compared to 1990, we are still unable to fully evaluate the current levels of threat posed by harvest because of the potential for lag effects" (Courtney and Gutiérrez 2004:11-7); (2) "Currently the primary source of habitat loss is catastrophic wildfire, although the total amount of habitat affected by wildfires has been small" (Courtney and Gutiérrez 2004:11-8); and (3) "We are convinced that Barred Owls are having a negative impact on Spotted Owls at least in some areas" (Gutiérrez *et al.* 2004:7-43) and "there are no grounds for optimistic views suggesting that Barred Owl impacts on Northern Spotted Owls have been already fully realized" (Gutiérrez *et al.* 2004:7-38).

On June 1, 2006, the Service convened a meeting of seven experts to help identify the most current threats facing the species. Six of the seven were experts on the biology of the spotted owl, and a seventh was an expert on fire ecology. The workshop was conducted as a modified Delphi expert panel in which the seven experts scored the severity of threat categories. The baseline assumption of this meeting was that existing habitat conservation strategies (*e.g.*, the NWFP) would be in place. With that assumption, the experts identified and ranked threats to the spotted owl. The 2007 Recovery Team then had an opportunity to interact with them to discuss their individual rankings and thoughts on spotted owl threats. The experts re-ranked the threats if they felt this was relevant given the substance of the discussion.

These experts identified past habitat loss, current habitat loss, and competition from barred owls as the most pressing threats to the spotted owl, even though timber harvest recently has been greatly reduced on Federal lands. They noted that evidence of these three threats is presented in the scientific literature. The range of threat scores made by the individual experts was narrowest for barred owl competition and slightly greater for habitat threats, indicating that there was more agreement about the threat from barred owls. The experts identified disease and the effect of climate change on vegetation as potential and more uncertain future threats.

The experts also ranked the threats by importance in each province. Among the 12 physiographic provinces, the more fire-prone provinces (Eastern Washington Cascades and Eastern Oregon Cascades, California Cascades, Oregon and California Klamath) scored high on threats from ongoing habitat loss as a result of wildfire and the effects of fire exclusion on vegetation change. West-side provinces (Western Washington Cascades and Western Oregon Cascades, Western Washington Lowlands, Olympic Peninsula, and Oregon Coast Range) generally scored high on threats from the negative effects of habitat fragmentation and ongoing habitat loss as a result of timber harvest. The province with the fewest number of threats was Western Oregon Cascades, and the provinces with the greatest number of threats were the Oregon Klamath and the Willamette Valley.
(end excerpt)

Between 2006 and 2011, additional scientific research has indicated that northern spotted owl populations have continued to decline at a rate of 2.7% per year, with declines being associated with both habitat loss and barred owl presence (Forsman et al. 2011). The northern spotted owl is doing poorer than at the time of the last 5-year review, and observed population declines indicate an increased possibility for this species to become endangered in the future. At this time, we do not know what the outcome of barred owl-spotted owl competition will be. Barred owls generally have a greater negative impact on spotted owls in northern areas; however, the relationship between the two species is highly variable across range of the northern spotted owl. While populations are declining, spotted owls are still present across the majority of the species range.

Given the declining population trends, habitat loss, and threats from barred owls, the northern spotted owl meets the definition of a threatened species. The term "threatened species" means any species which is likely to become an endangered species within the foreseeable future throughout all or a significant portion of its range. The term "endangered species" means any species which is in danger of extinction throughout all or a significant portion of its range.

Recommendations for Future Actions:
The 2011 Revised Recovery Plan identifies 33 Recovery Actions that have been developed to meet Recovery Objectives and Criteria. The recovery objectives of the 2011 Revised Recovery Plan for the northern spotted owl include the following:

1. Spotted owl populations are sufficiently large and distributed such that the species no longer requires listing under the ESA;
2. Adequate habitat is available for spotted owls and will continue to exist to allow the species to survive without the protection of the ESA; and
3. The effects of threats have been reduced or eliminated such that spotted owl populations are stable or increasing and spotted owls are unlikely to become threatened again in the foreseeable future.

Recovery Criteria include the following:

Recovery Criterion 1 – Stable Population Trend: The overall population trend of spotted owls throughout the range is stable or increasing over 10 years, as measured by a statistically reliable monitoring effort.

Recovery Criterion 2 – Adequate Population Distribution: Spotted owl subpopulations within each province (*i.e.*, recovery unit) (excluding the Willamette Valley Province) achieve viability, as informed by the HexSim population model or some other appropriate quantitative measure.

Recovery Criterion 3 – Continued Maintenance and Recruitment of Spotted Owl Habitat: The future range-wide trend in spotted owl nesting/roosting and foraging habitat is stable or increasing throughout the species range, from the date of Revised Recovery Plan approval, as measured by effectiveness monitoring efforts or other reliable habitat monitoring programs.

Recovery Criterion 4 – Post-delisting Monitoring: To monitor the continued stability of the recovered spotted owl, a post-delisting monitoring plan has been developed and is ready for implementation within the States of Washington, Oregon, and California, as required in section 4(g)(1) of the ESA.

Recovery actions developed to meet these objectives and criteria include increased protection of spotted owl sites and habitat, encouraging forest management practices that will develop future spotted owl habitat, examination of effectiveness of removing barred owls from areas to enhance spotted owl recovery, and continued demographic monitoring of spotted owl populations to assess effectiveness of recovery actions.

Abstract. A controversy exists in the Pacific Northwest of the United States between logging of old-growth coniferous forests and conservation of Northern Spotted Owl (*Strix occidentalis caurina*) populations. This species has a strong association with old-growth forests that also have economic value as timber. Research questions relevant to conservation of this species include how temporal trends in Northern Spotted Owl populations are influenced and how spatial configuration of old-growth forests affects these populations. To address these questions, we studied a population of marked Northern Spotted Owls on 95 territories in northwestern California from 1985 through 1994. We examined the magnitude of temporal and spatial variation in life history traits (survival, reproductive output, and recruitment), the effects of climate and landscape characteristics on temporal and spatial variation in these traits, respectively, and how this variation affected aspects of population dynamics. We used a components-of-variation analysis to partition sampling from process variation, and a model selection approach to estimate life history traits using capture–recapture and random-effects models. Climate explained most of the temporal variation in life history traits. Annual survival varied the least over time, whereas recruitment rate varied the most, suggesting a ''bet-hedging'' life history strategy for the owl. A forecast of annual rates of population change (λ), estimated from life history traits, suggested that Northern Spotted Owl populations may change solely due to climate influences, even with unchanging habitat conditions. In terms of spatial variation, annual survival on territories was positively associated both with amounts of interior old-growth forest and with length of edge between those forests and other vegetation types. Reproductive output was negatively associated with interior forest, but positively associated with edge between mature and old-growth conifer forest and other vegetation types. A gradient existed in territory-specific estimates of fitness derived from these life history estimates. This gradient suggested that a mosaic of older forest interspersed with other vegetation types promoted high fitness in Northern Spotted Owls. Habitat quality, as defined by fitness, appeared to buffer variation in annual survival but did not buffer reproductive output. We postulated that the magnitude of λ was determined by habitat quality, whereas variation of λ was influenced by recruitment and reproductive output. As habitat quality declines, variation in λ should become more pronounced.

Key words: California; climate effects; components of variation; environmental stochasticity; fitness; fragmentation; habitat effects; habitat mosaics; model selection; Northern Spotted Owl; population rates of change; Strix occidentalis caurina.

Introduction

The Northern Spotted Owl (*Strix occidentalis caurina*) is a medium-sized owl that inhabits conifer forests of the Pacific Northwest, including northwestern California, USA (Forsman et al. 1984, Gutiérrez et al. 1995). Pairs of Northern Spotted Owls occupy large home ranges ($\geq$1200 ha), portions of which are actively defended against conspecifics (see review in Thomas et al. 1990). This species exhibits strong affinities for mature and old-growth forests (reviewed in Thomas et al. 1990), and may incorporate large tracts ($\geq$400 ha) of these forests into its home range (Forsman et al. 1984, Carey et al. 1990, Solis and Gutiérrez 1990). Thus, mature and old-growth coniferous forest has been considered equivalent to Northern Spotted Owl habitat (see Thomas et al. 1990). Forests potentially suitable for spotted owls in the Pacific Northwest have declined by 61% since the 18th century because of logging; most of this decline has occurred in the last 60 yr (U.S. Forest Service 1992). In addition to reduction in size, once-contiguous blocks of mature and old-growth forests have become increasingly fragmented into mosaics of different seral stages.

A major conflict developed in managing spotted owl populations because of the high economic value of the remaining timber present within spotted owl habitat (Dixon and Juelson 1987). This conflict escalated when the Northern Spotted Owl was federally listed as a threatened subspecies in 1990 (U.S. Fish and Wildlife

Manuscript received 23 April 1998; revised 17 July 1999; accepted 24 October 1999; final version received 15 November 1999.

[3] E-mail: alanf@cnr.colostate.edu

Service 1990). Various assessments predicted declines among females in Northern Spotted Owl populations (Marcot and Holthausen 1987, Lande 1988, Noon and Biles 1990, Franklin 1992). Compelling evidence indicated that population declines were a function of loss of mature and old-growth forests (U.S. Fish and Wildlife Service 1990).

Long-term research questions regarding Northern Spotted Owls have been based primarily on conservation agendas. Such questions include: ''What influences population trends in Northern Spotted Owls over time?'' and ''How does the spatial distribution and extent of mature and old-growth forests affect Northern Spotted Owl populations?'' (after Noon and McKelvey 1996). These and other questions regarding Northern Spotted Owl populations can be addressed with empirical data because demographic parameters for this species are relatively easy to estimate from field data, compared with most avian predators (see Franklin et al. 1996*a*). In this paper, we attempted to address these questions by examining (1) the magnitude of variation in life history traits, (2) the factors that may influence variation in life history traits, and (3) how this variation might affect population dynamics.

The role of variation in population dynamics

Populations of organisms, and the life history traits that characterize them, vary over space and time. Understanding this variation is necessary for understanding life history strategies and population dynamics, as well as for developing conservation strategies (Rhodes and Odum 1996). In addition to spatial and temporal variation, individuals within populations also vary in their abilities to cope with their environment (Łomnicki 1988). Thus, three sources of variation—temporal, spatial, and individual—affect population dynamics and the life history traits (e.g., survival, reproductive output, and recruitment) that define those dynamics. These sources of variation are also important for determining population persistence over time and space (White 2000). In this paper, we concentrate only on temporal and spatial variation. Although we consider individual attributes, such as age and sex, we do not incorporate individual variation resulting from phenotypic and genetic variation.

There are important considerations regarding spatial and temporal variation in biological systems. First, a distinction must be made between *process variation* ($\sigma^2_{process}$), the variation in a given parameter ($\hat{\theta}$) over time and space, and *sampling variation* ($\mathrm{var}(\hat{\theta}|\theta)$), the variation attributable to estimating a parameter from sample data (Box et al. 1978, White 2000). Here, we are interested in the natural variability, estimated as process variation, of life history traits and measures of fitness. Sampling variation is of little interest, except that it must be properly dealt with to estimate process variation.

If no sampling variation is associated with parameter values measured over time or space, then process variation can be estimated as follows:

$$\hat{\sigma}^2_{process} = \frac{1}{n}\sum_{i=1}^{n}(\theta_i - \bar{\theta})^2 \quad (1)$$

(Burnham et al. 1987). However, parameters such as life history traits are never measured without sampling variance, although sampling variance is often ignored. Therefore, the total variation (σ^2_{total}) estimated in a set of parameter estimates over time or space is a combination of process and sampling variation, which can be generally viewed as follows (Skalski and Robson 1992):

$$\hat{\sigma}^2_{total} = \hat{\sigma}^2_{process} + \widehat{\mathrm{var}}(\hat{\theta}\,|\,\theta). \quad (2)$$

Typically, the relationship in Eq. 2 becomes more complex as process or sampling variation is temporal, spatial, or both (see Burnham et al. 1987). Process variation in population parameters can be further decomposed into additional components of interest, such as temporal and spatial process variation, where

$$\sigma^2_{process} = \sigma^2_{temporal} + \sigma^2_{spatial}. \quad (3)$$

Such decomposition of variance components is termed components of variance analysis (Box et al. 1978, Searle et al. 1992). Although knowing the relative magnitude of temporal and spatial variance components is necessary to understand population dynamics, the factors that cause temporal and spatial variation are also important, especially for understanding ecological relationships and developing conservation strategies. If climate and habitat quality are considered to be useful starting points for examining the determinants of temporal and spatial variation, respectively (see *Climate and temporal variation* and *Habitat quality and spatial variation*), a sound, statistically based model can be developed that relates these factors to life history traits using meaningful covariates. Once such models are developed, process variation can be partitioned as

$$\sigma^2_{process} = \sigma^2_{model} + \sigma^2_{residual} \quad (4)$$

where $\sigma^2_{process}$ is either temporal or spatial process variation in a life history trait; σ^2_{model} is the amount of that process variation theoretically explainable by some model incorporating the factors thought to be responsible for that variation; and $\sigma^2_{residual}$ is the amount of $\sigma^2_{process}$ not explained by the model. For example, explainable variation in temporal process variation due to climatic factors can be viewed as $\sigma^2_{temporal} = \sigma^2_{climate} + \sigma^2_{residual}$, where $\sigma^2_{residual}$ is the amount of temporal variation not explained by climatic factors in the model.

Once an understanding of the magnitude of process variation in life history traits and the factors that affect it has been achieved, an approach relating this process variation to overall population dynamics is needed. We chose the finite rate of population change (λ) as the common currency to relate temporal variation to population growth rates (Caswell 1989*a*) and spatial variation to fitness (Caswell 1989*b*, McGraw and Caswell 1996). Ricklefs (1983) and Nur (1987) suggest that the finite rate of population change (λ) is a good estimate of fitness because it explicitly incorporates age-specific survival and fecundity. Although interpretations of λ may differ slightly when it is used as a measure of population growth rate or as fitness, at least the effects of temporal and spatial variation can be compared using the same metric. For example, the finite rate of population change can be viewed as the average fitness across individuals within a year, as well as the growth rate of the population (Danchin et al. 1995).

Climate and temporal variation

Temporal variation is important in defining life history tactics and understanding the evolutionary processes that may shape life history traits. Much of life history theory ignores the influence of temporal variation when, in fact, the influence of temporal variability on life history traits, such as survival and recruitment, can have different consequences for life history tactics (Stearns 1976, 1992). The effect of temporal variation on life history tactics depends on several factors such as the amount of variation, the covariation among life history traits, the life history being considered, and factors that also affect long-term rates of population change (Tuljapurkar 1989, Benton and Grant 1996).

Temporal variation in population dynamics is often represented as environmental stochasticity, a nearly continuous series of perturbations over time that simultaneously affect birth and death rates of all individuals in a population (Shaffer 1987, Lande 1993). Extremes in environmental stochasticity are viewed as random catastrophic events when they produce sudden and large reductions in population size (Mangel and Tier 1993). Environmental stochasticity can accelerate the risk of extinction even in large populations (Goodman 1987, Shaffer 1987), especially in populations whose long-term growth rate is near zero (Lande 1993). However, understanding how environmental stochasticity affects population processes and extinction probabilities requires an understanding of the effects of environmental stochasticity on organisms (Boyce 1992). Models attempting to approximate population processes have progressed from simple, deterministic forms to increasingly complex, stochastic forms that induce random temporal variation on model parameters. Population viability analyses, in particular, incorporate forms of environmental stochasticity when predicting the probability of persistence of a given population. However, Boyce (1992) points out that environmental stochasticity is usually approximated poorly in such models because it is represented as unstructured, random noise rather than as a structured temporal process. If environmental stochasticity is, in reality, a structured process, then it becomes predictable to some degree and should no longer be represented as random noise. This implies that changes in temporal conditions can be explained in some manner. Thus, there is a real need for empirical understanding of whether environmental stochasticity can be represented as structured variation, and how this variation affects populations, especially through its influence on life history traits.

Climatic variation is one structured source of temporal variation that may affect avian populations through its influence on life history traits, largely in a density-independent manner (Boyce 1984). Extremes in climatic variation also can function as catastrophic events and have been associated with sudden large-scale mortality in avian populations (Tompa 1971, Johnson et al. 1991, Rogers et al. 1991, Smith et al. 1991). Most studies have focused on the effect of climatic variation on reproductive output (Kostrzewa and Kostrzewa 1990, 1991, Rotenberry and Wiens 1991, Cooper and Lutjeharms 1992, Dykstra and Karasov 1993, Neal et al. 1993, Swenson et al. 1994), with less emphasis on the effect of this variation on survival (e.g., Martinson and Grondahl 1966, Peach et al. 1994, Cézilly et al. 1996). Few studies empirically examine the effects of climate, as a source of temporal variation, on the collective suite of life history traits of a single avian species (but see Grant and Grant 1989, Jouventin and Weimerskirch 1991), and the overall influence of such variation on population growth rates.

Rotenberry and Wiens (1991) identify two major scales over which climatic variation could affect life history traits: within-year effects reflecting day-to-day variation, and among-year effects attributed to variation over larger temporal and spatial scales. In this study, we deal solely with among-year effects as a measure of temporal variation. When considering annual temporal variation, one can express the total variation (σ^2) in an *estimated* life history trait ($\hat{\theta}$) as $\sigma^2_{\text{temporal}} + \overline{\text{var}}(\hat{\theta}|\theta)$ in its simplest form, where $\sigma^2_{\text{temporal}}$ is temporal process variation (the variance of the parameter θ among years) and $\overline{\text{var}}(\hat{\theta}|\theta)$ is the mean sampling variation due to estimation of θ within years. Temporal process variation can be partitioned further into variation due to climate ($\sigma^2_{\text{climate}}$) and residual, unexplained variation ($\sigma^2_{\text{residual}}$) such that

$$\sigma^2_{\text{temporal}} = \sigma^2_{\text{climate}} + \sigma^2_{\text{residual}}. \tag{5}$$

If climate is a primary mechanism governing temporal variation, then $\sigma^2_{\text{climate}}$ should be large relative to $\sigma^2_{\text{residual}}$; the reverse suggests that other influences are responsible for temporal variation.

When estimating the effects of climatic variation on Northern Spotted Owl populations, we addressed three questions in a step-wise fashion, using 10 yr of data on marked spotted owls in northwestern California. First, we asked: *What is the magnitude of temporal process variation in key life history traits of Northern Spotted Owls?* We approached this question by estimating $\sigma^2_{\text{temporal}}$ in capture–recapture estimates of survival, recruitment (the number of new individuals in the population per individual from the previous year), and reproductive output (the number of young fledged per pair), using components of variance analysis that accounted for sampling variance in the parameter estimates. Second, we asked: *Is temporal process variation explained primarily by climatic variation?* That is, does $\hat{\sigma}^2_{\text{climate}}$ explain a large portion of $\hat{\sigma}^2_{\text{temporal}}$. Finally, we asked: *What are the long-term consequences of climatic variation on population growth and stability if climatic variation strongly influences life history traits?* We evaluated this last question by applying climate models describing variation in life history traits and rates of population change to a 30-yr climate trace. In this way, we attempted to assess the probable behavior of these climate models in describing temporal variation, given that selected climate models were reasonable approximations of nature.

Habitat quality and spatial variation

Habitat for a particular organism can be defined as an area with the combination of resources and environmental conditions necessary to allow occupancy, survival, and reproduction of individuals (Morrison et al. 1992). Habitat use by an organism can be described at four nested scales (Johnson 1980): the overall geographic range of the species, the home range or territory within the geographic range, various habitat components within the territory, and specific foraging locations within those habitat components. This study focuses on the territory scale, specifically in terms of macrohabitat (Block and Brennan 1993): the extent and configuration of vegetation stands within territories.

Habitat occupied by a particular species often spans a gradient from low to high quality, in which quality can be defined based on the habitat's effect on the survival and reproductive performance of individuals occupying particular grades of habitat. High-quality habitat promotes some combination of survival and reproductive performance that increases an individual's contribution to future generations (Van Horne 1983). As such, habitat is a key component in shaping an individual's fitness. Individual fitness can be loosely defined as a composite measure of reproduction and survival (Stearns 1992): a measure of the relative genetic contribution by an individual to the next generation (Charlesworth 1970, Nur 1987). Fitness is generally considered to be an individual measure; as an individual's probability of survival and offspring production increases, so does its fitness. However, Fretwell and Lucas (1970) combined the concepts of habitat and individual fitness into the idea that habitat quality confers fitness on individuals where the quality of habitat occupied by individuals of a given species is related to the average potential contribution from that habitat to the gene pool of succeeding generations. According to density-dependent habitat selection, individuals should occupy only habitats that maximize their fitness (Morris 1989). Wiens (1989*a*:301) referred to this effect of habitat quality on an individual as the *fitness potential* of habitat, denoted here as λ_H. However, λ_H can be a reflection of either habitat quality or some interaction between the individual and the habitat it occupies (Newton 1989*a*). At two extremes, individual fitness and fitness realized only when an individual occupies a certain habitat can be either additive or compensatory. If additive, λ_H is a combination of individual fitness and realized fitness that may also include interactions. If compensatory, then individual fitness is only realized when some optimal habitat is occupied; λ_H is then a direct measure of individual fitness. In either case, habitat fitness potential is a useful measure for both defining the quality of an animal's habitat and determining the relative contributions to the overall population of individuals occupying those habitats.

For territorial species, two competing theories of habitat selection have been proposed to explain how habitat quality affects habitat fitness potential in territorial species: the ideal-free distribution and the ideal-despotic distribution (Fretwell and Lucas 1970). Under the ideal-free distribution, high-quality habitats are occupied first. As the density of individuals increases, the fitness potential of high-quality habitats declines because of density-dependent influences and habitats of lesser quality are occupied. Habitat fitness potential in lower quality habitat now becomes equivalent to that of the high-quality habitat. When the entire habitat quality gradient is occupied, habitat fitness potential becomes similar across the whole gradient. Under the ideal-despotic distribution, habitat selection is constrained by the activities of dominant individuals. Dominant individuals achieve higher habitat fitness potential by occupying higher quality habitats, whereas less dominant individuals are relegated to lower quality habitat. In both distributions, ''ideal'' refers to the assumption that individuals have the dispersal and cognitive abilities to locate the best available territory (Pulliam and Danielson 1991).

If the gradient of all potentially suitable habitats for a species is assumed to be fully occupied, then a prediction from the ideal-free distribution is that habitat fitness potential among territories exhibiting different habitat characteristics should be relatively uniform (Morris 1989); spatial process variation (the variation among territories) in habitat fitness potential should be essentially zero. Under the ideal-despotic distribution, habitat fitness potential should be unequal among territories of differing habitat configurations; spatial process variation should be greater than zero. Whether a species follows the ideal-free or ideal-despotic model has important implications for population dynamics. Under the ideal-free distribution, individuals are assumed to have similar individual fitness (Fretwell and Lucas 1970); fitness is a function of habitat and density. However, under the ideal-despotic distribution, individuals in high-quality habitat are inherently more fit;

fitness is a function of both the individual and the habitat it occupies.

In field studies, fitness, whether individual or habitat-realized, is often poorly defined using either surrogate indices (such as behavioral responses) or only a single component (such as survival, reproduction, or some index of either) to represent fitness (Nur and Clobert 1988). However, fitness is a function of both survival and reproduction. Variation in external factors (such as habitat) can affect each of these components differently, with different combinations yielding different fitness values.

Here, we attempt to address a series of questions relating landscape habitat configuration in spotted Owl territories to survival, reproduction, and, ultimately, fitness. We examine spatial process variation in terms of habitat quality, ignoring the influence of temporal variation discussed previously. First, we address *whether Northern Spotted Owl survival and reproductive output vary with respect to landscape habitat covariates at the individual territory scale.* Noon and McKelvey (1996) considered that a within-population scale, with reproductive pairs as the sampling unit, was more relevant than a between-subpopulations scale for assessing relationships between demography and habitat in Northern Spotted Owls. Here, we are particularly interested in the effects of fragmentation of mature and old-growth forest on life history traits and fitness of Northern Spotted Owls. We define fragmentation as the conversion of continuous patches into smaller patches surrounded by a matrix of other vegetation types (after Wiens 1989*b*). Second, we ask *whether a compromise exists in these components of fitness.* Does one habitat element favor survival and another favor reproductive output, or is there a unifying habitat element that favors both? Third, *is there spatial process variation in fitness, or is fitness relatively uniform across territories?* In other words, does spatial variation in fitness among Northern Spotted Owl territories follow an ideal-free or an ideal-despotic distribution?

When considering only spatial variation, estimated variation ($\hat{\sigma}^2$) in estimates of fitness can be approximated as $\hat{\sigma}^2 = \hat{\sigma}^2_{\text{spatial}} + \widehat{\overline{\text{var}}}(\hat{\lambda}_H | \lambda_H)$, where $\hat{\sigma}^2_{\text{spatial}}$ is the estimated spatial process variation of fitness among territories, and $\widehat{\overline{\text{var}}}(\hat{\lambda}_H | \lambda_H)$ is average estimated sampling variation due to estimating fitness. Given some model and measures of habitat, spatial process variation can be further expressed as

$$\sigma^2_{\text{spatial}} = \sigma^2_{\text{habitat}} + \sigma^2_{\text{residual}} \tag{6}$$

where $\sigma^2_{\text{habitat}}$ is the spatial process variation of fitness attributed to habitat differences among territories; and $\sigma^2_{\text{residual}}$ is residual variation attributed to other factors, such as individual variation. Similarly, variation in survival and reproductive output, the components of fitness, can be estimated. Understanding variation in fitness among spotted owl territories provides insights into how differences in habitat quality influence spotted owl populations, and into conservation strategies to manage those populations.

Influences of climate and habitat on population dynamics

Blondel (1991) suggests that effects of extreme climatic events may be overcome by habitat heterogeneity, in which high-quality habitat buffers some individuals from such extreme events. This concept of buffering by high-quality habitats has little empirical support except for Van Horne et al. (1997), who found differential demographic responses to a drought and a prolonged winter by Townsend's ground squirrels (*Spermophilus townsendii*) in two different habitats.

Strategies proposed for organisms dealing with both climatic and habitat variation include short-term responses, such as large-scale spatial shifting of populations within a landscape in response to temporal shifts in climate (Karr and Freemark 1983, Kindvall 1995), and long-term, adaptive responses, such as increasing longevity of individuals to encompass as much temporal variation as possible, thus ensuring that a number of ''good'' years will be included in an individual's life-span (Newton 1989*b*). In the first strategy, population responses are based on changes in habitat quality for a given species in relation to climate; changes in climate alter habitat quality and individuals move in response to those changes. The second strategy assumes that habitat quality is more stable over time and that organisms are responding to this habitat stability in the face of temporal variation. Although the first strategy is probably irrelevant for nonmigratory, territorial species such as the Northern Spotted Owl, the second strategy is relevant for territorial species. A third strategy is that individuals should compete for habitats that dampen climatic variation, if climatic variation is important in determining variation in life history traits. This latter hypothesis is particularly relevant to territorial species and incorporates protection from extremes in climatic variation as a component of habitat quality.

Regarding effects of climate and habitat in population dynamics, we first asked the question: *What proportion of the total process variation in life history traits is explained by variation in climate, habitat, and other unknown factors?* For example, does climate account for only a minor proportion of the variation in survival and reproductive output, or does it contribute a proportion similar to that contributed by habitat? In addition, we examined whether there was sufficient residual process variation not accounted for by either habitat or climate that may be caused by other factors not examined in this study. We then asked the question: *Are survival and reproductive output impacted by an interaction between climate and habitat variation?* This can be rephrased as: *Do territories containing habitat that promotes high survival and reproduction buffer the occupants of those habitats from extremes*

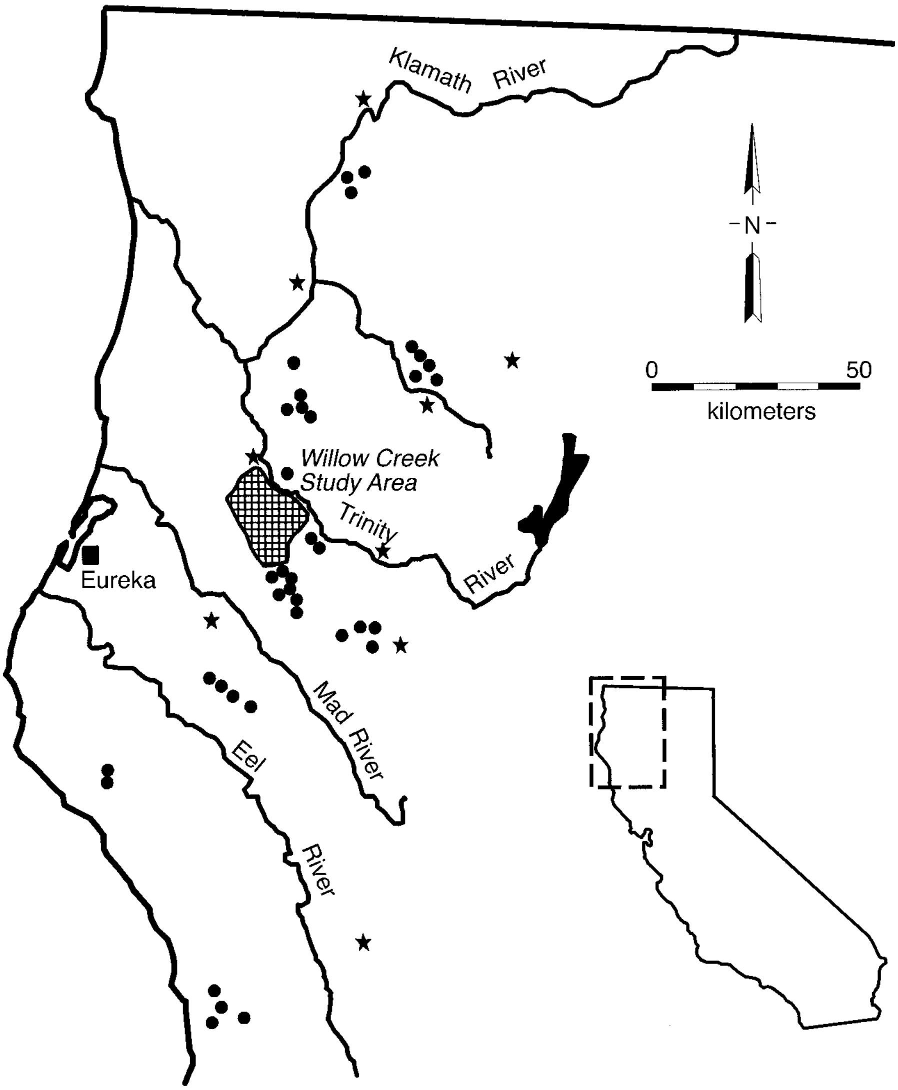

FIG. 1. Location of the Willow Creek study area (hatched area), satellite Northern Spotted Owl sites (dots), and weather stations (stars) in northwestern California.

in climatic variation? An interaction between habitat and climate would be expressed in which individuals occupying territories with "good" habitat quality maintain higher survival and reproduction during periods of "bad" climatic extremes than do those individuals occupying territories of "inferior" habitat quality. Both of these questions are relevant to conservation strategies because habitat variation can, theoretically, be controlled and predicted to some extent, whereas climate variation cannot. In addition, we evaluated what roles climatic and habitat variation may play in the population dynamics of Northern Spotted Owls.

STUDY AREA

We studied Northern Spotted Owls within a 10 000-km^2 area in the North Coast Range and Klamath Mountains of northwestern California, USA (Fig. 1) that included portions of three National Forests and isolated parcels administered by the Bureau of Land Management. Within this area, a 292-km^2 study area, near Willow Creek, Humboldt County, California, was established and was systematically surveyed each year from 1985 through 1994 to estimate density of Northern Spotted Owls (Franklin et al. 1990). The Willow Creek study area contained 49 Northern Spotted Owl sites (areas where owls exhibited territorial behavior sensu Franklin et al. 1996*a*). Twelve 10–30 km^2 satellite survey areas were also used, containing an additional 41 owl sites. These satellite areas were selected to increase sample size over a wider geographic area, and were surveyed from 1987 through 1994.

Elevations in the study area ranged from 200 to 1700 m. The study area was located within the Klamath physiographic province (Küchler 1977), which has

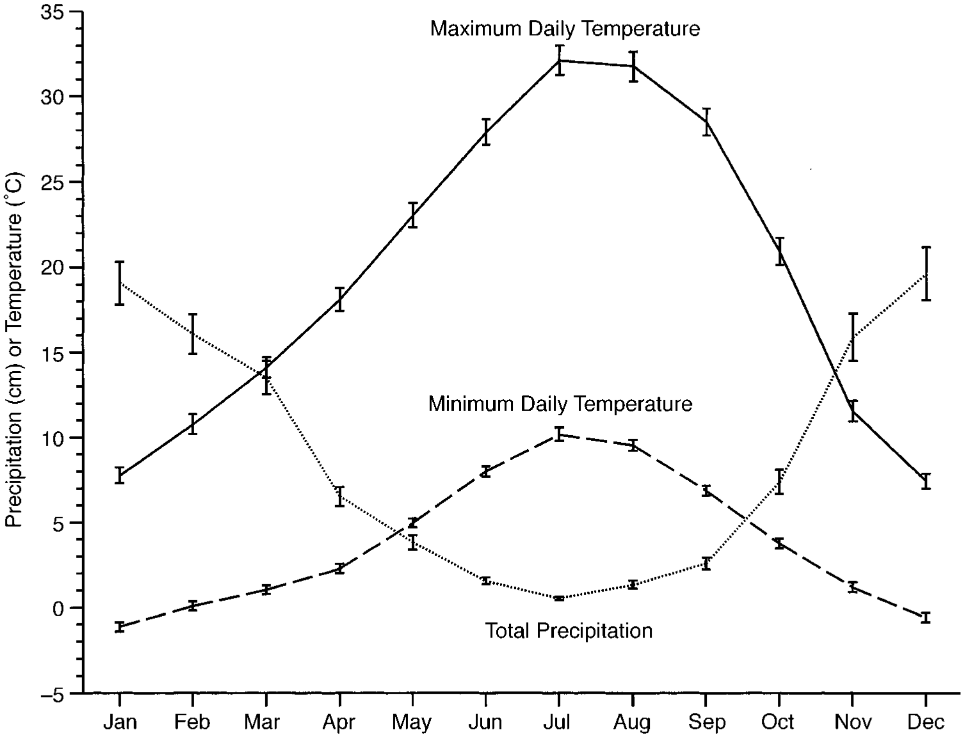

FIG. 2. Seasonal variation in climate in northwestern California. Data are means with 95% confidence intervals for nine weather stations distributed within the study area (see Fig. 1) from April 1954 through April 1994.

unique characteristics not found in other parts of the Northern Spotted Owl's range. This physiographic province encompassed southern Oregon and northern California, where forests were generally characterized by 3–5 major conifer species, often mixed with several hardwood species. Early-seral stages were often dominated by hardwoods, whereas older seral stages were dominated by a conifer overstory, a midstory of hardwood trees, and an understory of hardwood shrubs. As elevations increased, forested stands tended to be dominated solely by conifers. Below 1200 m, forests were dominated by a Douglas-fir (*Pseudotsuga menziesii*) overstory and a hardwood subcanopy dominated by madrone (*Arbutus menziesii*), tanoak (*Lithocarpus densiflora*), and canyon live oak (*Quercus chrysolepis*). Above 1200 m, forests were dominated by white fir (*Abies concolor*) associated with pines (*Pinus* spp.). Because of differing site qualities, pure hardwood stands also occurred, dominated by Oregon white oak (*Quercus garryana*), tanoak, or canyon live oak. Whittaker (1960) considered this forest region to be one of the most complex and diverse in the western United States, because of this blend of conifer and hardwood species.

The climate was mediterranean (Major 1977), characterized by cool, wet winters and hot, dry summers (Fig. 2). The growing season for vegetation was limited by the cool temperatures in winter and lack of precipitation during the summer. This climate was subject to periodic droughts at 10–15 yr intervals (Major 1977). The Klamath physiographic province has the highest patterns of lightning strikes in the Pacific Northwest; and pre-settlement fire-return rates averaged 11–20 yr at lower elevations and 37 yr at higher elevations (Agee 1993). Most pre-settlement fire appeared to be of low-to-moderate severity, resulting in hardwood understory removal, but retention of large overstory trees. High-severity fires, resulting in removal of most overstory trees, occurred infrequently (Agee 1993). Hardwood brush often became established first after severe fires, and could persist for decades before conifers eventually dominated (Thornburgh 1982).

Since the exclusion of fire by intentional suppression, logging has had the greatest influence on forests in this region (Beardsley and Warbington 1996). Logging patterns of mature and old-growth coniferous forests are similar to those in Oregon, which Spies et al. (1994) described as follows. Dominant silvicultural practices are to develop even-aged plantations, primarily of Douglas-fir (*Pseudotsuga menziesii*), in a dispersed fashion. This is achieved primarily through clear-cutting in regularly shaped blocks of ~16 ha, although earlier clear-cutting practices led to clearcuts of 32–41 ha. Hardwood species that become established after clear-cutting are usually removed through thinning. Logging on public lands began in the 1960s in our study area. In the 1930s and 1940s, ≥56% of productive coniferous forest land in California was considered to be old growth prior to commercial logging on public lands (Bolsinger and Waddell 1993). Approximately 31% of the four National Forests in northwestern California is now covered by mature and old-growth conifer forests, defined as having trees >53 cm diameter at breast height (Beardsley and Warbington 1996). Much of the remaining old-growth in the Pacific Northwest is on National Forests within the Klamath Mountains province in southern Oregon and northwestern California, USA (Bolsinger and Waddell 1993).

Study Species

Previous studies in our study area have demonstrated a strong association between Northern Spotted Owls and mature and old-growth forests at the scales of (1) home ranges within the geographical distribution (Blakesley et al. 1992, Hunter et al. 1995), and (2) habitat components within home ranges (Lahaye 1988, Solis and Gutiérrez 1990).

The primary prey of spotted owls in the study area are, in decreasing importance: dusky-footed woodrat (*Neotoma fuscipes*), northern flying squirrel (*Glaucomys sabrinus*), red tree vole (*Phenacomys longicaudus*), and deer mice (primarily *Peromyscus maniculatus*) (see Franklin 1997). *Neotoma* and *Glaucomys* are the most important prey taken, in terms of both frequency and biomass. Based on a number of studies with similar climatic regimes (Howell 1926, Linsdale and Tevis 1951, Tevis 1956, Sadleir 1974, Van Horne 1981, Wells-Gosling and Heaney 1984, Carey 1991, Witt 1991), these four prey species reproduce primarily in the spring and early summer. Breeding seasons of prey are probably determined by availability of high-quality forage during the spring. The primary plant species providing forage for Northern Spotted Owl prey in the spring are oaks, conifers, and hypogeous fungi. *Neotoma* forages heavily on evergreen schlerophyll vegetation, such as tanoak and *Quercus* species in northern California (Linsdale and Tevis 1951, Atsatt and Ingram 1983). In southwestern Oregon, *Glaucomys* eats almost exclusively hypogeous fungi (Maser et al. 1986), whereas *Phenacomys* feeds exclusively on conifer needles, principally from Douglas-fir (Howell 1926, Carey 1991). *Peromyscus* consumes primarily conifer seeds in spring (Jameson 1952, Tevis 1956). In general, phenology of important plant species coincides with the breeding seasons of spotted owl prey. Leaf production for oaks and conifers (Douglas-fir) begins in early spring (Burns and Honkala 1990). Flower production for oaks and other hardwoods extends from May through August, whereas seed production occurs between August and November (Burns and Honkala 1990), providing important food sources for overwintering *Neotoma* and *Peromyscus*. Sporocarp biomass of hypogeous fungi used by *Glaucomys* is highest in March–September (Luoma et al. 1991).

There is conflicting evidence as to whether Northern Spotted Owls are dependent primarily on interior mature and old-growth coniferous forest, are edge dependent, or are dependent on a mixture of interior habitat and edge. *Neotoma* attains its highest densities in early-seral stages where dense hardwood brush is abundant, and achieves low densities in mature and old-growth forests (Sakai and Noon 1993). Other small mammals important in the diet of Northern Spotted Owls are also found in higher densities in early- to mid-seral stages (Raphael 1988). For this reason, Carey and Peeler (1995) suggest that the mixed-conifer forests of the Klamath Mountains have the greatest diversity and biomass of prey for Northern Spotted Owls. In northern California, Zabel et al. (1995) found spotted owls foraging near edges of late- and early-seral stage forests more often than expected. Ward et al. (1998) reported that woodrat abundance was greatest at spotted owl foraging sites at the ecotone between late- and early-seral stages. Thus, there is a dichotomy between the strong association for spotted owls with late-seral stage forests and the primary prey source for owls that are associated with early-seral stages.

The link between older forests and life history traits, such as survival and reproductive output, is currently tenuous in Northern Spotted Owls. Using turnover rates as an index of survival, Bart and Earnst (1992) found that persistence of adults was significantly correlated with the proportion of mature and old-growth forest within Northern Spotted Owl territories. Bart and Forsman (1992) and Ripple et al. (1997) found similar positive correlations between amounts of mature and old-growth forest and reproductive output in Northern Spotted Owls, on the scale of aggregations of territories and individual territories, respectively. However, in all cases, relationships with other habitat configurations were not considered, and Bart and Earnst (1992) and Ripple et al. (1997) used indices of life history traits, rather than direct parameter estimates. In addition, the link between habitat and fitness is still lacking. The problem with studies that examine only the components of fitness (survival and fecundity) is that potential trade-offs maximizing long-term survival and fecundity are often ignored. In other words, factors that maximize either survival and fecundity may be different, and neither component by itself may reflect fitness.

Methods

We used the following general analytical approach in assessing the effects of variation in climate covariates on the three life history traits of Northern Spotted Owls. After developing the biological background for potential effects of climate on Northern Spotted Owls, we divided the annual cycle into specific life history periods to identify when climatic stresses may affect spotted owls. We relied on existing biological information to identify these periods. In dividing the annual cycle into specific periods, we reduced the number of climatic covariates from arbitrary weekly or monthly intervals to those included in fewer, more biologically meaningful, intervals (Appendix A). We used these steps to develop a priori verbal hypotheses, which we then expressed as models that could be fit to the available data. In these models, the response variables were life history traits (survival, reproductive output, and recruitment) and the explanatory variables were climate covariates (temperature and precipitation during life history periods) and individual covariates (age and sex). Thus, we had suites of candidate statistical models for each life history trait that were developed prior to analyzing the empirical data and that related the respective life history trait to climatic covariates. These suites of candidate models were analogous to the 26 predator–prey models suggested by Berryman et al. (1995), some of which represented competing theories. The importance of a priori model development in data analysis, as opposed to analyzing data by iteratively searching the data for relationships (i.e., data dredging), has been alluded to by Hofacker (1983) and Chatfield (1995), and more recently has been formalized by Burnham and Anderson (1998).

After a priori hypothesized models were developed, we used an objective model selection criterion (AICc; see *Selection of hypothesized models*) to rank and calibrate the candidate hypothesized models in terms of their ability to explain the empirical data. In this way, a ''best approximating'' model was selected from each suite of candidate models as the most parsimonious explanation of the data. Other candidate models were then ranked below in terms of their plausibility to explain the same data. Model selection based on AIC has an advantage in that multiple hypotheses can be ranked according to their importance in explaining the data; a hypothesis-testing approach only allows for rejection or failure to reject two models at a time (Akaike 1974). Burnham and Anderson (1998) present other, numerous reasons for using AIC-based model selection rather than hypothesis testing when dealing with data collected in an observational study such as this one. Model selection, based on AIC, has been used extensively in capture–recapture studies (see Lebreton et al. 1992).

The analytical strategy that we outline here avoids models with more covariates than can be supported by the data, which often results in imprecise parameter estimates, and excessive data dredging, which can result in spurious explanatory models (Freedman 1983). Thus, the strategy that we use here balances precision and bias when selecting an appropriate model to relate variation in life history traits to climatic covariates (Burnham and Anderson 1992).

Data collection

Life history traits.—The general design for collection of field data to estimate survival, reproductive output, and recruitment was to monitor marked individuals over time. Each year, we attempted to locate and individually identify all spotted owls in the Willow Creek and satellite study areas. Territorial spotted owls were located with multiple surveys, using vocal imitations of their calls to elicit responses (Forsman 1983, Franklin et al. 1996*a*), from April through August of each year. Surveys were not conducted on days when precipitation occurred. Northern Spotted Owls were aged by plumage characteristics as fledged young of the year, 1-, 2-, or ≥3-yr old (Moen et al. 1991); sexes were distinguished by vocalizations (Forsman et al. 1984). Once located, owls ≥1 yr old were checked for reproductive output. Using specific criteria outlined in Franklin et al. (1996*a*), each pair of owls visited was categorized as having 0, 1, 2, or (rarely) 3 fledged young. Individuals were uniquely identified through capture, recapture, or resighting of colored leg bands using several techniques (see Forsman 1983, Franklin et al. 1996*a*). Locking numbered aluminum bands were placed on one leg of each captured owl, and a colored plastic leg band with colored vinyl tabs (Forsman et al. 1996) was placed on the opposing leg to identify individuals without recapturing in subsequent years. If identification of color marks was ambiguous, birds were recaptured and the numbered band was read. We used the term ''recapture'' to describe physical recapture of marked individuals or resighting of previously color-marked individuals. Although juveniles were recaptured as ≥1-yr olds, these data were not used to estimate juvenile survival because of potential biases (see Franklin et al. 1996*a*).

Climate covariates.—To estimate climatic covariates, we first divided the annual cycle experienced by spotted owls into critical periods based on weather conditions and specific life history stages (see Appendix A for details). These critical periods were the *winter stress period* (November–February), the *early nesting period* (March–April), the *late nesting period* (May), the *heat stress period* (July–August), and the *dispersal period* (September–October).

Within each defined life history period, we obtained daily measurements for amounts of precipitation and minimum and maximum temperatures from nine weather stations operated by the U.S. Weather Service (Fig. 1). These stations were selected because they provided adequate spatial coverage of the study areas and had complete records both during and before the study. The range of weather station elevations included 83% of the elevational distribution for owl capture locations. Therefore, we assumed that data from the weather stations were representative of conditions experienced by spotted owls in the study area. We also assumed that changes between years adequately represented real changes as long as climate conditions within years were reasonably represented, because the relationship of interest was year-to-year variation.

Climate covariates had to be biologically meaningful in their effects on owls, and had to be precisely estimated (CV < 10%) when averaged across stations within years, because we did not incorporate sampling variances of covariates into statistical analyses. For precipitation, we used the number of days of measurable precipitation (≥0.03 cm) within each life history period because we felt that the duration of precipitation was more important in its effects than the absolute amount. Regardless, the annual number of days of precipitation was highly correlated with annual precipitation amount within the life history periods ($r = 0.87–0.94$, df = 8, $P < 0.001$). The number of days with precipitation averaged across stations within years was precise (CV = 2.5–7.1%).

Estimating daily temperature only from daily maximum and minimum temperatures can be problematic. Means of maximum and minimum temperature in a given day fail to account for the duration of temperatures, and typically underestimate the actual mean daily temperature, based on hourly data (Lindsey and Newman 1956). Therefore, we estimated degree-hours (the product of temperature and the time over which temperatures occur; Lindsey and Newman 1956, Tuhkanen 1980) by modeling hourly temperature over the course of a 24-h day using a cosine model (from Allen 1976):

$$\text{Hourly temperature} = T_{\min} + \left(\frac{T_{\max} - T_{\min}}{2}\right)\left[1 - \cos\left(\frac{\gamma\pi}{24}h - \frac{\delta\pi}{24}\right)\right] \quad (7)$$

where $T_{\max}$ and $T_{\min}$ were daily maximum and minimum temperatures, respectively; h was the hour of the day; and γ and δ were parameters controlling phase angle and width, respectively. Daily degree-hours were estimated by integrating Eq. 7 from $h = 0$ to 24. Parameters γ and δ were estimated for life history periods using Eq. 7 in nonlinear regression (Proc NLIN; SAS Institute 1990) with hourly data available from two weather stations. Degree-hours were estimated for each day and were then averaged within the life history periods for each year. Daily temperature models explained a high proportion of the variation in hourly temperature over the course of a day ($R^2 = 0.912–0.995$) within the life history periods. Estimates of γ (CV = 1.4–5.0%) and δ (CV = 5.2–11.2%) from Eq. 7 were precise. Degree-hours averaged across stations within years were precise (CV = 1.2–3.6%). As an additional covariate during the heat stress period, we estimated surplus stress units, in terms of increased oxygen consumption by the owls (mL O_2/g/h), attributed to daily temperatures, and the length of time that they were maintained, according to:

$$\text{cc } O_2 \text{ g}^{-1} \text{ h}^{-1} = \int_{h_a}^{h_b} [0.649 + 0.008(f(H)) - 0.905]\, dt \quad (8)$$

where $f(H)$ was Eq. 7, h_a was the hour when temperatures began exceeding the 32°C threshold temperature when owls exhibited heat stress, and h_b was the hour when temperatures decreased below the 32°C threshold temperature. The linear equation in Eq. 8 is the regression equation estimated by Ganey et al. (1993) for oxygen consumption in Mexican Spotted Owls (*Strix occidentalis lucida*) above their thermal neutral zone. In using the equation from Ganey et al. (1993), we assumed that Northern Spotted Owls had a physiological response to temperature similar to that of Mexican Spotted Owls.

Landscape habitat covariates.—We used a digital vegetation map, developed by the California Timberland Task Force (TTF), that covered both private and public lands over the extent of our entire study area (Geographic Resource Solutions 1996). This map was developed from 1990 Landsat Thematic Mapper imagery that was resampled to a pixel size of 25 × 25 m. Pixels were aggregated into polygons with a minimum polygon size of 2 ha. Polygon attributes pertinent to this study were (1) average quadratic mean diameter (Husch et al. 1982) at breast height of all conifer trees in the polygon, (2) average quadratic mean diameter at breast height of all hardwood trees in the polygon, (3) canopy closure of all trees in the polygon, and (4) percentage of conifers in the total canopy closure. This vegetation map was chosen because it covered all lands regardless of ownership, it covered the entire study area, and it contained polygon attributes classifiable into vegetation types relevant to spotted owls. Although other vegetation maps existed, they lacked one or more of these attributes.

We initially defined two habitats: spotted owl habitat and high-density dusky-footed woodrat habitat. Based on previous experience with Landsat coverages that were used to define habitats on the Willow Creek study area (Hunter et al. 1995), these were the only two habitats that we felt could be reliably estimated. Spotted owl habitat was based on the strong association of the owl with mature and old-growth forests for nesting, roosting, and foraging on the study area (Solis and Gutiérrez 1990, Blakesley et al. 1992, Hunter et al. 1995). Woodrat habitat was based on vegetation characteristics associated with high densities of dusky-footed woodrats (Sakai and Noon 1993). However, Northern Spotted Owls were not known to forage within this habitat (Solis and Gutiérrez 1990), but possibly along its edges (Zabel et al. 1995). Therefore, we initially distinguished woodrat habitat from spotted owl habitat based on the definition of habitat used here (Morrison et al. 1992). Both habitats were defined using the polygon attributes in the TTF vegetation map. Two phases of field verification were used to iteratively assess the accuracy of our definitions for the two habitats (Franklin 1997). However, woodrat habitat was poorly classified (68.6% probability that stands on the ground were correctly classified in the TTF coverage). In addition, analyses including this habitat did not suggest that woodrat habitat was important in explaining spatial variation in spotted owl survival and reproductive output. Therefore, we did not consider this habitat further. In the end, we used two habitats: spotted owl habitat vs. other vegetation types. Spotted owl habitat was mature and old-growth forest with a quadratic mean diameter of conifers ≥53 cm, quadratic mean diameter of hardwoods ≥15 cm, percentage of conifers ≥40%, and overstory canopy coverage ≥70%. This definition corresponded to other classifications used to define spotted owl habitat (Solis and Gutiérrez 1990) and to definitions used in other studies in this area (Blakesley et al. 1992, Hunter et al. 1995). By including hardwood tree species, our definition of spotted owl habitat indirectly reflected multiple canopy layers, an important component identified in previous studies (Solis and Gutiérrez 1990). Based on both phases of field verification (Franklin 1997), spotted owl habitat was correctly classified 89.0% of the time using the TTF vegetation coverage.

We used a 0.71 km radius circle around territory centers to represent spotted owl territories. Landscape habitat characteristics were then measured within these circles as covariates, when estimating survival and reproductive output of individual spotted owls occupying territories represented by the circles. Rationales and methods used to derive the 0.71 km radius circles as sampling units are described as follows. First, territory centers were estimated for all territories by averaging the UTM (Universal Transverse Mercator) coordinates representing roost and nest locations at each site. Multiple roosts at the same territory within the same year were included only once when averaging. However, if individuals roosted or nested at the same location in different years, those locations were included because they represented choices by individuals between years. In general, roost and nest locations at individual territories were tightly clustered; coefficients of variation for mean Easting and Northing UTM coordinates were ≤0.1 for 90% of the territories. Second, the radius of the circle was estimated as one-half of the median nearest neighbor distance (Hunter et al. 1995) between 37 territory centers in the Willow Creek Study area only. We assumed that the locations of almost all territories were known in the Willow Creek study area, to provide an adequate measure of territory adjacency. This median measure (0.71 km) was similar to the mean (0.75 km), with a range of 0.21–1.21 km.

We considered the 0.71 km radius circles as territory core areas for spotted owls in this study because of the small area (1.58 km^2) relative to expected home range size in northwestern California (4.2–5.9 km^2; Zabel et al. 1995). Hunter et al. (1995) and Meyer et al. (1998) found that landscape characteristics had the highest levels of significance between random sites and sites used by Northern Spotted Owls in the Klamath province when 0.8-km circles were used as a sampling unit, as opposed to larger diameter circles centered around the same sites. Meyer et al. (1998) suggested that characteristics of the inner core represented by these size circles may be most influential in determining territory locations for Northern Spotted Owls.

In describing landscape characteristics within territories, we chose not to use indices such as fractal dimension, contagion, evenness, and the variety of patch indices commonly used in landscape ecology to describe fragmentation and landscape pattern. Often these indices do not capture obvious differences in landscape pattern (Ripple et al. 1991, Groom and Schumaker 1993, Li and Reynolds 1994), are ad hoc (thus lacking an appropriate theoretical basis as meaningful measures), and are highly correlated with each other (Li and Reynolds 1994). In addition, we did not use metrics that included area in the denominator, such as patch density, because all territory circles were the same size. The metrics that we chose to describe landscape characteristics within spotted owl territories were those that we considered to be the fundamental characteristics describing habitat amounts, patch size, patch abundance, patch shape, and patch spacing. Together, the patch characteristics accounted for varying degrees of fragmentation.

Within the 0.71 km radius circles around territory centers, we chose nine habitat covariates and one topographic covariate (elevation) to examine with respect to spotted owl survival and reproduction (Table 1). We estimated mean elevation (ELEV) for each spotted owl territory by averaging the elevations of each roost and nest site used to estimate the centers of each territory. SOHAB and SOMP were estimates of amounts of spotted owl habitat, whereas SODIS was an estimate of the spatial distribution of patches of owl habitat (Ripple et al. 1991, Groom and Schumaker 1993). SOEDG, in conjunction with SOCOR, was a measure of patch shape (Groom and Schumaker 1993). For example, patches with little SOCOR and high SOEDG indicated linear patch shapes. The core habitat covariates, SOCOR and SONCA, are additional measures of general patch shape because they account for relative amounts of interior habitat vs. edge (Groom and Schumaker 1993). The combination of SOCOR and SONCA also measures fragmentation (Temple 1986) by measuring the amount and distribution of interior habitat; many small patches will have little or no core habitat. We used a 100-m distance from the edge to define core habitat area, because ecological characteristics of old-growth coniferous forests begin to stabilize beyond this distance (Spies et al. 1994, Chen et al. 1995), and the negative edge-associated impacts on forested habitats, in general, have been ameliorated after this distance (Temple 1986).

We estimated covariates for each spotted owl territory using operations in the ARC/INFO geographic information system (ESRI 1987). We first made a new coverage from the TTF vegetation map, which only included polygons of either spotted owl habitat or other vegetation types. Territory centers were circumscribed by the 0.71-km sampling radius and coverages for each

TABLE 1. Age and landscape habitat covariates used in models to estimate survival and reproductive output for Northern Spotted Owls in northwestern California.

Variable	Definition	Original metric†	Rescaled metric‡
*a*2	Dummy variable with 1-yr-old age class vs. ≥2-yr-old age class		
*a*2′	Dummy variable with 1- and 2-yr-old age class vs. ≥3-yr-old age class		
*a*3	Dummy variables with 1-yr-old age class vs. 2-yr-old age class vs. ≥3-yr-old age class		
SOHAB	Total amount of Northern Spotted Owl habitat	ha	ha ÷ 10
SONP	No. discrete patches of spotted owl habitat	*n*	*n*
SOMP	Maximum patch size of spotted owl habitat	ha	ha ÷ 10
SOEDG	Total amount of edge between spotted owl habitat and all other vegetation types	m	km
SODIS	Mean nearest neighbor distance between patches of spotted owl habitat measured from edge to edge of patches	m	m ÷ 10
SOCOR	Total amount of spotted owl core habitat, defined as the amount of spotted owl habitat ≥ 100 m from an edge	ha	ha
SONCA	No. patches of spotted owl core habitat	*n*	*n*
ELEV	Mean elevation of spotted owl territory	m	m ÷ 100

† Original scale on which the covariate was measured.

territory were then developed, containing the two categories within each circle. We used program FRAGSTATS (McGarigal and Marks 1995) to estimate each of the habitat covariates for each spotted owl territory. We manually checked measurements of a subsample ($n = 15$) of the territories to ensure that FRAGSTATS was correctly estimating the habitat covariates. Prior to analyses, covariates were rescaled in order to avoid large values in quadratic terms and interactions (Table 1).

Logging occurred within the sampling circle on nine territories over the course of the study. We adjusted polygons for loss of habitat due to timber harvest, based on U.S. Forest Service timber harvest records and aerial photographs, made new coverages of these territories, and estimated habitat covariates for both before and after logging.

Formulation of hypothesized models

Model development.—Prior to analyzing the empirical data, we explored ways in which climate and habitat configuration might affect spotted owls, based on the existing literature. We used this information to develop qualitative, potential effects of climate and habitat conditions on the owls, and incorporated these into statistical models as a priori hypotheses for analyzing the empirical data on the three life history traits. We used three forms of models when translating ideas into statistical models: a linear, a pseudothreshold, and a quadratic form (Fig. 3). For survival analyses, these model forms were incorporated using a logit link function (see *Modeling survival*).

The linear form of models could be written as

$$\theta = \beta_0 + \beta_1(x_1) + \cdots + \beta_n(x_n) \tag{9}$$

and the quadratic form as

$$\theta = \beta_0 + \beta_1(x_1) + \beta_2(x_1^2) + \ldots + \beta_{2n-1}(x_n) + \beta_{2n}(x_n^2) \tag{10}$$

where θ was the life history trait and x_i was the ith covariate. For the sake of parsimony in quadratic forms of the models, we used the squared differences of covariate values from their mean (denoted by preceding the covariate name with a *D*), which were calculated as

$$Dx_{ij} = (x_{ij} - \bar{x}_i)^2 \tag{11}$$

where x_{ij} was the jth value of the ith covariate. By using the squared differences, we could rewrite Eq. 10 as

$$\theta = \beta_0 + \beta_1(Dx_1) + \cdots + \beta_n(Dx_n). \tag{12}$$

This saved an extra parameter for each covariate used in the quadratic form of the models. However, the form in Eq. 12 was a restricted quadratic because it assumed that the curve was centered on the covariate mean. Therefore, quadratic models using the squared differences were also examined with the full quadratic terms ($x_i + x_i^2$) as a check.

The pseudothreshold form of models was

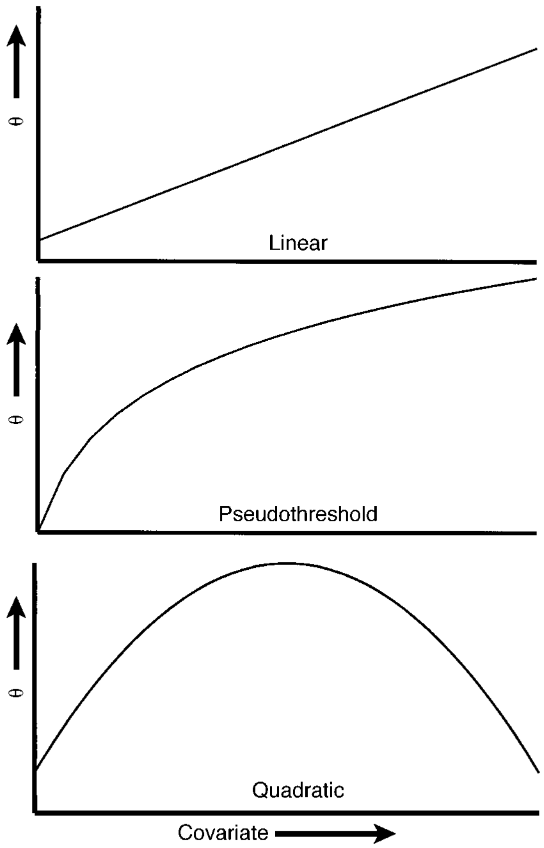

FIG. 3. Model forms used in hypothesized models relating landscape habitat covariates to life history traits (θ).

$$\theta = \beta_0 + \beta_1 \log_e(x_1 + 0.5) + \cdots + \beta_n \log_e(x_n + 0.5). \quad (13)$$

Covariate names in these models were preceded by an L (e.g., LSOCOR). In using log transforms, we added 0.5 to covariate values to account for values of zero. This was considered a pseudothreshold because an asymptote (threshold) was approached, but never reached, using the log transform. However, we considered this a parsimonious approximation to a true threshold model.

Each model structure indicated different predictions for each of the hypothesized models. A linear structure predicted that effects of the covariates changed at some constant rate; a pseudothreshold structure predicted that effects changed at a constant rate to some point and then approached (but did not reach) an asymptote; and a quadratic structure predicted some optimal maximum at intermediate effects, and lower effects at the extremes (Fig. 3). In denoting combinations of effects in models, we used ''+'' to denote an additive effect, where no interactions were considered, and used ''*'' to denote inclusion of interactions (Lebreton et al. 1992).

Climate models.—We hypothesized that variation in precipitation and ambient temperature can affect spotted owls directly through energetic constraints, and indirectly through the population dynamics and activity patterns of their prey, and the food resources required by those prey. Collectively, we referred to models examining the relationship between the life history traits and climate covariates as climate models. The underlying biological rationale for developing the following hypothesized climate models is detailed in Appendix A.

Prior to data analysis, we developed eight hypothetical climate models for survival (Table 2). The late nesting period was not included in survival models because of overlap with sampling periods when owls were captured. Models 1–6 in Table 2 examined climate effects within each period based on biological characteristics outlined previously, but with no drought effects. Longer term drought effects were considered in model 7, using a quadratic model in which survival could be negatively affected at either end of the drought–mesic continuum. Model 8 in Table 2 hypothesized that optimal growing conditions (e.g., wet winters followed by warm springs) in one year can positively influence prey populations in the following year and, hence, may increase spotted owl survival over the winter stress period. Additional variations of the hypothesized models included quadratic forms of the covariates and inclusion of age and sex effects.

We proposed 11 a priori climate models for reproductive output (Table 2) in which only the winter stress, early nesting, and late nesting periods were considered relevant. The complexity of hypothesized models for reproductive output was constrained by the existing sample of 10 yr, because annual means were used as the response. In Northern Spotted Owls, we presumed that food during the winter stress, early nesting, and late nesting periods was crucial for determining reproductive success, based on food supplementation experiments with other raptor species (Ward and Kennedy 1994, 1996, Wiehn and Korpimäki 1997). Models 1–3 in Table 2 reflected the effects of high precipitation alone on the ability of males to provide adequate food for incubating females or nestlings. Model 4 hypothesized that cold, wet winters negatively affected a female's ability to attain adequate body condition for reproduction, whereas models 5 and 6 examined the effects of both temperature and precipitation on hunting success of males and their ability to provide females with sufficient food during the early and late nesting periods. Lacking sufficient food, we surmised that females would leave nests for extended periods to forage, exposing eggs and young to the chilling effects of cold, wet weather. Models 7 and 8 examined the combined effects of wet and cold on the postulated effects from models 4–6. Models 9–11 hypothesized that optimal climatic conditions promoting the production of plant forage for prey led to increased reproductive output by the owls (see Appendix A).

We hypothesized six additional models to explain the effects of climate on recruitment (Table 2). Model

Hypothesis	Model	Model structure	Expected result†
Survival (logit ϕ)			
1) Negative effects of high temperatures in H.	ϕ_{T_H}	$\beta_0 + \beta_1(T_H)$	$\beta_1 < 0$
2) Negative effects of high precipitation and cold temperatures in W (no drought effect).	$\phi_{P_W+T_W}$	$\beta_0 + \beta_1(P_W) + \beta_2(T_W)$	$\beta_1 < 0, \beta_2 > 0$
3) Negative effects of high precipitation and cold temperatures in E (no drought effect).	$\phi_{P_E+T_E}$	$\beta_0 + \beta_1(P_E) + \beta_2(T_E)$	$\beta_1 < 0, \beta_2 > 0$
4) Negative effects of combined precipitation in both W and E.	$\phi_{P_W+P_E}$	$\beta_0 + \beta_1(P_W) + \beta_2(P_E)$	$\beta_1 < 0, \beta_2 < 0$
5) Positive effects of high precipitation in W followed by warm temperatures in E.	$\phi_{P_W+T_E}$	$\beta_0 + \beta_1(P_W) + \beta_2(T_E)$	$\beta_1 > 0, \beta_2 > 0$
6) Negative effects of high precipitation and cold temperatures in both W and E (no drought effect).	$\phi_{P_W+T_W+P_E+T_E}$	$\beta_0 + \beta_1(P_W) + \beta_2(T_W) + \beta_3(P_E) + \beta_4(T_E)$	$\beta_1 < 0, \beta_2 > 0$ $\beta_3 < 0, \beta_4 > 0$
7) Negative effects of high precipitation or drought, both combined with temperatures, in both W and E.	$\phi_{P_W+P_W^2+P_E+P_E^2+T_W+T_E}$	$\beta_0 + \beta_1(P_W) + \beta_2(P_W)^2 + \beta_3(P_E) + \beta_4(P_E)^2 + \beta_5(T_W) + \beta_6(T_E)$	$\beta_1 > 0, \beta_2 < 0$ $\beta_3 > 0, \beta_4 < 0$ $\beta_5 > 0, \beta_6 > 0$
8) Lagged positive effect of high precipitation in W and warm temperatures in E in time *t* on survival in $t + 1$.	$\phi_{P'_W+T'_E}$	$\beta_0 + \beta_1(P'_W) + \beta_2(T'_E)$	$\beta_1 > 0, \beta_2 > 0$
Reproductive output (*R*)			
1) Negative effects of high precipitation in E.	R_{P_E}	$\beta_0 + \beta_1(P_E)$	$\beta_1 < 0$
2) Negative effects of high precipitation in L.	R_{P_L}	$\beta_0 + \beta_1(P_L)$	$\beta_1 < 0$
3) Negative effects of high precipitation in both E and L.	$R_{P_E+P_L}$	$\beta_0 + \beta_1(P_E) + \beta_2(P_L)$	$\beta_1 < 0, \beta_2 < 0$
4) Negative effects of high precipitation and cold temperatures in W (no drought effect).	$R_{P_W+T_W}$	$\beta_0 + \beta_1(P_W) + \beta_2(T_W)$	$\beta_1 < 0, \beta_2 > 0$
5) Negative effects of high precipitation and cold temperatures in E.	$R_{P_E+T_E}$	$\beta_0 + \beta_1(P_E) + \beta_2(T_E)$	$\beta_1 < 0, \beta_2 > 0$
6) Negative effects of high precipitation and cold temperatures in L.	$R_{P_L+T_L}$	$\beta_0 + \beta_1(P_L) + \beta_2(T_L)$	$\beta_1 < 0, \beta_2 > 0$
7) Negative effects of high precipitation and cold temperatures in both E and L.	$R_{P_E+T_E+P_L+T_L}$	$\beta_0 + \beta_1(P_E) + \beta_2(T_E) + \beta_3(P_L) + \beta_4(T_L)$	$\beta_1 < 0, \beta_2 > 0$ $\beta_3 < 0, \beta_4 > 0$
8) Negative effects of high precipitation and cold temperatures in both W and E.	$R_{P_W+T_W+P_E+T_E}$	$\beta_0 + \beta_1(P_W) + \beta_2(T_W) + \beta_3(P_E) + \beta_4(T_E)$	$\beta_1 < 0, \beta_2 > 0$ $\beta_3 < 0, \beta_4 > 0$
9) Positive effects of high precipitation in W followed by warm temperatures in E.	$R_{P_W+T_E}$	$\beta_0 + \beta_1(P_W) + \beta_2(T_E)$	$\beta_1 > 0, \beta_2 > 0$
10) Positive effects of high precipitation in W followed by warm temperatures in L.	$R_{P_W+T_L}$	$\beta_0 + \beta_1(P_W) + \beta_2(T_L)$	$\beta_1 > 0, \beta_2 > 0$
11) Positive effects of high precipitation in W followed by warm temperatures in E and L.	$R_{P_W+T_E+T_L}$	$\beta_0 + \beta_1(P_W) + \beta_2(T_E) + \beta_3(T_L)$	$\beta_1 > 0, \beta_2 > 0$ $\beta_3 > 0$
Recruitment rate (*b*)			
1) Negative effects of high precipitation in D.	b_{P_D}	$\beta_0 + \beta_1(P_D)$	$\beta_1 < 0$
2) Negative effects of high precipitation in both D and W.	$b_{P_D+P_W}$	$\beta_0 + \beta_1(P_D) + \beta_2(P_W)$	$\beta_1 < 0, \beta_2 < 0$
3) Negative effects of high precipitation and cold temperatures in D.	$b_{P_D+T_D}$	$\beta_0 + \beta_1(P_D) + \beta_2(T_D)$	$\beta_1 < 0, \beta_2 > 0$
4) Negative effects of high precipitation in D, W, and E.	$b_{P_D+P_W+P_E}$	$\beta_0 + \beta_1(P_D) + \beta_2(P_W) + \beta_3(P_E)$	$\beta_1 < 0, \beta_2 < 0$ $\beta_3 < 0$
5) Negative effects of high precipitation and cold temperatures in D with high precipitation in W.	$b_{P_D+T_D+P_W}$	$\beta_0 + \beta_1(P_D) + \beta_2(T_D) + \beta_3(P_W)$	$\beta_1 < 0, \beta_2 > 0$ $\beta_3 < 0$
6) Negative effects of high precipitation and cold temperatures in both D and W.	$b_{P_D+T_D+P_W+T_W}$	$\beta_0 + \beta_1(P_D) + \beta_2(T_D) + \beta_3(P_W) + \beta_4(T_W)$	$\beta_1 < 0, \beta_2 > 0$ $\beta_3 < 0, \beta_4 > 0$

Notes: *P* and *T* indicate precipitation and temperature covariates, respectively. Abbreviations for life history periods where covariates apply are: W, winter stress; E, early nesting; L, late nesting; D, dispersal; and H, heat stress period.

† Expected direction in regression coefficients, given that the hypothesized model is correct to use.

1 was a hypothesis that high precipitation would negatively affect recruitment by negatively affecting the hunting success of juveniles when they first disperse. We based models 2 and 4 on a similar supposition, but over the longer period of time when young owls must first fend for themselves during dispersal. In models 3, 5, and 6, we considered the effects of temperature in addition to precipitation. Because recruitment is a function of survival and reproduction, we tested all of the Table 2 hypothesized models related to those parameters. We made an additional prediction based on potential population dynamics: if floaters were present in sufficient numbers, then climate covariates that negatively affect the survival of territory holders should

TABLE 3. A priori hypothesized models used to relate the effects of landscape habitat characteristics with survival and reproduction of Northern Spotted Owls in northwestern California; θ represents either apparent survival or reproductive output.

13) $\theta_{SOCOR+SOMP+SOEDG}$	$\beta_{SOCOR} > 0$, $\beta_{SOMP} > 0$, $\beta_{SOEDG} < 0$	$\beta_{ln(SOCOR)} > 0$, $\beta_{ln(SOMP)} > 0$, $\beta_{ln(SOEDG)} < 0$	$\beta_{SOCOR} > 0$, $\beta_{(SOCOR)^2} < 0$ $\beta_{SOMP} > 0$, $\beta_{(SOMP)^2} < 0$ $\beta_{SOEDG} > 0$, $\beta_{(SOEDG)^2} < 0$

Note: Subscripted covariates represent the structure of the model, and covariates are described in Table 1.
† Represented as $\beta_0 + \beta_1 x + (-\beta_2 x^2)$.

positively affect recruitment; otherwise, covariates negatively affecting survival also should negatively affect recruitment. This prediction applied to all of the Table 2 hypothesized models for survival and recruitment.

Habitat models.—We developed 13 base hypothesized models to examine the effects of the 10 covariates on Northern Spotted Owl survival and reproduction (Table 3). The response variable (θ) was either apparent survival or reproductive output, and the independent variables were combinations of the nine habitat covariates, age, and elevation effects. These models were centered around three basic themes: habitat amounts only, distribution of habitat patches, and shape of habitat patches (i.e., edge effects). In addition, there were two general effects, which we felt could influence all of the base hypothesized models. The first was age: we predicted that 1–2 yr old owls would have lower apparent survival and lower reproductive output than owls ≥3 yr old. Based on a limited sample, Carey et al. (1992) found that radio-tagged 1-yr-old Northern Spotted Owls suffered high mortality in highly fragmented landscapes. Therefore, the initial age effect in survival analyses included a 1-yr-old class vs. a class with owls ≥2 yr old (denoted as *a*2 in models; Table 1). Franklin et al. (1996*b*) found that 1- and 2-yr-old owls fledged fewer young, on average, than did owls ≥3 yr old on this study area. Therefore, the initial age effect in reproductive output analyses included a class with 1- and 2-yr old owls vs. a class with owls ≥3 yr old (denoted as *a*2′ in models). During modeling procedures, we also examined the age effect by separating owls into 1-, 2-, and ≥3-yr-old classes (denoted as *a*3; see Table 1). The second general effect was ELEV: we predicted that both survival and reproductive output would be negatively affected as elevation increased, because of harsher climatic conditions at higher elevations, and a shift from Douglas-fir/hardwood forests at lower elevations to more pure fir stands at higher elevations, which were less productive in terms of prey biomass (Carey et al. 1992).

Alternate forms (Eqs. 9, 10, and 13) of the same model represented alternate hypotheses as to whether the Northern Spotted Owl is primarily an interior, edge, or mixed interior–edge species. For example, a life history trait positively associated with SOCOR and negatively associated with SOEDG in a linear or pseudothreshold relationship suggests an interior species; the opposite trend would indicate an edge species; and a quadratic relationship would indicate a mixed interior–edge species.

Model 1 in Table 3 was based on the hypothesis that survival and reproductive output increase as the amount of spotted owl habitat increases, as suggested by Bart and Earnst (1992) and Bart and Forsman (1992). The quadratic form of this model suggested some optimal amount of vegetation type (such as mature and old-growth forest) that promotes high survival or reproductive output, with too much or too little of the vegetation type being suboptimal. Hypothesized models 2–5 incorporated patch dynamics in which a single large patch promotes higher survival or reproductive output than do many small, distantly spaced patches under the linear and pseudothreshold forms, and some optimal maximum under the quadratic forms. Hypothesized models 6–13 incorporated amounts of habitat, patch distribution, and patch shape to varying degrees, and included the possibility of alternate hypotheses concerning the juxtaposition of edge and interior spotted owl habitats and their distribution within the territory.

Estimation of life history traits

Modeling survival.—Capture–recapture models were used to estimate conditional survival probabilities (ϕ) for Northern Spotted Owls from the banding data (Franklin et al. 1996*a*). Capture–recapture estimates of juvenile survival (probability of fledged young surviving their first year) are not considered here because of likely biases due to permanent emigration from study areas (Franklin et al. 1996*b*). Instead, recruitment was estimated with the climate covariates (see *Modeling recruitment*).

We examined capture–recapture data for goodness-of-fit to a global model, using tests in program RELEASE (Burnham et al. 1987:71–77). Goodness-of-fit for reduced models was assessed by computing likelihood ratio tests between global and reduced models, and then adding the χ^2 values and degrees of freedom from these tests to global model values (Lebreton et al. 1992). The requisite assumptions of capture–recapture models are outlined in Burnham et al. (1987), most of which can be tested in program RELEASE. No loss of bands was observed through double banding of owls with both color and U.S. Fish and Wildlife Service (USFWS) bands. Permanent emigration probably was negligible for owls $\geq$1 yr old (Franklin et al. 1996*b*). We used program MARK (White and Burnham 1999) for analysis of capture–recapture data. We used 95% confidence intervals to assess the degree to which the signs of estimated slope parameters (β_i) in models were reliably estimated (Graybill and Iyer 1994).

In climate models, estimates of ϕ represent apparent survival, defined as the probability that an owl survives and remains within the study area to year $t + 1$, given that it was alive at the start of year t. Recapture probabilities (p) must also be modeled and are the probability that an animal alive in year t is captured in year t. Recapture probabilities are nuisance parameters, but must be properly treated; otherwise, estimators of survival probabilities will be biased or imprecise (Lebreton et al. 1992). Parameter estimation was based on Fisher's method of maximum likelihood (Lebreton et al. 1992). Relationships of estimated survival probabilities to climatic covariates were modeled using the logit transformation, which constrains $0 \leq \theta \leq 1$, where θ represents either ϕ or p (Lebreton et al. 1992). These parameters could then be modeled as a linear logistic function, e.g., $\text{logit}(\theta_w) = \beta_0 + \beta_1(w)$, where w is a categorical (e.g., age class) or a continuous (e.g., precipitation) covariate. In addition to climate covariates, we included age (a), sex (s), and time effects in the models. Time was modeled both as a categorical (t) and linear (lt) effect without any climate covariates. In addition to modeling the same effects on p, we also modeled the structure of p constrained by different capture methods used during the study, denoted as p_c. During 1985–1987, birds were physically recaptured each year to read their USFWS bands, whereas from 1988 through 1994, owls were primarily resighted using color bands. Models with p_c represented a single estimate of p for 1986–1987 and a single estimate of p for 1988–1994.

In climate models, precipitation was denoted as P and temperature degree-hours as T. Life history periods were denoted with subscripts; W for the winter stress period, E for the early nesting period, L for the late nesting period, H for the heat stress period, and D for the dispersal period. This notation was also used for models of recruitment and reproductive output.

In terms of habitat covariates, we estimated apparent survival (ϕ), defined as the probability that an owl on territory i survives and remains on territory i to year $t + 1$, given that it was alive at the start of year t. We used the same capture history matrix used with the climate models, except for two adjustments. These adjustments were necessary because we examined effects on individuals rather than on annual cohorts of individuals (as with the climate models). First, ''losses on capture'' (Jolly 1965) were used to account for movements of individuals between territories. For example, a capture history for individual 1 that occupied territory A for the first five years and territory B for the second five years might appear as follows:

	1	2	3	4	5	6	7	8	9	10	Frequency
Capture occasion:	1	2	3	4	5	6	7	8	9	10	Frequency
Territory:	A	A	A	A	A	B	B	B	B	B	
Capture history:	1	1	1	0	1	1	1	1	0	1	1

where frequency is the number of capture histories. However, using ''losses on capture,'' the capture history for this individual was rewritten as two capture histories, one for territory A and one for territory B:

Capture occasion:	1	2	3	4	5	6	7	8	9	10	Frequency
Territory:	A	A	A	A	A	B	B	B	B	B	
Capture history 1	1	1	1	0	1	0	0	0	0	0	−1
Capture history 2:	0	0	0	0	0	1	1	1	0	1	1

Second, territories in which timber harvest had occurred during the study were considered to be a movement from the pre-harvest territory to the post-harvest territory after the year when harvest had occurred. Capture histories on these territories were dealt with in the same manner, using ''losses on capture'' as movements of individuals between territories. Use of losses on capture resulted in the loss of information on survival between the occasions when movements or timber harvest occurred. However, in losing this information, no assumption was required as to which territory affected survival during these intervening periods. For each individual capture history, we attached landscape covariates associated with the territory occupied by that individual. Thus, the sampling unit to which inferences were made was individuals on territories.

Modeling reproductive output.—In counting the number of fledged young within each year, we assumed detection probabilities of fledged young equal to 1.0 after two visits to a site. There are numerous biases that may affect estimation of reproductive output (see Franklin et al. 1996*a*). As long as biases were unaffected by climate and did not vary from year to year, our estimates of reproductive output provided a reasonable approximation as a basis for examining temporal effects.

Data analysis for climate models was performed on mean annual reproductive output, R_t ($t = 1, 2, \ldots, 10$ yr), which was defined as the mean annual number of young fledged per pair and which was estimated from the number of owl pairs assessed for reproductive output each year ($n = 38$–74). To examine the effects of climate covariates, we used linear regression models with expected annual reproductive output (R) as the response. The use of linear regression assumed normally distributed subpopulations within years and similar subpopulation variances across years (Graybill and Iyer 1994:110). Our data probably met the first assumption because means, in general, are normally distributed under the Central Limit Theorem, regardless of the underlying distribution (Johnson 1995). The second assumption could not be met. Annual sampling variances were proportional to their means, but were not distributed as Poisson ($P < 0.01$) because fewer broods of one young were observed relative to broods of zero and two young. To deal properly with the lack of homogeneity of variances in estimating $\sigma^2_{\text{residual}}$, we used a maximum likelihood equivalent of least squares regression (Sakamoto et al. 1986:181), which accounted for separate variance components. The generalized linear model we used was $\hat{R}_i = \mathbf{X\beta} + \varepsilon_i + \gamma_i$, where $\mathbf{X}$ was the design matrix, $\boldsymbol{\beta}$ was the vector of parameters, $\varepsilon_i \sim \mathcal{N}(0, \sigma^2_{\text{residual}})$ that incorporated residual variation unexplained by the model, and $\gamma_i \sim \mathcal{N}(0, \text{var}(\hat{R}_i \mid R_i))$ that incorporated sampling variation around the R_i. Solution of this model was expressed as the likelihood to be maximized (McCullagh and Nelder 1989:24, 254):

$$\ln \mathcal{L}(\boldsymbol{\beta}, \sigma^2_{\text{residual}}) = -\frac{1}{2}\ln|\mathbf{D}| - \frac{1}{2}\mathbf{Y}'[\mathbf{D}^{-1} - (\mathbf{D}^{-1}\mathbf{X})(\mathbf{X}'\mathbf{D}^{-1}\mathbf{X})^{-1}(\mathbf{D}^{-1}\mathbf{X})']\mathbf{Y} \quad (14)$$

where $\mathbf{D}$ was the dispersion matrix with $\sigma^2_{\text{residual}} + \widehat{\text{var}}(\hat{R}_i \mid R_i)$ as the diagonal elements and $\sigma^2_{\text{residual}} + \widehat{\text{covar}}(\hat{R}_i, \hat{R}_j \mid R_i, R_j)$ as the off-diagonal elements, and $|\mathbf{D}|$ was the determinant of $\boldsymbol{D}$. Eq. 14 was solved numerically for $\sigma^2_{\text{residual}}$ at the maximum log likelihood, which was equivalent to minimizing the sum of the squared ε_i under least squares estimation procedures (Draper and Smith 1981:88). The β_i were estimated as $\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{D}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{D}^{-1}\mathbf{Y}$, with the corresponding variance–covariance matrix as $\hat{\mathbf{V}} = (\mathbf{X}'\mathbf{D}^{-1}\mathbf{X})^{-1}$. This procedure was a regression model that included random measurement error and allowed for direct estimation of $\sigma^2_{\text{residual}}$.

In addition to the climate covariates included in the hypothesized reproduction models (Table 2), we included age and sex effects in models as the proportion of the pairs checked each year that had males (m) and females (f) $\geq$3 yr old. We evaluated the goodness-of-fit of models to the data, based on deviance estimates and examination of residual plots. Deviance was estimated as $2(\ln \mathcal{L}_{\max} - \ln \mathcal{L}_{\text{model}})$, where $\ln \mathcal{L}_{\max}$ is the maximum achievable log likelihood, given the data, and $\ln \mathcal{L}_{\text{model}}$ is the log likelihood for the model of interest (McCullagh and Nelder 1989:33). We used deviance to test whether a given model adequately fits the data relative to the saturated model (in which the number of parameters equals the number of data points), which is asymptotically distributed as χ^2 with $n - K$ degrees of freedom. We also visually examined plots of standardized residuals against time, the predictors, and $\hat{R}$ for indications of lack of normality or heteroscedasticity (Graybill and Iyer 1994:251).

To examine the effects of landscape habitat covariates, we estimated reproductive output (mean annual number of young fledged per territory, again denoted as R) using general linear mixed models. Mixed models were used to appropriately estimate the standard error of the sex, age, and landscape covariates that were considered fixed effects. Territory was considered a random effect, such that standard errors of the fixed effects were estimated using the number of territories ($n = 95$) rather than the total number of reproductive outcomes occurring over all territories ($n = 598$). In addition, mixed models allowed for direct estimation of variance components, notably the spatial process variation in reproductive output among owl territories. Ideally, territories should have been randomly sampled from a larger population in order to be considered random effects, but they were not. However, the focus of the analysis was on habitat effects, where the territories acted as blocks, and not on territory effects. Therefore, we considered territories to be a random effect, recognizing that they were not randomly drawn from a larger population.

The form of the general linear mixed model we used was

$$\mathbf{Y} = \mathbf{X\beta} + \mathbf{Zu} + \mathbf{e} \quad (15)$$

where **Y** is an n-vector of observed reproductive output over t years and s territories; **X** was an n by p known design matrix representing p effects; $\boldsymbol{\beta}$ was a p-vector of unknown fixed-effect regression parameters; **Z** was an n by q known design matrix for the random-effects portion of the model; **u** was the q-vector of unknown random coefficient parameters; and **e** was the n-vector of random (often measurement) errors whose elements were not required to be independent (Wolfinger 1993, Littell et al. 1996). The variance of y is $\sigma^2_{\text{spatial}} + \sigma^2_{\epsilon}$, where $\sigma^2_{\text{spatial}}$ is the spatial process variance component among spotted owl territories, and σ^2_{ϵ} is the variance due to random errors. The covariance matrix of **Y** is denoted as: $\mathbf{V}(\mathbf{Y}) = \mathbf{ZGZ}' + \mathbf{E}$, where **G** is the diagonal matrix containing variance components (i.e., $\sigma^2_{\text{spatial}}$), and **E** contains the error variances, i.e., σ^2_{ϵ} (Jennrich and Schluchter 1986, Wolfinger 1993). The random variable **u** and error vector **e** are assumed to be distributed as multivariate normal with a mean vector of zero and covariance matrix **E**. Thus, **Y** is assumed to be distributed as multivariate normal with mean $\mathbf{X}\boldsymbol{\beta}$ and variance $\mathbf{ZGZ}' + \mathbf{E}$. Several lines of evidence support the use of a normal-based approach in analyzing these data. ANOVA methods are robust to fairly severe departures from normality and heterogeneity in sampling variances, even with data distributed as a negative binomial (Mitchell 1977, White and Bennetts 1996). Although Poisson regression in a generalized linear model may adequately deal with overdispersion in count data, such as that used in estimating reproductive output, ANOVA is more robust to considerable departures from non-normality and heterogeneity of sampling variances than is Poisson regression when count data are not distributed as Poisson (White and Bennetts 1996).

The error variance matrix **E** can be structured to account for heterogeneous sampling variance structures using maximum likelihood approaches (Littell et al. 1996), which are analogous to a weighted regression (Draper and Smith 1981:108). Thus, the problem of heterogeneous sampling variances discussed previously can be dealt with adequately. We used a maximum likelihood-based approach in PROC MIXED of program SAS (SAS Institute 1997) to model first the covariance structure of **E** and then to examine the fixed effects in the hypothesized models and their variants. Following Diggle (1988) and Wolfinger (1993), we used restricted maximum likelihood estimation in an over-fitted model that included all of the fixed effects to explore various covariance structures in **E** to model annual sampling variances. Selection of an appropriate covariance structure was based on AICc (see *Model selection*) using the number of estimated covariance parameters, but not the number of estimated fixed effects, because restricted maximum likelihood estimation is based solely on the covariance parameters. Once an appropriate covariance structure was achieved for properly weighting the years, full maximum likelihood estimation, rather than restricted maximum likelihood estimation, was used as the basis for examining hypothesized models because the latter eliminates the fixed effects (Wolfinger 1993).

We modified the data slightly to estimate reproductive output with the landscape habitat covariates. First, we excluded eight Northern Spotted Owl territories in which reproductive output had not been adequately estimated for at least three years. This reduced the number of territories included in the analysis to 87. In addition, we included only reproductive outcomes in which the female age was known (to allow for adequate modeling of female age effects). Female age has a strong effect on reproductive output (Franklin et al. 1996*b*), whereas male age seems to have little effect (Franklin 1992). Thus, reproductive output was redefined as the mean annual number of young fledged per female of known age.

Modeling recruitment.—Recruitment is a function of survival of young through their first year, reproductive output, and immigration. Immigration in Northern Spotted Owls may be from interterritorial movements or from a surplus population of nonterritorial birds, i.e., floaters (Franklin 1992). Spotted owls are highly territorial and tend to exhibit high site and mate fidelity (Forsman et al. 1984, Gutiérrez et al. 1995), suggesting that spacing behavior may limit the number of individuals that are able to breed. Thus, recruitment is an important parameter because it represents the successful integration of young into the breeding population, even when that entry is delayed by several years (young may enter a floating, surplus population before attaining a territory; Franklin 1992). Recent developments in capture–recapture theory (e.g., Schwarz and Arnason 1996) allowed recruitment to be modeled using the approach previously outlined.

Recruitment was estimated from a subset of the capture–recapture data using modeling procedures in program POPAN-4 (Arnason et al. 1995). This subset included data from the Willow Creek study area and 12 sites from satellite areas that had been consistently surveyed since 1985. Recruitment was modeled with the climate covariates under a framework similar to that for survival probabilities, with some exceptions. In the most general model under POPAN-4, maximum likelihood estimates are computed simultaneously for ϕ_t, p_t, and two new parameters: ψ_t, the fraction of total net births that enter the system between t and $t + 1$ (called entry probabilities), and N_{tot}, the total number of animals that enter the system and survive until the next sample time (Schwarz and Arnason 1996) during the 10-yr study period. Population size, N_t, is then estimated from these parameters. Parameter estimates of, ϕ, p, and ψ can be constrained by external covariates. Model selection procedures followed those described in *Modeling survival.* However, POPAN-4 does not allow the inclusion of group effects, such as sex, so we were unable to estimate recruitment separately for males and females.

In all recruitment models, ϕ and p were structured based on the best climate model selected from the survival analysis. Hypothesized models were first analyzed in terms of ψ. After selection of the ''best'' model in terms of ψ, we estimated recruitment rate (b) as

$$\hat{b}_t = \frac{\hat{\psi}_t \hat{N}_{\text{tot}}}{\hat{N}_{t-1}} \tag{16}$$

where $\hat{N}_{t-1}$ was the estimated territorial population size from the previous year, and $\hat{\psi}_t \hat{N}_{\text{tot}}$ represented the number of new recruits into the territorial population at time t. Thus, b was the number of new recruits in the territorial population at time $t + 1$ per territory holder in time t. The variance–covariance matrix for $\hat{b}$ was estimated using the delta method (Bajpai et al. 1978: 146). The estimates of b and their sampling variance–covariance matrix were used in Eq. 14 with the climatic covariates from the selected model to obtain regression coefficients, and their standard errors, in terms of b rather than ψ.

Selection of hypothesized models for life history traits

The most critical problem in analyzing empirical data is selecting an appropriate model that is supported by the science of the situation, by the data, and that has enough parameters to avoid bias, but not so many that precision is lost (Burnham and Anderson 1992). We used a bias-corrected version of Akaike's Information Criterion, AICc (Akaike 1973, Hurvich and Tsai 1989, Burnham et al. 1995) as the basis for objectively ranking models and selecting an appropriate ''best approximating'' model. AICc was defined as

$$\text{AICc} = -2(\ln \mathcal{L}) + 2K + \frac{2K(K+1)}{n-K-1} \tag{17}$$

where $\ln(\mathcal{L})$ is the natural logarithm of the likelihood function evaluated at the maximum likelihood estimates for a given model; K is the number of estimable parameters from that model; and n is sample size. In the capture–recapture models, n was the sum of the total number of animals captured and released in each year. The ''best approximating'' model for each life history trait was selected based on minimum AICc.

Models were ranked and compared using ΔAICc (Lebreton et al. 1992, Burnham and Anderson 1998) and Akaike weights (Buckland et al. 1997). ΔAICc was computed as

$$\Delta\text{AICc}_i = \text{AICc}_i - \text{AICc}_{\min} \tag{18}$$

where AICc_i was the AICc value for the ith model in a suite of models being compared, and $\text{AICc}_{\min}$ was the minimum AICc value among those models. In short, ΔAICc_i is an estimate of the relative distance between the best approximating model and model i. Akaike weights (w_i) were computed for each ith model as follows:

$$w_i = \frac{\exp\left[-\left(\frac{\Delta\text{AICc}_i}{2}\right)\right]}{\sum \exp\left[-\left(\frac{\Delta\text{AICc}_i}{2}\right)\right]}. \tag{19}$$

ΔAICc and Akaike weights were used to address model selection uncertainty. In general, models within 1–2 AICc units of the selected model were considered competing models. Because standard errors estimated for the life history traits are conditional on the selected model, there was another element of uncertainty in selecting an appropriate model when evaluating estimates of precision (Buckland et al. 1997). Therefore, estimates of precision in the parameters may have been somewhat optimistic. We were unable to account for this uncertainty due to model selection using current methods (Buckland et al. 1997), because we were interested in $\hat{\beta}_i$ and $\widehat{\text{SE}}(\hat{\beta}_i)$, which corresponded to different effects among models.

We had a number of variations that represented the specified effects of the base hypothetical models in Tables 2 and 3; of these variations on the same model, we selected the best approximating model based on minimum AICc. Thus, each hypothesized model was represented by a suite of models that included age and elevation effects, interactions between effects, and different forms (i.e., linear, pseudothreshold, and quadratic) of the covariates. We then used the model with minimum AICc from each suite to represent each of the hypothesized models. After model selection, the influence of additional effects, such as sex, on the ''best'' model selected was assessed by examining Akaike weights for the best approximating model, using models that included or excluded pertinent effects of interest. The utility of slope parameters (β_i) in models was assessed based on the degree to which 95% confidence intervals overlapped zero (Graybill and Iyer 1994).

We examined potential correlations between covariates after the analysis of hypothesized models to avoid subjective biases in formulation of the models. Information on correlations between covariates was then used to explore better models for the data than those initially hypothesized. Sensitivity of either $\hat{\phi}$ or $\hat{R}$ to changes in covariates in the best approximating models was assessed by (1) setting covariate values to their mean, (2) changing the covariate of interest by 25% of its mean value, (3) estimating percentage change in $\hat{\phi}$ or $\hat{R}$ due to the 25% change in the covariate of interest, and (4) ranking covariates based on the percentage change in $\hat{\phi}$ or $\hat{R}$. Sensitivities were expressed as percentage change in the parameter.

Estimation of fitness

Rates of population change.—We estimated annual rates of population change (λ) as a function of both recruitment rate and apparent survival. Population size can be expressed in terms of the difference equation:

$$N_{t+1} = (\beta + i)N_t + (1 - d - e)N_t \qquad (20)$$

where, β *d*, *i*, and *e* are rates of birth, death, immigration, and emigration, respectively. Because our estimates of recruitment rate and apparent survival can be expressed as $\hat{b} = \hat{\beta} + \hat{\imath}$ and $\hat{\phi} = 1 - \hat{d} - \hat{e}$, Eq. 20 can be rewritten as $\hat{N}_{t+1} = \hat{b}\hat{N}_t + \hat{\phi}\hat{N}_t$. By definition, annual estimates of λ can be expressed as $\hat{\lambda}_t = \hat{N}_{t+1}/\hat{N}_t$, which can then be rewritten, in terms of recruitment rates and apparent survival, as

$$\hat{\lambda}_t = \hat{b}_t + \hat{\phi}_t. \qquad (21)$$

Sampling variances for $\hat{\lambda}_t$ were estimated as $\widehat{\text{var}}(\hat{\lambda}_t) = \widehat{\text{var}}(\hat{b}_t) + \widehat{\text{var}}(\hat{\phi}_t) + 2\widehat{\text{cov}}(\hat{b}_t,\hat{\phi}_t)$ (Bajpai et al. 1978).

To evaluate potential long-term consequences of climate variation on life history traits and rates of population change, we examined the behavior of climate models for each life history trait using a long-term record of climatic observations from 1955 through 1984 obtained from the same weather stations used to develop the climate models. We examined model behavior using a forecasting philosophy (what could happen, given that a particular empirical model is correct and underlying conditions remain similar) rather than as prediction (what will happen) (Caswell 1989*a*:20). We also used the same covariates as those used to develop the models, and that appeared in the final selected climate models. Sampling variances of estimates from before the study period were estimated using the delta method (Bajpai et al. 1978).

Habitat fitness potential.—To estimate fitness, we used the Leslie matrix approach outlined by McGraw and Caswell (1996), but with some modifications. We estimated the necessary components of fitness (survival and reproductive output) based on landscape habitat characteristics, not on individual attributes. Therefore, we defined *habitat fitness potential* (λ_H) as the fitness conferred on an individual occupying a territory of certain habitat characteristics. This definition does not imply that territories have fitness themselves, because territories with high habitat fitness potential may not always be occupied; occupancy was not included in the estimation of fitness. Rather, λ_H can be viewed as the potential fitness that an individual can achieve if it occupies a particular territory with certain habitat characteristics.

To estimate λ_H, we used the best approximating models for survival and reproductive output to estimate survival, fecundity, and their sampling variances for each of the 95 Northern Spotted Owl territories. Sampling variances were estimated using the delta method (Bajpai et al. 1978), which incorporated the covariance matrix from the best approximating model. Fecundity (the mean number of female young fledged per female) was estimated by dividing estimates of reproductive output by two; the sampling variances for fecundity were calculated by dividing the sampling variances for reproductive output by 4 (see Franklin et al. 1996*a*). Because fecundity was female based, λ_H was applicable to female fitness only.

Once survival and fecundity had been estimated for each of the 95 territories, λ_H was estimated for each territory as the dominant, real eigenvalue of an estimated stage-based Leslie matrix. This matrix took the following form:

$$\begin{bmatrix} \hat{\phi}_{1,2}\hat{m}_{1,2} & \hat{\phi}_{1,2}\hat{m}_3 & \hat{\phi}_3\hat{m}_3 \\ \hat{\phi}_{1,2} & 0 & 0 \\ 0 & \hat{\phi}_{1,2} & \hat{\phi}_3 \end{bmatrix} \qquad (22)$$

where $\hat{\phi}$ was apparent survival; and $\hat{m}$ was fecundity, with subscripts ''1, 2'' representing parameter estimates for 1- and 2-yr-old owls, and subscript ''3'' representing estimates for owls >3 yr old. The form of the matrix was based on the age effects found in the best models for survival and reproductive output (see *Results*). For example, estimates of ϕ and reproductive output for territory A were obtained from the best models for survival and reproductive output, respectively, using the habitat covariates from territory A. After transforming reproductive output to fecundity, we then used these estimates in matrix 22 to estimate λ_H for territory A.

The final form of the matrix depended on the age structure in the best approximating models for survival and reproductive output. Standard errors of territory-specific estimates of λ_H were estimated using the delta method, which incorporated the standard errors for territory-specific estimates of the survival and fecundity estimates. Incorporation of age structure into the estimates of λ_H further complicated its interpretation. If age structure was incorporated into the best approximating models for either survival or reproductive output, then λ_H was based on a female first colonizing a territory as a 1- or 2-yr-old.

Components of variation analysis

We used the annual means estimated directly from the data as a basis for estimating temporal process variation ($\sigma^2_{\text{temporal}}$) in reproductive output. The capture–recapture data were initially modeled with time effects to determine whether temporal process variation existed. If a time-dependent model (ϕ_t or b_t) explained the data better than did a model with time-invariant parameters ($\phi_\cdot$ or $b_\cdot$), the annual estimates from that model were used to estimate $\sigma^2_{\text{temporal}}$. Temporal process variation in each of the life history parameters and rates of population change was estimated as the numerical solution of the following equation for $\sigma^2_{\text{temporal}}$ (after Burnham et al. 1987:263):

$$\left[\frac{1}{n-1}\right]\left[\left(\mathbf{P} - \hat{\bar{\theta}}\,\mathbf{1}\right)'\mathbf{D}\left(\mathbf{P} - \hat{\bar{\theta}}\,\mathbf{1}\right)\right]' = 1 \qquad (23)$$

where

$$\hat{\bar{\theta}} = [(\mathbf{DP})'\ \mathbf{1}][(\mathbf{D1})'\ \mathbf{1}]^{-1} \quad (24)$$

and $\mathbf{D} = (\sigma^2_{\text{temporal}}\ \mathbf{I} + \mathbf{V})^{-1}$; **P** is a vector containing the annual estimates of either ϕ, R, b, or λ; n is the number of annual estimates; **1** is a vector of 1's; **I** is an identity matrix; **V** is the conditional (sampling) variance–covariance matrix for the estimates; and $\hat{\bar{\theta}}$ is the weighted mean of the parameter of interest. We used the relationship for temporal variation where $\hat{\sigma}^2_{\text{temporal}} = \hat{\sigma}^2_{\text{climate}} + \hat{\sigma}^2_{\text{residual}}$ to estimate the amount of variation due to climate ($\sigma^2_{\text{climate}}$). Because $\sigma^2_{\text{residual}}$ was estimated when modeling reproductive output, $\sigma^2_{\text{climate}}$ was estimated as $\hat{\sigma}^2_{\text{temporal}} - \hat{\sigma}^2_{\text{residual}}$ where $\sigma^2_{\text{temporal}}$ was estimated using Eq. 23. For survival and recruitment, the contribution of $\hat{\sigma}^2_{\text{climate}}$ in explaining $\hat{\sigma}^2_{\text{temporal}}$ was estimated by regressing annual estimates of logit(ϕ) or b, including their sampling variances and covariances, obtained from the time-dependent models (ϕ_t or b_t) against the climatic covariates included in the ''best'' climatic model selected for each life history trait. The form of the regression followed Eq. 14 to estimate $\sigma^2_{\text{residual}}$. The estimated amount of variation explained by the best climate model ($\sigma^2_{\text{climate}}$) could be assessed as $\hat{\sigma}^2_{\text{temporal}} - \hat{\sigma}^2_{\text{residual}}$. Weighted means of parameters were estimated using Eq. 24.

To estimate the amount of spatial process variation ($\sigma^2_{\text{spatial}}$) in survival, we first estimated survival probabilities for each territory, using the same structure on the capture probabilities as the best approximating model. We estimated $\sigma^2_{\text{spatial}}$ using Eqs. 23 and 24. The amount of this variation explained by the best approximating model ($\hat{\sigma}^2_{\text{model}}$) was estimated as the empirical variance of the predicted estimates of $\phi(\tilde{\phi}_i)$ from the following model:

$$\hat{\sigma}^2_{\text{model}} = \frac{\sum_{i=1}^{95} (\tilde{\phi} - \bar{\tilde{\phi}})^2}{n - 1} \quad (25)$$

where $n = 95$ territories. We estimated 95% confidence intervals as:

$$\frac{\sum_{i=1}^{95} (\tilde{\phi} - \bar{\tilde{\phi}})^2}{\chi^2_{94,\,0.975}} \le \sigma^2_{\text{model}} \le \frac{\sum_{i=1}^{95} (\tilde{\phi} - \bar{\tilde{\phi}})^2}{\chi^2_{94,\,0.025}} \quad (26)$$

following Burnham et al. (1987:265).

In the general linear mixed model approach for estimating reproductive output, we estimated $\sigma^2_{\text{spatial}}$ using an intercepts-only (''means'') model in PROC MIXED in SAS (SAS Institute 1997). This model retained the best covariance structure for **E** (Eq. 15) used in the hypothesized model, included territories as a random effect, and used restricted maximum likelihood procedures (Wolfinger 1993). We also ran the best approximating model again, using restricted maximum likelihood procedures to obtain an estimate of the spatial process variation not accounted for by the fixed effects ($\hat{\sigma}^2_{\text{residual}}$). At this point, restricted maximum likelihood procedures estimated variance components based on the residuals after the fixed effects had been fit to the model (Searle et al. 1992:250). Thus, the use of these two models allowed decomposition of $\hat{\sigma}^2_{\text{spatial}}$ into the component explained by the fixed-effects model ($\hat{\sigma}^2_{\text{model}}$) and the component not explained by the fixed-effects model ($\hat{\sigma}^2_{\text{residual}}$). If the best approximating model included only habitat covariates, then the amount of $\hat{\sigma}^2_{\text{spatial}}$ explained by habitat variation ($\hat{\sigma}^2_{\text{habitat}}$) equaled ($\hat{\sigma}^2_{\text{model}}$). However, if age effects were included in the best approximating model, then the amount of spatial process variation due to the age of individuals ($\hat{\sigma}^2_{\text{age}}$) was partitioned by estimating $\hat{\sigma}^2_{\text{residual}}$, using the design matrix for an age effects model and estimating $\hat{\sigma}^2_{\text{age}}$ as $\hat{\sigma}^2_{\text{spatial}} - \hat{\sigma}^2_{\text{residual}}$. An estimate of $\hat{\sigma}^2_{\text{habitat}}$ was then found similarly, using the design matrix containing habitat covariates only from the best approximating model. Log-based 95% confidence intervals for $\hat{\sigma}^2_{\text{spatial}}$ were estimated using $\widehat{\text{SE}}(\hat{\sigma}^2_{\text{spatial}})$ from PROC MIXED and formulas in Burnham et al. (1987:212). We directly estimated $\sigma^2_{\text{spatial}}$ for habitat fitness potential using Eqs. 22 and 23. Log-based 95% confidence intervals were also estimated for $\hat{\sigma}^2_{\text{spatial}}$ of habitat fitness potential.

Coefficients of process variation were estimated as

$$\frac{\sqrt{\hat{\sigma}^2_{\text{process}}}}{\hat{\bar{\theta}}} \quad (27)$$

where $\hat{\bar{\theta}}$ was the weighted mean (based on Eq. 24) of parameters of interest. Coefficients of process variation were used to estimate the degree to which parameters varied over time or space.

Relative contributions of climatic and habitat variation

We examined the importance of climatic and habitat variation by comparing models explaining variation due to climate and habitat, and by comparing components of process variation. In a model selection approach, we combined the effects in the best approximating model used to describe the effects of climate and habitat, respectively, on apparent survival and reproductive output. We used the model selection approach in the following manner to address the question of whether habitat quality buffered individuals from the extremes of climate. For each life history parameter, we analyzed models that combined the climate and habitat covariates from the best approximating models in additive models. We compared these models to ones that included all possible combinations of interactions between climate and habitat covariates. Only the full interactions between climate and habitat covariates were included. We used the notation of (climate covariates)*(habitat covariates) to indicate both main effects and their interactions.

Models with interactions between climate and habitat suggest that habitat might buffer or intensify the effects of climate on individuals, depending on the sign of the slope parameter for the interaction. AICc and Akaike weights were used to determine whether an additive model (one indicating that habitat quality did not buffer climate effects) or a model with interactions (one indicating that habitat quality buffered climate effects) was the best approximating model for the data. In models examining effects on reproductive output, year was considered a fixed effect. Model selection was based on comparisons of AICc and Akaike weights computed for each model. If either of the models containing the climate or habitat covariates alone was strongly selected as the best approximating model, then this suggested that either climatic variation or habitat variation alone was responsible for variation in the life history trait being examined. However, if the model containing both sets of covariates was selected as the best approximating model, this suggested that both climate and habitat were important in influencing process variation of life history traits. This approach examined the relative importance of climate and habitat effects on survival and reproductive output.

In order to estimate the magnitude of the effects of climate and habitat on variation of survival and reproductive output, we used a components of process variation approach. We compared the estimates of the components of process variation separately for survival and reproductive output. The total process variation examined in this study for each life history trait (σ^2_{total}) can be expressed as

$$\sigma^2_{\text{total}} = \sigma^2_{\text{temporal}} + \sigma^2_{\text{spatial}} = \sigma^2_{\text{model}} + \sigma^2_{\text{residual}} \qquad (28)$$

where $\sigma^2_{\text{temporal}}$ and $\sigma^2_{\text{spatial}}$ are the estimates of total temporal and spatial process variation, respectively; σ^2_{model} is the amount of process variation explained by both the models relating the life history trait to climate, habitat, and other effects; and $\sigma^2_{\text{residual}}$ is the amount of process variation unexplained by any of the modeled effects. The estimate of σ^2_{model} can be further partitioned into

$$\sigma^2_{\text{model}} = \sigma^2_{\text{climate}} + \sigma^2_{\text{habitat}} + \sigma^2_{\text{other}} \qquad (29)$$

where $\sigma^2_{\text{climate}}$ was estimated based on the best approximating model containing climate covariates; $\sigma^2_{\text{habitat}}$ was estimated from the best approximating model containing landscape habitat covariates; and σ^2_{other} was any other effects, such as age or sex, that were included in the final models. The proportion of σ^2_{model} accounted for by climate, habitat, or other effects can then be expressed as

$$\frac{\sigma^2_x}{\sigma^2_{\text{model}}} \qquad (30)$$

where x is climate, habitat, or other. In this way, we estimated the relative contributions of climate, habitat, and other effects to total process variation.

Results

Effects of climate on temporal variation in population processes

Survival probabilities.—From 1985 through 1994, we marked 57 1-yr-old, 45 2-yr-old, and 206 ≥3-yr-old Northern Spotted Owls; these were roughly equal by sex (150 females and 158 males ≥1 yr old). A global model $\{\phi_{s*a*t}, p_{s*a*t}\}$ allowing survival and recapture probabilities to vary over time by sex (s) and age classes (a) with all interactions was found to adequately fit the data ($\chi^2 = 50.02$, df = 79, $P = 0.99$). No overdispersion was evident in the data ($\chi^2_{\text{gof}}/\text{df} = 0.633$).

Before modeling with the climatic covariates, we first examined the capture–recapture data for significant time variation, in addition to sex and age class effects, and the interactions between those effects on ϕ and p. These models ranged from the global model with 84 parameters to the simplest model $\{\phi_., p_.\}$ with only two parameters. Intermediate models included various combinations of pooled age classes with and without sex and time effects. Based on minimum AICc, model $\{\phi_t, p_{s+c}\}$ was selected as the best approximating model ($K = 12$ parameters), given only the sex, age, and time effects examined. This model indicated that survival probabilities varied over time, with no sex or age effects, and that recapture probabilities were best structured based on differences in recapture methods during the study that varied by sex. The next four time-only models ranked by AICc (ΔAICc = 0.461–1.667) also included a year-dependent (t) structure in ϕ and included p_c.

We then examined the eight hypothesized climatic models (Table 2) in addition to 79 climatic models representing variations on the hypothesized models (e.g., quadratic structure on, ϕ, different structures on p). Of these models, $\{\phi_{P_E+T_E}, p_{s+c}\}$ was selected as the best approximating model based on AICc (Table 4), where the annual estimates of P_E and T_E explained time variation better than just the time model $\{\phi_t, p_{s+c}\}$. The data did not support inclusion of sex effects or a quadratic term in the selected model to simulate the negative effects of drought (Table 5). Model $\{\phi_{P_E+T_E}, p_{s+c}\}$ still exhibited adequate goodness-of-fit to the capture–recapture data ($\chi^2 = 125.63$, df = 157, $P = 0.97$). Therefore, we retained $\{\phi_{P_E+T_E}, p_{s+c}\}$ as the most parsimonious explanation of survival in spotted owls ≥1 yr old. This model was a better explanation of the data than those based on variable or linear time models (Table 4). Model $\{\phi_{P_E+T_E}, p_{s+c}\}$ explained variation in survival as

$$\hat{\phi} = \frac{1}{1 + \exp[-(0.11164 - 0.06753P_E + 0.01035T_E)]} \qquad (31)$$

where $\widehat{\text{SE}}(\hat{\beta}_0) = 1.0844$; $\widehat{\text{SE}}(\hat{\beta}_1) = 0.0346$ (95% CI = -0.1353, 0.0003); and $\widehat{\text{SE}}(\hat{\beta}_2) = 0.0038$ (95% CI = 0.0029, 0.0178). Confidence intervals for both slope pa-

‡ Number of estimable parameters.

rameters suggested that the effects were real. Recapture probabilities were high, with $\hat{p} = 0.723$ ($\widehat{\text{SE}}(\hat{p}) = 0.050$) and 0.797 ($\widehat{\text{SE}}(\hat{p}) = 0.058$) for females and males in 1986–1987, respectively, and $\hat{p} = 0.912$ ($\widehat{\text{SE}}(\hat{p}) = 0.018$) and 0.940 ($\widehat{\text{SE}}(\hat{p}) = 0.022$) for females and males in 1988–1994, respectively. Under $\{\phi_{P_E+T_E}, p_{s+c}\}$, annual survival was negatively affected by increased precipitation (P) and positively affected by increased temperature (T) during the early nesting period (E). Thus, cold, wet springs had a negative effect on survival, whereas warm, dry springs had a positive effect (Fig. 4a). Changes in apparent survival predicted from Eq. 31 were most sensitive to changes in T_E (17.8% change in $\hat{\phi}$) followed by changes in P_E (4.5% change in $\hat{\phi}$). The model selected accounted for a substantial amount of the temporal process variation in survival probabilities (Table 6). However, the coefficient of temporal variation based on $\hat{\sigma}^2_{\text{temporal}}$ was relatively small, suggesting that temporal process variation in annual survival probabilities was low (Table 6).

One model, $\{\phi_{P_W+P_E}, p_{s+c}\}$, was weighed almost equally with $\{\phi_{P_E+T_E}, p_{s+c}\}$ and was considered a potential competitor to this model (Table 4), representing another possible explanation for survival that was still negatively affected by increased precipitation in the early nesting period, but positively affected by increased precipitation during the winter. The covariates P_E and P_W were not highly correlated ($r = 0.29$), which suggested that model $\{\phi_{P_W+P_E}, p_{s+c}\}$ was not competitive because of colinearity between P_E and P_W. However, inclusion of the covariate P_W in model $\{\phi_{P_E+T_E}, p_{s+c}\}$ (e.g., as $\{\phi_{P_W+P_E+T_E}, p_{s+c}\}$) was not well supported (Table 5). Therefore, we retained the selected model $\{\phi_{P_E+T_E}, p_{s+c}\}$ in analyses of population rates of change, but suspected that model $\{\phi_{P_W+P_E}, p_{s+c}\}$ may be important in future analyses when more data have been collected, or in other data sets.

Reproductive output.—Annual estimates of R varied from 0.150 to 0.810 (Fig. 4b). Estimation of R did not require the intermediate modeling process used with

TABLE 5. Ranking of the best approximating models for apparent survival, reproductive output, and recruitment for Northern Spotted Owls in northwestern California, relative to models in which specific effects were included, excluded, or changed.

Model	Change in best approximating model	AICc	ΔAICc$_i$	w_i

the capture–recapture data. Therefore, resulting estimates were used directly in the components of variance analysis. We examined the 11 hypothesized climate models (Table 2) in addition to 56 intermediate models that included the age and sex covariate (m and f) and different nonlinear structures of the climatic covariates. Of the models examined, model $\{R_{P_L^2}\}$ had the lowest AICc (Table 4) and was selected as the best approximating model given the data. We were unable to compare other models with model $\{R_t\}$ using AICc because model $\{R_t\}$ was saturated (i.e., $K = n$). The form of model $\{R_{P_L^2}\}$ was

$$\hat{R} = 0.8394 - 0.0030\ (P_L)^2 \qquad (32)$$

where R was mean annual reproductive output and P_L was the number of days of measurable precipitation during the late nesting period. The goodness-of-fit test based on deviance indicated no evidence for lack of fit of the data to the model selected ($\chi^2 = 6.051$, df = 7, $P = 0.534$). Examination of residual plots did not suggest any violation of the key assumptions in linear regression. Therefore, model $\{R_{P_L^2}\}$ was considered an appropriate model for relating mean annual reproductive output with climatic variation in the linear modeling framework. Parameter estimates were precise for this model, with $\widehat{\text{SE}}(\hat{\beta}_0) = 0.0538$ and $\widehat{\text{SE}}(\hat{\beta}_1) = 0.0004$ (95% CI = −0.0040, −0.0021). Confidence intervals for $\hat{\beta}_1$ did not overlap zero, supporting a negative trend in reproductive output with respect to precipitation during the late nesting period.

Model $\{R_{P_L^2}\}$ represented hypothesized model 2 (Table 2), which predicted a negative relationship between reproductive output and precipitation during the late nesting period. The quadratic effect in this, and in model $\{R_{P_L+P_L^2}\}$, was not indicative of a drought effect, as proposed in some of the models. Rather, it appeared to describe more of a plateau effect in reproductive output at lower levels of precipitation (Fig. 4b). The one extreme point in Fig. 4b was not considered an outlier, but a real event that represented a region-wide reduction in reproductive output throughout the range of the Northern Spotted Owl (see Burnham et al. 1996). In not including the P_L term in the quadratic, model $\{R_{P_L^2}\}$ restricts maximum reproductive output at zero number of days of precipitation. However, lack of this term in the selected model suggests that this was an appropriate restriction (Table 5). Based on Akaike weights, the selected model was heavily weighted (Table 4), suggesting that the other hypothesized models were not competitive with the selected model. Inter-

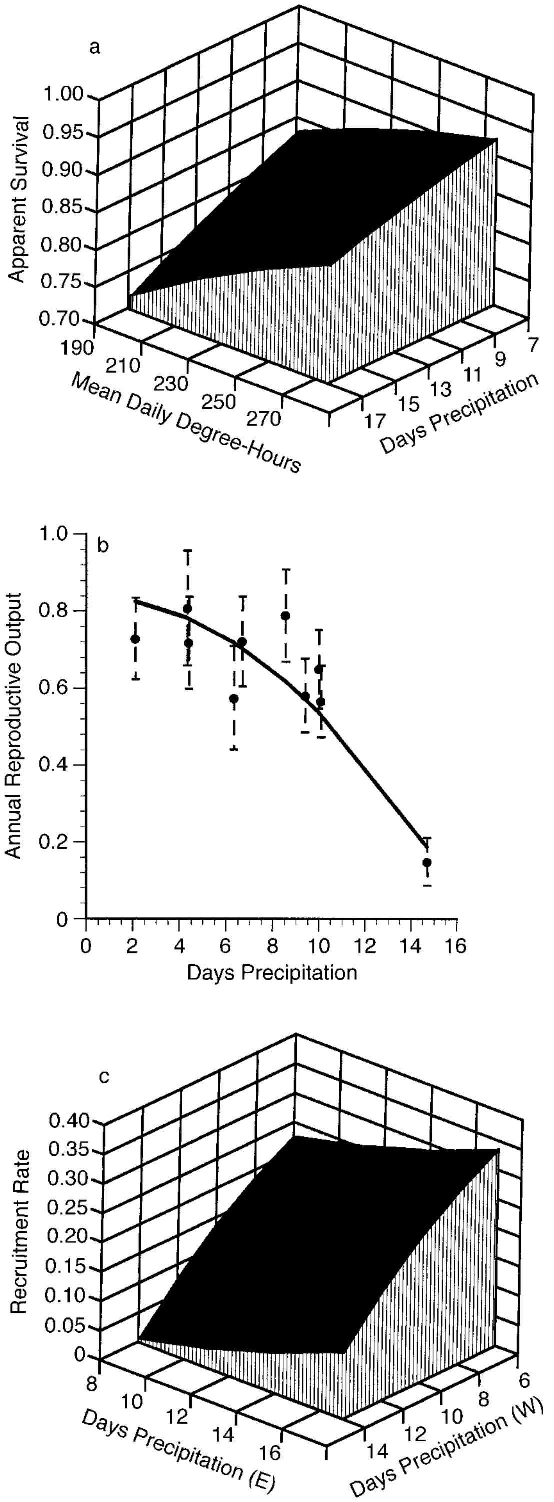

FIG. 4. Predicted values of (a) apparent survival of Northern Spotted Owls ≥1 yr old in relation to precipitation and temperature in the early nesting period; (b) annual reproductive output (mean ± 1 $\widehat{\mathrm{SE}}$) of Northern Spotted Owls relative to number of days of precipitation in the late nesting period; and (c) recruitment rate of Northern Spotted Owls relative to number of days of precipitation in the winter stress period (W) and early nesting period (E) in northwestern California.

estingly, the covariate P_L was present in the first three models ranked by AICc (Table 4), suggesting that it was an important covariate for explaining reproductive output.

Model $\{R_{P_L^2}\}$ estimated no significant residual variation (Table 6), indicating that this model explained all of the estimable temporal process variation. The 95% confidence intervals for $\sigma^2_{\mathrm{temporal}}$ for reproductive output did not overlap zero, and the coefficient of temporal process variation was much greater relative to survival probabilities (Table 6). All of these suggested that $\sigma^2_{\mathrm{temporal}}$ in reproductive output was large and was mostly explained by climatic variation, primarily precipitation during the late nesting period.

Recruitment rate.—We relied on the results of the goodness-of-fit procedures used for the survival analysis as the basis for assessing goodness-of-fit in the recruitment models. Survival and recapture probabilities were modeled as $\{\phi_{P_E+T_E}, p_c\}$, the best climate model describing survival, in all models used to estimate recruitment. Recapture probabilities were structured as p_c rather than p_{s+c} (as in the best climate model for ϕ) for recruitment models because POPAN-4 did not allow for group (i.e., sex) effects in estimation procedures. When we examined time effects only, model $\{\psi_t, \phi_{P_E+T_E}, p_c\}$ had the lowest AICc among models with linear time $\{\psi_{lt}, \phi_{P_E+T_E}, p_c\}$ and no time $\{\psi., \phi_{P_E+T_E}, p_c\}$ (Table 5). Estimates of ψ from the time-dependent model were then transformed into recruitment rates (b), which were used to estimate components of temporal process variation in recruitment rates.

We examined 33 additional recruitment models that included the hypothesized models describing climatic effects on survival, reproductive output, and recruitment (see Table 2). Model $\{\psi_{P_W^2+P_E^2}, \phi_{P_E+T_E}, p_c\}$ was selected as the most parsimonious model based on minimum AICc (Table 4). Model $\{\psi_{P_W+T_W+P_E+T_E}, \phi_{P_E+T_E}, p_c\}$ was a potential competitor based on Akaike weights (Table 4). This model differed from the selected model by including temperature covariates, T_W and T_E. Otherwise, it included the same precipitation covariates as the selected model. We concluded that model $\{\psi_{P_W^2+P_E^2}, \phi_{P_E+T_E}, p_c\}$ was best supported by the data based on minimum AICc, but that inclusion of covariates T_W or T_E might be supported in models based on additional data. Estimates of ψ from the selected model were transformed into recruitment rates ($\hat{b}$), which were regressed against the same climate covariates to yield (using random-effects models)

$$\hat{b} = 0.24732 - 0.00139(P_W)^2 + 0.00048(P_E)^2 \qquad (33)$$

as the model explaining variation in recruitment rates, with $\widehat{\mathrm{SE}}(\hat{\beta}_0) = 0.04121$, $\widehat{\mathrm{SE}}(\hat{\beta}_1) = 0.00037$ (95% CI = -0.00212, -0.00067), and $\widehat{\mathrm{SE}}(\hat{\beta}_2) = 0.00021$ (95% CI = 0.00007, 0.00089). Confidence intervals for the slope parameters did not overlap zero, suggesting that the trends were meaningful. In this model, recruitment rates were negatively affected by increased winter precipitation and positively affected by increased precipitation during the

early spring (Fig. 4c). Changes in recruitment predicted from Eq. 33 were most sensitive to changes in P_W (516.1% change in $\hat{b}$) followed by changes in P_E (51.8% change in $\hat{b}$).

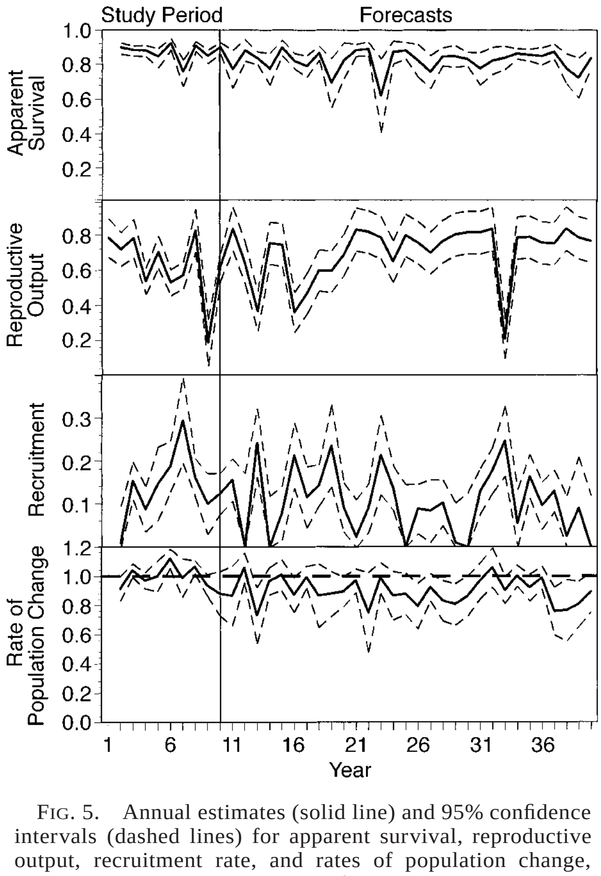

FIG. 5. Annual estimates (solid line) and 95% confidence intervals (dashed lines) for apparent survival, reproductive output, recruitment rate, and rates of population change, based on selected climate models for Northern Spotted Owls in northwestern California. The solid vertical line separates estimates for the study period and forecasts from a 30-yr climate trace recorded from 1955 to 1984, which does not represent future predictions beyond the study period. The horizontal dashed line represents $\lambda = 1$.

The climate model selected explained variation in ψ significantly better than did the random or linear time models (Table 5), with little residual variation estimated (Table 6). The coefficient of temporal process variation for b was substantially higher than those for the other life history parameters (Table 6), suggesting that it exhibited the greatest year-to-year variation relative to survival and reproductive output. Model $\{\psi_{P^2_W+P^2_E}, \phi_{P_E+T_E}, p_c\}$ explained all of the estimable temporal process variation, suggesting that the climatic covariates were primarily responsible for temporal process variation.

Population rates of change.—We used parameter estimates from the models selected to explain survival probabilities and recruitment rates to estimate annual rates of population change λ from Eq. 21 and their standard errors. Based on $\hat{\lambda}$ and $\widehat{SE}(\hat{\lambda})$, $\lambda = 1$ was contained within the 95% confidence intervals for $\hat{\lambda}$ (0.9594, 1.0578), suggesting that the population could be stationary during the study period. The level of temporal process variation in λ was low based on its coefficient of temporal process variation (Table 6).

Forecasts with climate models.—Fig. 5 shows the forecasts of point estimates, and their 95% confidence intervals, from the models selected to represent climatic variation in the demographic parameters and rate of population change, based on the 30-yr period from 1955 through 1984. These forecasts are properly interpreted as what might occur if a similar trend in climate were observed in the future, given that the models used are reasonably correct and other conditions affecting the estimates remain the same. Thus, the traces in Fig. 5 represent what could happen, given the conditions stated previously, rather than what will happen in future years. Therefore, inferences about small-scale variation in the long-term trends are limited. However, large-scale trends can provide some insights into how climate may affect these life history traits over time.

Three important results are evident in examining trends forecasted over 30 yr. First, point estimates of survival and recruitment, the parameters used to estimate λ, were negatively correlated (Pearson's $r = -0.340$, $P = 0.07$), but not strongly so. This may reflect the influence of precipitation during the early nesting period, which negatively affected survival but positively affected recruitment. However, there is also inherent sampling covariance between survival and recruitment because these two parameters were estimated from the same data. As expected, both survival and recruitment were positively correlated with λ. However, recruitment had a stronger correlation ($r = 0.705$, $P < 0.001$) than survival ($r = 0.412$, $P = 0.024$). Second, long-term variation in life history traits differed among the three traits examined. Both survival and reproductive output appear to have longer periods of relative stability punctuated by shorter periods exhibiting severe declines in both survival and reproduction, which represent catastrophic events for each of these parameters. Forecasts of survival estimates revealed two years in which survival estimates dropped below 0.70, with survival in one year as low as 0.62. Reproductive output reached extremely low levels (<0.4) in at least three years. Thus, the probability of catastrophic events (C) can be crudely estimated as $\hat{C} = 2/30 = 0.067$ for survival probabilities and $\hat{C} = 3/30 = 0.10$ for reproductive output. Catastrophic periods did not occur simultaneously for both survival and reproduction, suggesting that events causing variation in these parameters may not be linked. In contrast, recruitment rate was highly and consistently variable, reaching extremely low levels (<0.01) in six of the 30 yr ($\hat{C} = 0.20$). Finally, an average $\hat{\lambda}$ of 0.9118 (based on Eq. 24 from the annual estimates from Eq. 21) for the 30-yr climate trace was less than that estimated during the study period. Annual estimates of λ were significantly lower than a stationary population in 11 of those years, based on 95% confidence intervals (Fig. 5).

Effects of landscape habitat configuration on spatial variation in population processes

Survival probabilities.—We analyzed 280 models to evaluate the effects of habitat, age, and elevation covariates and their interactions on apparent survival. The best approximating a priori hypothesized model for survival was $\{\phi_{a2+LSOCOR+LSOMP+LSOEDG}, p_{c*ELEV}\}$ (model 13 in Table 7), which was twice as likely, based on Akaike weights, as the next ranked model, $\{\phi_{a2'+SOCOR+(SOCOR)^2+SODIS+(SODIS)^2}, p_{c*ELEV}\}$ (model 9 in Table 7). The c*ELEV structure on the recapture probabilities (p) was arrived at early in the modeling process where annual differences in capture technique interacted with mean elevation of territories. This structure on the p's was checked again at the later stages of the modeling process, and remained the best structure for all models.

The effects of SOCOR and SOEDG on ϕ appeared to be most important in the pseudothreshold form (i.e., LSOCOR) because (1) they were more precise (coefficients of variation = 0.37–0.50); (2) 95% confidence intervals of their slope parameters never overlapped zero in the other hypothesized models; and (3) one or both of these covariates appeared in the top three ranked hypothesized models (Table 7). However, slope parameters for the two covariates overlapped zero to a greater degree when they appeared in the squared difference form (i.e., DSOCOR), although the slope parameters for SOCOR as a quadratic (SOCOR + SOCOR^2) did not overlap zero (Table 7). The quadratic form of SOCOR had a shape similar to a pseudothreshold model, suggesting that SOCOR + SOCOR^2 was explaining the data as a pseudothreshold model similarly to LSOCOR.

The covariates SOMP, SOCOR, and SOHAB were all highly correlated ($r = 0.82$–0.96). The covariates LSOCOR and LSOMP in the best a priori hypothesized model also were highly correlated ($r = 0.88$). Therefore, we examined another model that incorporated all of the effects included in the top two a priori hypothesized models, $\{\phi_{a2+LSOCOR+LSOMP+LSOEDG}, p_{c*ELEV}\}$ and $\{\phi_{a2'+SOCOR+(SOCOR)^2+SODIS+(SODIS)^2}, p_{c*ELEV}\}$. This model $\{\phi_{a2'+LSOCOR+LSOEDG+SODIS+(SODIS)^2}, p_{c*ELEV}\}$ (starred model in Table 7) was 2.4 times as likely, based on Akaike weights, as the best a priori hypothesized model. All of the covariates were more precise (coefficients of variation = 0.30–0.56) in this combined model, and none of the 95% confidence intervals of the slope parameters overlapped zero except for LSOEDG, which overlapped only slightly (Table 7). In addition, none of the covariates included in the combined model was highly correlated pairwise ($r = -0.22$ to -0.48). Models including sex-, and age-covariate, and between-covariate interactions were not supported by the data as well as was model $\{\phi_{a2'+LSOCOR+LSOEDG+SODIS+(SODIS)^2}, p_{c*ELEV}\}$ (Table 8). However, the ΔAICc value between the model with an a2 vs. an a2′ age effect was very small, suggesting that either structure may be appropriate. This was also the case with the a priori hypothesized models in which the $\Delta AICc_i$ values between the same models, with one including an a2 and the other an a2′ structure, ranged from 0.01 to 5.61 with the a2′ structured model having a lower AICc value in 17 of 19 models. For this reason, we chose to retain the a2′ structure in model $\{\phi_{a2'+LSOCOR+LSOEDG+SODIS+(SODIS)^2}, p_{c*ELEV}\}$. Further exploration of this model with additional covariates did not yield a better model. Although it resulted from some data exploration, model $\{\phi_{a2'+LSOCOR+LSOEDG+SODIS+(SODIS)^2}, p_{c*ELEV}\}$ represented a minor alteration from two of the hypothesized models and, thus, retained much of the a priori thinking used to develop the models. Therefore, this model was retained for making inferences concerning the effects of landscape habitat features on survival. The form of the model was as follows:

increased in parallel for both age classes with increasing amounts of spotted owl habitat, increasing edge between spotted owl and other habitats, and increasing mean nearest neighbor distance between patches of spotted owl habitat at ~400 m, after which apparent survival declined with increasing distance (Fig. 6). Owls 1–2 yr old had lower survival than owls ≥3 yr old, and this difference was constant across changes in the habitat covariates (i.e., there was no interaction between age class and habitat covariates). Changes in apparent survival predicted from the model in Eq. 34 were most sensitive to changes in edge between spotted owl habitat and other habitats (11.1% change in $\hat{\phi}$), followed by changes in spotted owl core habitat (5.4% change in $\hat{\phi}$), mean nearest neighbor distance between spotted owl habitat patches (3.8% change in $\hat{\phi}$) and age class of the territorial occupants (2.0% change in $\hat{\phi}$).

In estimating $\sigma^2_{spatial}$ for apparent survival, we encountered problems with some of the estimates of sampling variances for ϕ (see Appendix B). Based on the estimates of $\sigma^2_{spatial}$ and the weighted mean survival probability across territories (Table 9), the coefficient of spatial process variation was 0.085, suggesting that spatial process variation in ϕ was relatively low. The habitat covariates in model $\{\phi_{a2'+LSOCOR+LSOEDG+SODIS+(SODIS)^2}, p_{c*ELEV}\}$ accounted for 66.7% of $\hat{\sigma}^2_{spatial}$, whereas age accounted for 8.8% of $\hat{\sigma}^2_{spatial}$. There was considerable uncertainty in the estimates of spatial process variation in survival based on the 95% confidence intervals, all of which included zero for each of the variance components (Table 9). This uncertainty was probably due to large sampling variation in the territory-specific estimates of ϕ relative to $\hat{\sigma}^2_{spatial}$ (Table 9). The cause of this large sampling variation was probably due to some territory-specific estimates based on only one or two individuals.

Reproductive output.—In running the general linear mixed models for reproductive output, we found a covariance structure that used low, medium, and high variance years to have the best approximating structure, based on minimum AICc computed from the restricted maximum log likelihood. This structure was used on all subsequent models examining the fixed effects in the hypothesized models and their variations.

We examined 122 models that included the 13 a priori hypothesized models in addition to variations on those models, which included effects due to age, elevation, and interactions. From this suite of models, the best approximating a priori model was $\{R_{a2'+SOCOR+SOEDG}\}$, based on minimum AICc (model 12 in Table 10). However, model $\{R_{a2'+SOMP+SOEDG}\}$ was a close competitor based on approximately equal Akaike weights. In these two models, the estimated slope parameter for SOEDG had greater precision (CV = 0.298–0.383), and was different from zero, based on confidence intervals, than slope parameter estimates for the habitat amount covariates, SOMP and SOCOR, which were much less precise (CV = 1.231–6.402), with confidence intervals that overlapped zero considerably (Table 10). The poor es-

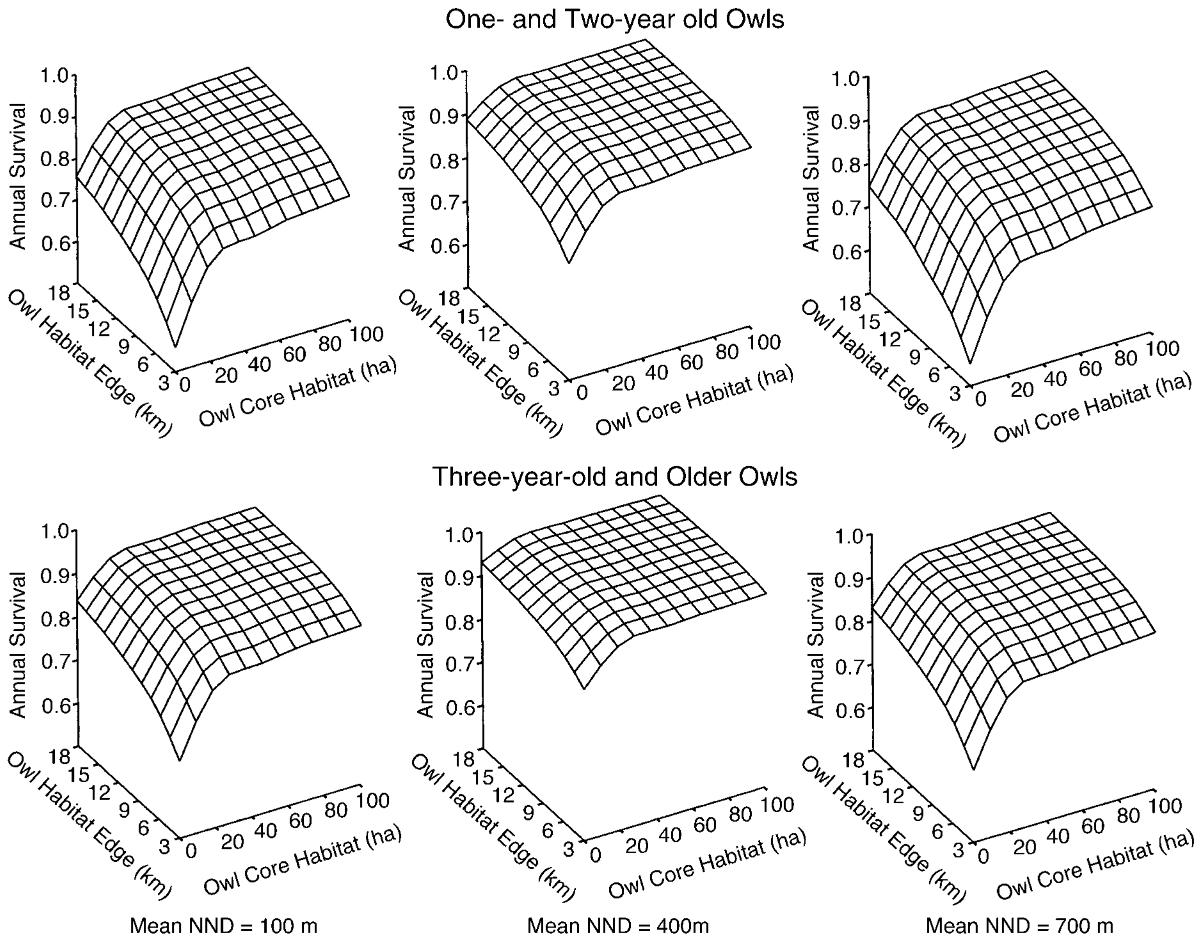

FIG. 6. Annual apparent survival (ϕ) of 1- and 2-yr-old and ≥3-yr-old Northern Spotted Owls in relation to the amount of core habitat, edge between spotted owl and other habitats, and nearest neighbor distance (NND) between patches of spotted owl habitat on territories in northwestern California. Estimates of apparent survival are based on model $\{\phi_{a2'+\mathrm{LSOCOR}+\mathrm{LSOEDG}+\mathrm{SODIS}+(\mathrm{SODIS})^2}, p_{c*\mathrm{ELEV}}\}$.

Notes: Models {$R_{a2+DELEV}$}, and {$R.$} are included for comparison. The starred model was achieved after further exploration. Covariates are described in Table 1.

† Numbers correspond to hypothesized models in Table 2.

‡ Number of estimated parameters.

§ Slope parameters based on re-scaled covariates (see Table 1).

timation of SOMP and SOCOR effects suggested that the top three a priori models may have been the best from the suite of models examined, but did not model the data very well. Therefore, we explored additional models that included other combinations of the covariates, with the best approximating a priori model as a starting point. We did not explore any additional models that included the covariates SOCOR, SOMP, and SOHAB together, because of the high correlations among these covariates.

We examined 55 additional models outside of the hypothesized models. From this suite of models, the best

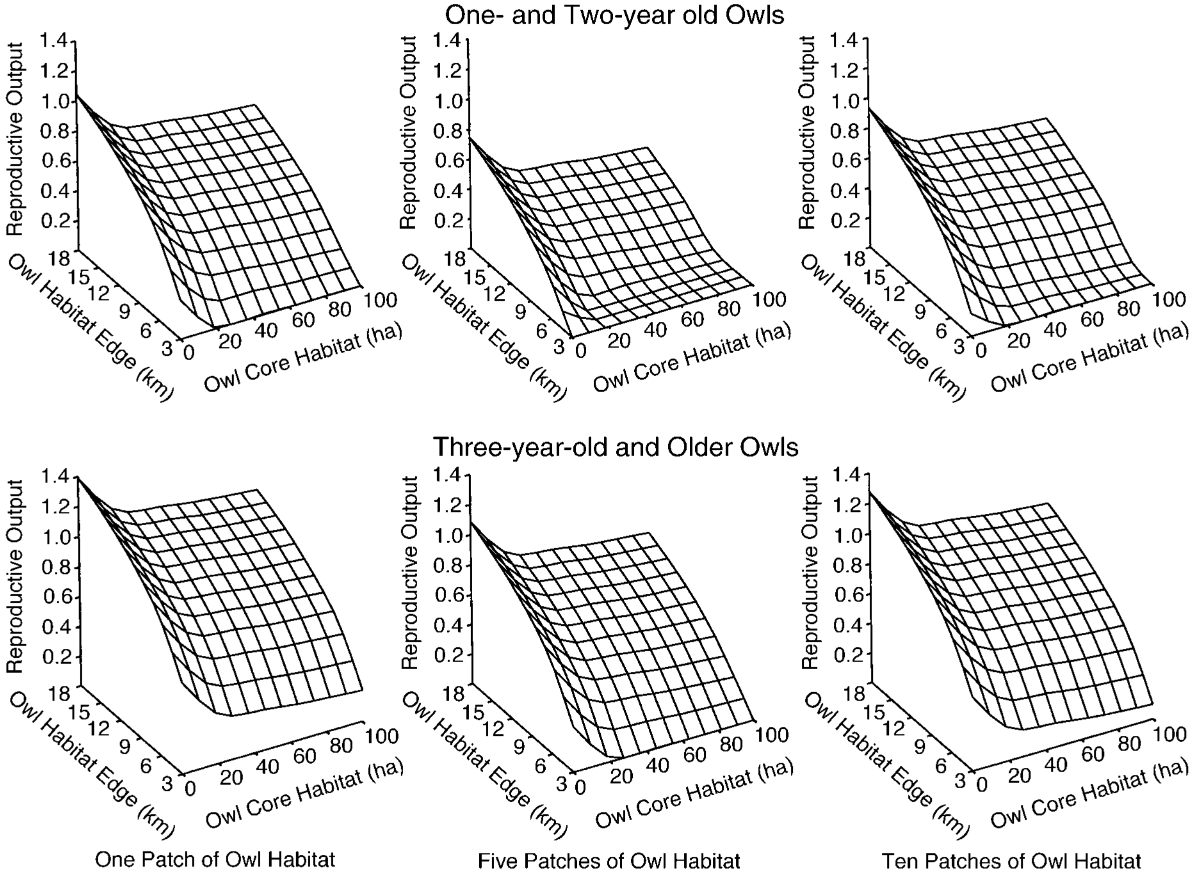

FIG. 7. Reproductive output (R) of 1- and 2-yr-old and ≥3-yr-old Northern Spotted Owls in relation to amount of core spotted owl habitat, edge between spotted owl and other habitats, and number of patches of spotted owl habitat on territories in northwestern California. Estimates of reproductive output are from model $\{R_{a2'+LSOCOR+LSOEDG+SONP+(SONP)^2}\}$.

approximating model based on minimum AICc was $\{R_{a2'+LSOCOR+LSOEDG+SONP+(SONP)^2}\}$, which was also a much better approximating model than any of the a priori hypothesized models (starred model in Table 10). The Akaike weight for model $\{R_{a2'+LSOCOR+LSOEDG+SONP+(SONP)^2}\}$ indicated that it was 3.6 times more likely than the nearest a priori hypothesized model. Close competitors within one AICc unit of this model, within the suite of models involved in data exploration, retained a similar structure but without the log effects and with some age interactions (Table 8). The form of model $\{R_{a2'+LSOCOR+LSOEDG+SONP+(SONP)^2}\}$ was

$$\hat{R} = -0.245 + 0.344(\text{AGE}) - 0.074(\text{LSOCOR}) + 0.473(\text{LSOEDG}) - 0.151(\text{SONP}) + 0.013(\text{SONP})^2 \quad (35)$$

where AGE was a dummy variable (0, either 1 or 2 yr old; 1, ≥3 yr old). The standard errors for the parameter estimates were $\widehat{\text{SE}}(\hat{\beta}_0) = 0.377$, $\widehat{\text{SE}}(\hat{\beta}_1) = 0.102$, $\widehat{\text{SE}}(\hat{\beta}_2) = 0.036$, $\widehat{\text{SE}}(\hat{\beta}_3) = 0.129$, $\widehat{\text{SE}}(\hat{\beta}_4) = 0.066$, and $\widehat{\text{SE}}(\hat{\beta}_5) = 0.0068$. All of the slope parameters were relatively precise (CV = 0.27–0.54).

This model was similar to the best hypothesized model $\{R_{a2'+SOCOR+SOEDG}\}$, except that there was a pseudothreshold effect on SOCOR and SOEDG, and the model included SONP. We used model $\{R_{a2'+LSOCOR+LSOEDG+SONP+(SONP)^2}\}$ with the understanding that inferences were somewhat limited because this model was developed by further exploration beyond the a priori hypothesized models. However, this model was based mostly on one of the a priori hypotheses (model 12 in Table 3). This model indicated that reproductive output was (1) negatively associated with female age class, with 1- and 2-yr-old owls fledging fewer young than owls ≥3 yr old (the dummy variable was scored 1 for owls ≥3 yr old); (2) negatively associated with the amount of core spotted owl habitat in a nonlinear fashion; (3) positively associated with the amount of edge between spotted owl habitat and other habitats in a nonlinear fashion; and (4) associated with the number of patches of spotted owl habitat by an inverse quadratic relationship in which reproductive output was highest when the number of patches was either few or many, and lowest when the number of patches was intermediate (Fig. 7). Changes in reproductive output predicted from Eq. 35 were most sensitive to changes in edge between spotted owl habitat and other habitats (382.0% change in $\hat{R}$), followed by changes in spotted owl core habitat (30.4% change in $\hat{R}$), number of spotted owl habitat patches (23.9% change in $\hat{R}$), and age class of the territorial occupants (22.4% change in $\hat{R}$).

Using the weighted mean for reproductive output (Table 9), the coefficient of spatial variation was 0.289, suggesting that reproductive output was relatively variable among territories, much more so than survival. The habitat covariates in model $\{R_{a2'+\mathrm{LSOCOR+LSOEDG+SONP+(SONP)^2}}\}$ explained 74.8% of this spatial process variation, whereas the age effect explained 2.7% (see Table 9).

Habitat fitness potential.—We estimated the habitat fitness potential of each spotted owl territory using the Leslie stage projection matrix in (22). As inputs to (22) for each territory, we estimated apparent survival ($\hat{\phi}$) using Eq. 34, and we estimated fecundity ($\hat{m}$) from Eq. 35 using the relevant landscape covariates from each of the territories. For example, we used the measures of LSCOR, LSOEDG, and SODIS from territory A to estimate age-specific ϕ for that territory using Eq. 34, and we used the measures of LSCOR, LSOEDG, and SONP from territory A to estimate age-specific R for that territory using Eq. 35. Estimates of m were derived by dividing $\hat{R}$ by 2. An estimate of λ_H was then obtained for territory A using the age-specific estimates of ϕ and m as inputs to matrix 22.

Estimated values of territory-specific habitat fitness potential ($\hat{\lambda}_H$) varied from 0.438 to 1.178 (Fig. 8a), with a weighted mean (using Eq. 24 with territory-specific estimates from matrix 22) of 1.075 (95% CI = 1.061, 1.089). The median coefficient of sampling variation among territories was 0.028, indicating that estimates of λ_H were quite precise. Based on estimates in Table 9, the coefficient of spatial process variation for $\hat{\lambda}_H$ was 0.052, suggesting that spatial process variation in the predicted habitat fitness potential among territories was relatively low. However, territory-specific estimates of λ_H followed a smooth progression from territories with relatively high fitness (with point estimates substantially greater than one), to territories that had low fitness (with values less than one; Fig. 9a). Based on the 95% confidence intervals of $\hat{\lambda}_H$ for each territory, three territories (3.2%) had point estimates less than one, with confidence intervals that did not overlap one; 26 territories (27.4%) had estimates either less than or greater than one, with confidence intervals that overlapped one; and 66 territories (69.4%) had estimates that were greater than one and confidence intervals that did not overlap one. This indicated that females on at least two-thirds of the territories more than replaced themselves and were potentially contributing a surplus to the population.

The components used to estimate λ_H, age-specific apparent survival and age-specific fecundity, appeared to contribute differently to the spatial process variation among territory-specific λ_H. First, $\hat{\lambda}_H$ was highly correlated with apparent survival (r = 0.83), but less so with fecundity (r = 0.57). Estimates of apparent survival used in estimating λ_H varied little when compared with fecundity estimates (Table 9, Fig. 8b, c). This was also apparent when estimates of apparent survival and fecundity for owls ≥3 yr old were compared along the gradient of territories ranked by $\hat{\lambda}_H$; apparent survival appeared to be relatively constant except for owls in territories that had very low fitness (Fig. 9b), whereas fecundity declined (Fig. 9c). This suggested that small changes in apparent survival were responsible for relatively large changes in $\hat{\lambda}_H$.

The combination of effects of landscape habitat characteristics on apparent survival and fecundity (and, hence, habitat fitness potential) can be illustrated by examining territories with relatively high, medium, and low habitat fitness potentials (Fig. 10). There are evident trade-offs in landscape habitat configurations

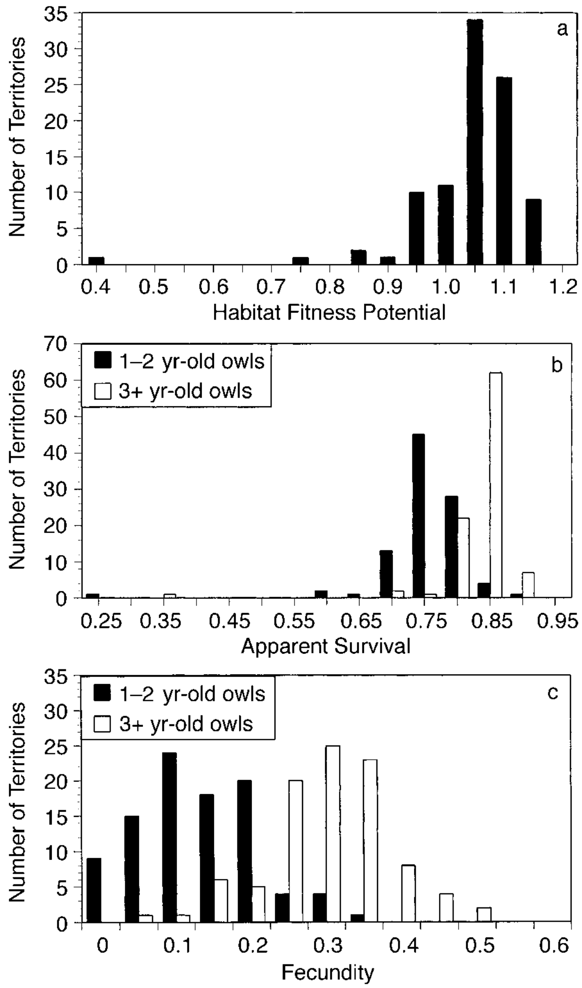

FIG. 8. Distributions of (a) estimated habitat fitness potential ($\hat{\lambda}_H$), (b) predicted estimates of apparent survival used to estimate λ_H, and (c) predicted estimates of fecundity used to estimate λ_H for 95 Northern Spotted Owl territories in northwestern California.

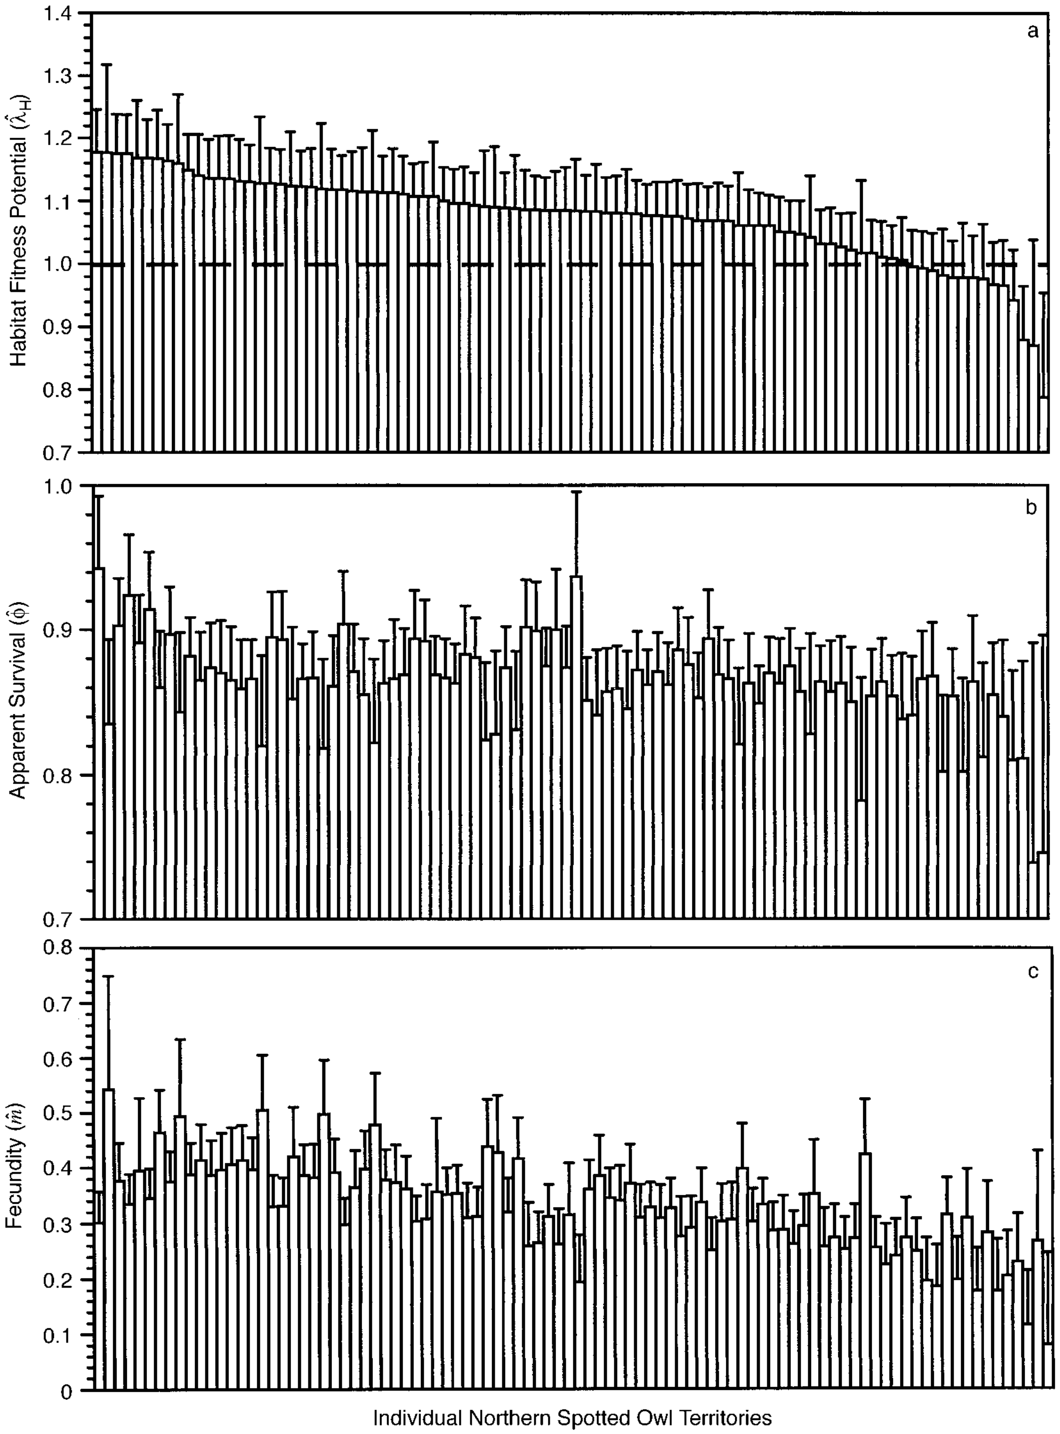

FIG. 9. Northern Spotted Owl territories in northwestern California (a) sorted by descending habitat fitness potential values with (b) corresponding estimates of apparent survival for owls ≥3 yr old, and (c) estimates of fecundity for owls ≥3 yr old. Each histogram bar is an individual territory. Error bars represent +2 SE of the mean. One territory with $\hat{\lambda}_H$ = 0.44 was not included, for ease in comparisons.

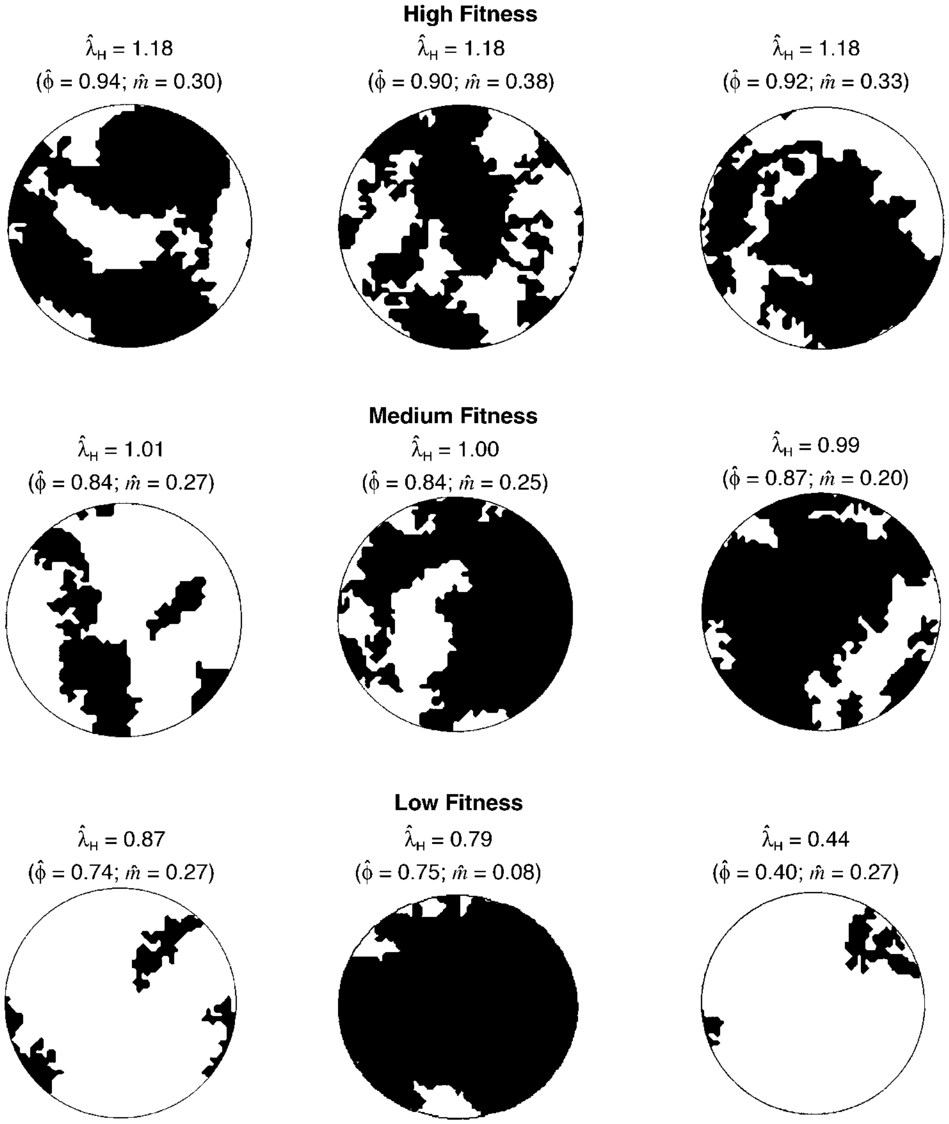

FIG. 10. Landscape habitat characteristics (within 0.71 km radius circles used to define Northern Spotted Owl territories) at three levels of habitat fitness potential in northwestern California. Dark areas are Northern Spotted Owl habitat; white areas are other vegetation types. Estimates of ϕ (apparent survival) and m (fecundity) are for owls $\geq$3 yr old.

within spotted owl territories where survival is maximized by maintaining relatively large core areas of habitat with some edge (see Eq. 34). In contrast, fecundity was maximized by minimizing the core area of spotted owl habitat, maximizing the amount of edge between spotted owl and other habitats, and either minimizing or maximizing the number of discrete patches of spotted owl habitat (see Eq. 35). In territories with high $\hat{\lambda}_H$, it appears that both adult survival and fecundity were high (Fig. 10). In territories with medium and low $\hat{\lambda}_H$, $\hat{\lambda}_H$ was a function of low survival and high fecundity, high survival and low fecundity, or low survival and low fecundity. Thus, the landscape configurations in territories with medium and low values of $\hat{\lambda}$ could maximize either one or the other of the components used to estimate $\hat{\lambda}_H$, but not necessarily both. In addition, high $\hat{\lambda}_H$ in territories appears to be associated with a mixture of spotted owl habitat vs. other vegetation types (e.g., some degree of heterogeneity). On the other hand, too much homogeneity in either spotted owl habitat or other vegetation types appears to result in low $\hat{\lambda}_H$.

Relative contributions of climatic and habitat variation to population processes

The coefficient of total process variation for apparent survival was 9.5%, based on the weighted mean for either temporal (Table 6) or spatial (Table 9) variation. Spatial process variation accounted for most of the total process variation in apparent survival (Table 11). The

TABLE 11. Sources of process variation in apparent survival and reproductive output in Northern Spotted Owls in northwestern California, with 95% confidence intervals in parentheses.

† Total variation accounted for by temporal and spatial process variation only (residual variation not included).

variation in apparent survival that was accounted for by the climate and habitat models ($\hat{\sigma}^2_{\text{model}}$) explained 80.0% of the total process variation ($\hat{\sigma}^2_{\text{model}}/\hat{\sigma}^2_{\text{total}}$ in Table 11), suggesting that these influences were primarily responsible for the observed process variation in this study. This left little residual variation (20.0%) to be explained by other factors not modeled here. Based on model selection, both climate and habitat influences appeared to be important in explaining variation in apparent survival; the additive model $\{\phi_{a2'+P_E+T_E+\text{LSOCOR}+\text{LSOEDG}+\text{SODIS}+(\text{SODIS})^2}\}$ containing both climate and habitat effects was ≥52 times as likely (based on Akaike weights) as either the habitat-only model $\{\phi_{a2'+\text{LSOCOR}+\text{LSOEDG}+\text{SODIS}+(\text{SODIS})^2}\}$ or the climate-only model $\{\phi_{P_E+T_E}\}$ (Table 12).

Spatial and temporal process variation accounted for roughly equal amounts of the total process variation in reproductive output (Table 11). The coefficient of total process variation was 39.7–40.5%, depending on whether we used the weighted mean for temporal (Table 6) or spatial (Table 9) variation. The variation in reproductive output that was explained by the climate and habitat models ($\hat{\sigma}^2_{\text{model}}$) accounted for 88.5% of the total observed process variation ($\hat{\sigma}^2_{\text{model}}/\hat{\sigma}^2_{\text{total}}$ in Table 11). Again, little residual variation (11.5%) was left to be explained by factors other than

† Based on rescaled climate covariates: $P_E/10$ and $T_E/100$. Habitat covariates are re-scaled as in Table 1.

climate or habitat. The importance of both temporal and spatial process variation in explaining total process variation was supported by model selection. Model $\{R_{a2'+P_L^2+LSOCOR+LSOEDG+SONP+(SONP)^2}\}$, which contained the additive effects of the best climate and habitat models, was >400 times as likely as either model $\{R_{P_L^2}\}$, with climate effects only, or model $\{R_{a2'+LSOCOR+LSOEDG+SONP+(SONP)^2}\}$, with habitat effects only (Table 12).

Effects of variation in climate on habitat quality.—In survival estimation, we used a structure on recapture probabilities (p) of p_{c*ELEV} for all models that differed from the structure of p_{s+c} used in models relating survival to climatic covariates. We used the p_{c*ELEV} structure in this analysis because it was used in models relating survival to habitat covariates, and it still incorporated some of the structure of p's used in the climate models.

Four models supported interactions between climate and habitat in apparent survival better than did model $\{\phi_{a2'+P_E+T_E+LSOCOR+LSOEDG+SODIS+(SODIS)^2}\}$, which included only additive effects between climate and habitat (Table 12). However, there were a number of problems encountered in modeling interactions with these data, because the form of the sample data did not allow for unique identifiability of parameters in models that contained certain interactions (see Appendix B). Thus, the best approximating model for apparent survival was $\{\phi_{a2'+(P_E+T_E)*(LSOEDG+SODIS)+LSOCOR+(SODIS)^2}\}$ (Table 12), which contained interactions between both climate covariates and habitat covariates LSOEDG and SODIS (Table 13). Based on Akaike weights, this model was four times as likely as the additive model containing both climate and habitat covariates but no interactions between the two sets of covariates (Table 12). Inferences from model $\{\phi_{a2'+(P_E+T_E)*(LSOEDG+SODIS)+LSOCOR+(SODIS)^2}\}$ were very limited because of the problems encountered in modeling interactions and the removal of the quadratic effect from any interactions with climate covariates (see Appendix B). The precision of slope parameters in model $\{\phi_{a2'+(P_E+T_E)*(LSOEDG+SODIS)+LSOCOR+(SODIS)^2}\}$ (Table 13) was similar to the best approximating models that included only climate effects or only habitat effects.

Model $\{\phi_{a2'+(P_E+T_E)*(LSOEDG+SODIS)+LSOCOR+(SODIS)^2}\}$ indicated that higher quality Northern Spotted Owl habitat, as described by the habitat covariates, buffered the adverse effects of climate (Fig. 11). In Fig. 11, we arbitrarily defined ''good'' habitat as habitat covariates (SOCOR = 65 ha of interior forest, SOEDG = 9 km, SODIS = 100 m) yielding $\hat{\phi}$ = 0.91; ''medium'' habitat as habitat covariates (SOCOR = 25 ha, SOEDG = 9 km, and SODIS = 50 m) yielding $\hat{\phi}$ = 0.86; and ''poor'' habitat as habitat covariates (SOCOR = 5 ha, SOEDG = 6 km, and SODIS = 50 m) yielding $\hat{\phi}$ = 0.78 when climate effects are ignored. The effects of interactions between climate and habitat covariates were examined in this more qualitative manner along a hypothetical climate gradient, because of the poor support for the best approximating model, $\{\phi_{a2'+(P_E+T_E)*(LSOEDG+SODIS)+LSOCOR+(SODIS)^2}\}$. The climate gradient used in Fig. 11 was based on data within the range of conditions observed during the study.

Of the three different habitat qualities, apparent survival declined 7.1% in good habitat as the climate gradient progressed from an optimal warm, dry spring to a cold, wet spring. Along the same climate gradient,

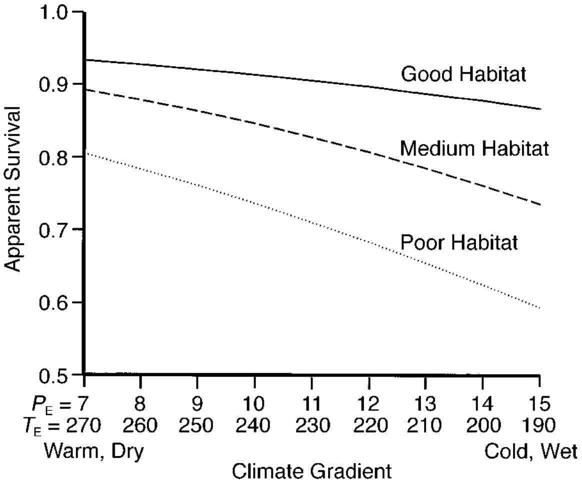

FIG. 11. Effects of climate on apparent survival of Northern Spotted Owls in three qualities of habitat in northwestern California. Predicted effects on apparent survival are based on model $\phi_{a2'+(P_E+T_E)*(LSOEDG+SODIS)+LSOCOR+(SODIS)^2}$. The climate gradient is a function of both P_E and T_E. Habitat quality is defined in *Results: Effects of variation in climate on habitat quality.*

apparent survival decreased 17.5% and 26.3% in medium and poor habitats, respectively (Fig. 11). These results indicate that individuals in good habitat had a much slower decline in survival as climatic conditions deteriorated than did individuals in poorer habitats. Thus, high habitat quality, as defined in this study, buffered the survival of territory occupants from the negative effects of climate. Aspects of habitat quality that buffered apparent survival were the habitat covariates LSOEDG ($\log_e$ transform of SOEDG) and SODIS, both of which describe patch configurations of mature and old-growth forest. In addition, predicted estimates of survival had $\tilde{\sigma}^2_{\mathrm{temporal}} = 0.0005$ for ''good'' habitat, $\tilde{\sigma}^2_{\mathrm{temporal}} = 0.0029$ for ''medium'' habitat, and $\tilde{\sigma}^2_{\mathrm{temporal}} = 0.0053$ for ''poor'' habitat. Thus, survival in ''poor'' habitat varied more than 10 times as much as survival in ''good'' habitat under the same conditions.

The best approximating model for reproductive output, $\{R_{\mathrm{a2'}+P_L^2+\mathrm{LSOCOR}+\mathrm{LSOEDG}+\mathrm{SONP}+(\mathrm{SONP})^2}\}$, was an additive model that included both climate and habitat covariates (Table 12). Based on the best approximating model, interactions between the climate and habitat covariates were not supported by the data. Based on Akaike weights, model $\{R_{\mathrm{a2'}+P_L^2+\mathrm{LSOCOR}+\mathrm{LSOEDG}+\mathrm{SONP}+(\mathrm{SONP})^2}\}$ was more than twice as likely as the next ranked model, which included interactions between the climate covariates and the habitat covariate LSOCOR (the $\log_e$ transform of SOCOR) (Table 12). The selection of model $\{R_{\mathrm{a2'}+P_L^2+\mathrm{LSOCOR}+\mathrm{LSOEDG}+\mathrm{SONP}+(\mathrm{SONP})^2}\}$ suggested that reproductive output of individuals was similarly affected by climate changes, regardless of the quality of the habitats they occupied. In other words, if habitat were classified similar to Fig. 11, then slopes of the three lines would be parallel for reproductive output and would differ by the slope parameter for P_L^2 (Table 13).

Discussion

Magnitude of temporal process variation in life history traits

Based on coefficients of temporal process variation, survival of adult Northern Spotted Owls varied the least, whereas recruitment varied the most, >15 times more than adult survival. In a variable environment, Northern Spotted Owls appear to follow a pattern in life history traits in which (1) adult survival is high with low temporal variation, (2) recruitment is low with high temporal variation, and (3) survival of territory holders and recruitment into the territorial population appear to be negatively correlated. Variation in reproductive output was intermediate between survival and recruitment, and was characterized more by infrequent catastrophes than by regular rises and falls in rates, such as in recruitment. Such a pattern suggested that spotted owls may employ a life history strategy similar to ''bet hedging,'' by which selection favors adult survival at the expense of present fecundity when the recruitment of offspring is unpredictable from year to year (Stearns 1976). This strategy does not necessarily impose a cost of reproduction when negative correlations exist between survival and recruitment, based on simulations by Benton and Grant (1996). However, the negative correlation in our study includes both process and sampling variation because of the sampling covariances between survival and recruitment estimates.

At least six scenarios underlie the bet-hedging tactic (Boyce 1988), and application of the observed pattern in Northern Spotted Owls to any one of these scenarios (or other patterns in life history traits) is premature without additional work. In a broad sense, the life history pattern exhibited by this owl does follow the trend of increased iteroparity in response to environmental stochasticity (Orzack and Tuljapurkar 1989), in which a long reproductive life-span allows for some eventual recruitment of offspring even if that recruitment does not occur each year.

Role of climatic variation in temporal process variation of life history traits

After accounting for sampling and demographic variation, climate explained almost all of the temporal process variation observed in the life history traits estimated for Northern Spotted Owls. This suggested that temporal variation in these populations may be driven primarily by annual variation in climate. The lack of sex and age effects within years was consistent with previous analyses of these data (Franklin et al. 1996*b*). The climate models developed here have the advantage of being empirically based, with good statistical rigor. However, the complexity of these models depended on the amount of available data and the observed climatic variation during the study. We expect that future parsimonious models will support additional climatic covariates with additional years of study. Therefore, the climate models that we developed to describe environmental variation here should be considered first approximations.

The climate models that we described do not demonstrate cause and effect. Unfortunately, neither the climate models nor the effects that they describe can be adequately tested with experiments because of the uncontrollable nature of climatic variation. Model validation is possible only through additional observations within the Klamath province of the Pacific Northwest, or by using a similar approach in other study areas. This also makes it difficult to test forecasts of the model back in time; no adequate estimates of reproductive output exist for northern California prior to 1983, and survival probabilities and recruitment rates were not estimated prior to this study. With additional years of data, we predict that the form of the climate models may change, as well as the importance of some of the covariates.

Based on the climate models selected, the period when life history traits for Northern Spotted Owls are generally affected by climate is during the spring rather than the winter. In terms of energetic costs, owls have their highest daily energy expenditures during the breeding season rather than the winter (Wijnandts 1984, Meczewa 1986). A plausible mechanism during this energetically stressful period is that precipitation may decrease hunting efficiency, prey activity, and prey populations, as we proposed during the formulation of the models that were ultimately selected as explanations of climatic variation. Extreme climate conditions during the early nesting period may exacerbate an energetic stress on an individual by decreasing its time to starvation. At a body mass of 550–650 g (Blakesley et al. 1990), Northern Spotted Owls would reach starvation levels, about 25% of their body mass (Handrich et al. 1993), within about 8 d at maintenance metabolic rates (based on an allometric equation in Kirkwood 1981). This rate is similar to those observed for captive Barn Owls, *Tyto alba* (Handrich et al. 1993). As energetic stress due to reproductive effort is added to maintenance metabolic rates, time to starvation will decrease and, hence, will increase the potential for lowered survival probabilities. In several other species of raptors, extremes in precipitation affect reproductive output, after young have hatched, by preventing efficient foraging by adults, reducing prey supplies, and causing direct mortality of young through chilling (Schipper 1979, Davis and Newton 1981, Village 1986, Mearns and Newton 1988, Kostrzewa and Kostrzewa 1990). These are the same mechanisms that were proposed for our hypothesized climate model, which was selected as the most appropriate model. However, we have the least confidence in the ability of the selected climate model to explain variation in reproductive output, because of the lack of additional extreme values and the absence of positive extreme values (e.g., very high reproductive output). Although the selected model may adequately explain negative effects of climate, this model does not encompass unknown climate effects that positively affect reproductive output.

The winter period was only important for explaining variation in recruitment. The negative effects of winter precipitation may have resulted through impacts on survival of young experiencing their first year of independence. The positive relationship of recruitment with spring precipitation supported the prediction that factors negatively affecting survival of territory holders would positively affect recruitment if floaters were present in sufficient numbers in the population; floaters would fill immediate vacancies resulting from the deaths of territory holders.

Long-term consequences of climatic variation on population growth and stability

The pattern of variation in rates of population change under the 30-yr climate trace suggested that Northern Spotted Owl populations may experience periods of decline caused solely by climatic variation. However, the inferences that we made here are relevant only if conditions other than climate remain the same as when the models were developed. Inferences here do not include what will occur, regardless of changes in other conditions that may affect Northern Spotted Owl populations. Thus, even if habitat conditions remain unchanged, Northern Spotted Owl populations may experience declines. Whether or not these long periods of decline would lead to extinction is unknown.

Despite the highly variable nature of recruitment, estimates of rates of population change have very low coefficients of temporal process variation. Recruitment may be the dynamic that controls Northern Spotted Owl populations, because of its highly variable nature. Noon and Biles (1990) and Lande (1991) found λ estimated for Northern Spotted Owls with deterministic, empirically based matrix models to be highly sensitive to small changes in adult survival. However, this type of model sensitivity does not necessarily imply that survival contributes much to variation in rates of population change (Boyce 1994) and, hence, to population dynamics. We argue that rates of population change in Northern Spotted Owls are at least as sensitive to recruitment as to survival, in the presence of temporal variation. Survival of $\geq$1-yr-olds exhibits little temporal process variation and, thus, sets the relative magnitude for rates of population change (e.g., λ can never be less than the $\geq$1-yr-old survival rate in Eq. 21). In this study, variation at or above the baseline value of λ set by $\geq$1-yr-old survival is determined by recruitment rates. Therefore, variation in recruitment determines the variation in λ above its relative magnitude set by $\geq$1-yr-old survival. For this reason, rates of population change were more correlated with recruitment in forecasts with the 30-yr climate trace than with $\geq$1-yr-old survival. If certain long-term climate trends can cause negative rates of population change, as suggested in this study, then climatic variation has the potential to negatively affect Northern Spotted Owl populations, even if no further habitat loss occurs. Thus, we conclude that temporal variation, as influenced by climate, is an additional factor to strongly consider in developing conservation strategies.

Most conservation plans for the Northern Spotted Owl assume that their overall population will decline from habitat loss and then stabilize as habitat amount eventually stabilizes (Gutiérrez et al. 1996). However, as populations decrease in size, the effects of catastrophes on life history traits will gain increasing importance in determining rates of population change. Catastrophic events can be characterized as density-independent, physical catastrophes (Boyce 1984) that may reduce the number of territorial holders in an unpredictable manner. The extent to which these catastrophic events in parameters affect the population as a whole is dependent on population size, spatial distribution, and regulatory mechanisms (Mangel and Tier 1993). In addition, climatic conditions that will catastrophically affect all parameters simultaneously over several years will occur with some unknown probability at some unpredictable time. Such a ''megacatastrophe'' will have a much stronger impact on a reduced population (Lande 1993).

Effects of landscape habitat characteristics on life history traits

There are many levels of uncertainty in the estimates of survival, reproductive output, and, hence, habitat fitness potential. First, there is model uncertainty, which was expressed in terms of the Akaike weights. Whenever a model is developed from empirical data, there is uncertainty as to whether the model selected is indeed the best model. Second, there was some data dredging used to select a best approximating model for both survival and reproductive output. However, data dredging here was limited, and was closer to the a priori approach rather than an approach based on unlimited data exploration. Third, there is the issue of scale. These results are scale dependent in both habitat and landscape extent. In terms of habitat within a territory scale, scale is relevant only to discrete habitat patches and not to within-patch variation. In addition, landscape extent in this study is limited to the territory scale and not to larger or smaller scales. Therefore, differences (or lack thereof) can only be attributed to the territory scale. Other scales such as a home range scale or cluster of territories may produce different results and should be appropriately analyzed. Fourth, there is uncertainty in the classifications of habitats and their distribution (see also Mowrer et al. 1996). Although we were able to classify Northern Spotted Owl habitat with a high level of certainty, we were unable to classify other habitats well. In addition, we were unable to determine whether estimated habitat patch configurations accurately matched those existing on the ground.

Although these levels of uncertainty do not negate the results of this study, our results should be considered more as working hypotheses from an observational study that require further experimental verification. Clearly, part of the value of this work is in reducing the number of potential landscape configurations that might affect Northern Spotted Owls in this area to a small subset, which then can form the basis of field experiments.

The habitat covariates in the best approximating models for apparent survival and reproductive output explained a large proportion of spatial process variation in these two life history traits. The best approximating models explaining variation in both apparent survival and reproductive output contained two covariates in common: the amount of core spotted owl habitat and the amount of edge between spotted owl and other habitats. However, the relationship between these two life history traits was reversed with respect to the amount of core spotted owl habitat; apparent survival was positively associated with the amount of core habitat, whereas reproductive output was negatively associated with core habitat. However, both life history traits were positively associated with the amount of edge between spotted owl and other habitats. In addition, the models relating habitat to both survival and reproductive output were strongly sensitive to the amount of edge.

Apparent survival among territories appeared to vary little in terms of spatial process variation. There may be several reasons for this low variation in survival among territories. First, high sampling variation of among-territory estimates increased the uncertainty in estimating process variation, even though some extremes (survival below 0.80) were noted on certain territories. Second, Northern Spotted Owls may only select a territory to defend that will promote high survival (T. Shenk, *personal communication*). Hunter et al. (1995) found that, at the territory scale of this study, areas used for nesting and roosting by Northern Spotted Owls in our study area contained larger amounts of mature and old-growth forests than did random areas. Thus, an owl has the following options: it defends an area that contains sufficient mature and old-growth forest to maintain high survival, it does not bother defending a territory, it disperses, or it dies. Once the owl selects a territory to defend, variation in its expected survival rate should be low if the habitat is of sufficient quality. We call this the ''all-or-nothing defense'' hypothesis. Our surveys included only owls exhibiting territorial behavior; hence, we estimated survival only for territorial individuals. Owls that did not acquire territories were not included in the sample because they were rarely found.

The spatial process variation in reproductive output among spotted owl territories was large compared with variation in survival. Reproductive output was dependent on a high degree of spotted owl habitat edge, a low amount of core area, and either few or many patches of spotted owl habitat. Although a high degree of spotted owl habitat edge implies large amounts of spotted owl habitat within a finite territory size, the requisite amount of edge can be also be achieved with minimal amounts of interior spotted owl habitat and numerous small patches or a highly convoluted single patch that minimizes the amount of interior habitat. However, low amounts of spotted owl habitat within a territory will not supply the high degree of edge predicted to support high reproductive output.

Gutiérrez (1985) outlined four hypotheses as alternative explanations for why Northern Spotted Owls require mature and old-growth forests, three of which are relevant to the ''all-or-nothing'' defense hypothesis: predation, thermoregulation, and sufficiency of prey. The predation hypothesis suggests that mature and old-growth forests provide sufficient cover for spotted owls to avoid predation from other avian predators such as Great Horned Owls, which are a primary predator of Northern Spotted Owls (Johnson 1992). Carey et al.

(1992) found densities of Great Horned Owls encountered near Northern Spotted Owls to be highest in the mixed-conifer forests of the Klamath Mountains province in southern Oregon. Great Horned Owls hunt primarily using vision (Johnsgard 1988) and probably lack the auditory morphology used by spotted owls to hunt effectively by sound alone in a vertically structured habitat such as mature and old-growth forests (see Volman and Konishi 1990). Therefore, Northern Spotted Owls may use areas of mature and old-growth forests that are not useable by Great Horned Owls, thus minimizing their risk of predation.

Under the thermoregulation hypothesis, mature and old-growth forests provide a more stable microclimate, and the complex vertical structure of these forests provides protection from inclement weather (Forsman et al. 1984, Ting 1998).

Under the prey hypothesis, mature and old-growth forests provide an abundant and accessible source of prey not available in other habitats. However, the primary prey species of Northern Spotted Owls in this study area is the dusky-footed woodrat (*Neotoma fuscipes*), which is most abundant in brush areas that are inaccessible to the owl, and has low abundance in mature and old-growth forests (Sakai and Noon 1993). Another important prey item, the northern flying squirrel (*Glaucomys sabrinus*), achieves high densities in both mid- and late-seral stage forests in northeastern California (Waters and Zabel 1995) and southern Oregon (Carey et al. 1992, Rosenberg and Anthony 1992). Northern flying squirrels have about one-half of the biomass of woodrats (Ward et al. 1998), and owls eating a high proportion of woodrats have smaller home ranges than those eating flying squirrels (Zabel et al. 1995). In addition, spotted owls in the Klamath Mountains province hunt along edges of mature and old-growth forests (Zabel et al. 1995). Ward et al. (1998) suggested that some degree of fragmentation within their territories may provide an energetic benefit to the owls; Northern Spotted Owls in California first selected dusky-footed woodrats over other species, and then selected foraging areas near ecotones between late- and early-seral forests where woodrats were both abundant and accessible. Our results corroborate this. Woodrats are probably more accessible at ecotones because of their lateral nocturnal movements from early-seral stages and other vegetation types with dense understories to late-seral stages with more open understories (Sakai and Noon 1997). By remaining within late-seral stage forests at these ecotones, spotted owls may avoid predation by Great Horned Owls while gaining access to prey in the ecotones (Zabel et al. 1995). Thus, sufficient core area interspersed with other vegetation types may provide protection from predators while offering a source of large, accessible prey. In addition, White (1996) found that owls on our study area that successfully fledged young ate significantly more large prey (mostly woodrats) than did unsuccessful owls. Thus, there appears to be a direct link from landscape habitat configuration, to the ability of owls to successfully capture large prey, to reproductive output. Here, we were able to establish a link between landscape habitat configuration on individual territories and survival and reproductive output of owls. This link seems plausible, based on interactions among owls, woodrats, and the juxtaposition of habitats supporting both.

At some level, all three of the hypotheses outlined by Gutiérrez (1985) probably account for the use of mature and old-growth forests by spotted owls, and also support the ''all-or-nothing defense'' hypothesis. For example, the presence of sufficient core habitat may allow Northern Spotted Owls to actively defend an area while avoiding predation, whereas sufficient edge may provide foraging opportunities where prey are both abundant and accessible. The age effect seen in both survival and reproductive output may be due to differences in the ability of the two age classes to survive (such as experience or hunting ability), and physiological differences in terms of reproduction, rather than differences in habitat. Interactions between age of the owls and habitat were not supported by the best approximating model; apparently, younger birds were not necessarily relegated to poorer habitat that lowered their potential for survival.

Effects of landscape habitat on fitness

Estimates of habitat fitness potential are female-based and a territory must necessarily be occupied by a pair in order for habitat fitness potential to be realized. Territory occupancy is best estimated where detectability of birds can be modeled, such as in a capture–recapture framework. We were unable to estimate occupancy because detectability, territory abandonment, and territory reoccupation were all confounded. Although ad hoc estimators could be used, we chose not to do this because such estimators ignore detectability.

There appears to be a dichotomy between the effects of landscape habitat characteristics on survival and on reproductive output. Survival seems positively associated with some level of interior mature and old-growth coniferous forest and the edge between those forests and other vegetation types, whereas reproductive output is enhanced by convoluted edge with little interior habitat. Thus, there is evidently a trade-off in potential need for interior habitat and potential need for ecotones within a territory. This trade-off was expressed in estimates of habitat fitness potential in Northern Spotted Owls, where high fitness balanced having both core owl habitat for maintaining high survival and having some mosaic of older forest and other vegetation types for maximizing reproduction and maintaining high survival. This mosaic was expressed as small patches of other vegetation types with convoluted edges, dispersed within and around a main patch of mature and old-growth forest (Fig. 10). Examining the effects of just one of the components of habitat fitness potential as a surrogate for fitness would be misleading. A landscape pattern within a territory that promotes either high survival or high fecundity alone does not necessarily promote high fitness (Fig. 10). McGraw and Caswell (1996) found a similar problem in relating lifetime reproductive output with individual fitness of the European Sparrowhawk (*Accipiter nisus*); lifetime reproductive output was a poor surrogate for fitness.

Based on differences in estimates of spatial process variation, habitat-related variation in fecundity is probably most responsible for variation in fitness. Reproductive output had much higher spatial variation than did survival. However, this qualitative assessment is tempered by the fact that Leslie matrix models, such as those used here to estimate fitness, tend to be most sensitive to changes in adult survival (Noon and Biles 1990). Low spatial variation in survival can still have large effects on estimates of fitness because the matrix model used to estimate habitat fitness potential tends to be sensitive to small changes in adult survival (Noon and Biles 1990). The high positive correlation between point estimates of survival and habitat fitness potential suggests that changes in habitat fitness potential were tracking smaller changes in survival.

Thus, we propose that, once a territory with suitable habitat characteristics is selected for defense, individuals enjoy high survival. The quality of that territory then determines the reproductive output of individuals. Habitat fitness potential is then determined more by within-territory landscape configurations that control reproductive output than by survival rates, as long as the landscape configuration controlling survival remains intact.

Forest fragmentation and fitness

In conservation biology, forest fragmentation generally has a negative connotation, especially with respect to potentially interior forest species such as the Northern Spotted Owl (Wiens 1994). In the early years of wildlife management, edge (and hence fragmentation) was often promoted as generally beneficial for wildlife (Yoakum and Dasmann 1971). Fragmentation can be beneficial for populations of some species and deleterious for others. Andrén (1992) found that densities of five sympatric species of corvids differed along a gradient of landscape fragmentation; differing degrees of fragmentation were beneficial to some species but not to others. Other organisms appear to react little to fragmentation at different scales (Beyer et al. 1996, Johannesen and Ims 1996).

The mosaics of older forest and other vegetation types that we observed on spotted owl territories resulted from human-caused (e.g., logging) and natural disturbances (e.g., fire), as well as edaphic and topographic factors. Heterogeneity of vegetation types within spotted owl territories in the Klamath Mountains province has been determined by both past and present landscape disturbances. Past disturbances were governed primarily by wildfires, and present disturbances by logging. Thus, our measures of fragmentation do not strictly conform to the definition of Wiens (1989*b*) for habitat fragmentation, because the mosaics that we observed were not entirely due to conversion of continuous habitat into smaller patches through some disturbance process. Although edge between mature and old-growth forest and other vegetation types appeared to be a key habitat component, we emphasize that this component is still poorly understood because of our inability to discriminate among other vegetation types. For example, edge, as we measured it, could represent ecotones with a clearcut from logging, or an oak forest resulting from edaphic conditions.

Two key questions are (1) to what degree are the mosaics observed in Northern Spotted Owl territories having a high habitat fitness potential due to fine-scale fragmentation of mature and old-growth forest from disturbance; and (2) can logging practices mimic this fine-scale fragmentation? Current logging practices probably do not generate the type of mosaic that we observed in high-fitness territories; clear-cut logging leaves large, regularly shaped patches with clean edges. Fire disturbance, on the other hand, tends to leave smaller, irregularly shaped patches having convoluted edges (see Agee 1991). In addition, fire disturbance leaves a variety of seral stages based on the frequency of low, moderate, and severe burns over time. However, it is poorly understood how fire shaped past landscape mosaics. The appearance of landscape mosaics prior to fire suppression and logging would greatly increase our ability to develop silvicultural practices that might be neutral or possibly beneficial to Northern Spotted Owls in the Klamath Mountains province. In addition, our definition of edge needs to be further examined in terms of which seral stages adjacent to mature and old-growth forest most strongly affect spotted owl reproduction.

Are Northern Spotted Owls ideal-free or ideal-despotic?

The presence of spatial process variation among habitat fitness potentials estimated for individual territories suggested that Northern Spotted Owls follow an ideal-despotic distribution. Although the coefficient of spatial process variation for habitat fitness potential was small (5%), spatial process variation in habitat fitness potential differed from zero and there was a clear gradient in habitat fitness potential. However, extremes were not great in terms of relative magnitude. Unfortunately, no other studies have directly estimated habitat fitness potential for a species with a life history similar to that of the Northern Spotted Owl. The closest was McGraw and Caswell (1996), who estimated individual fitness for European Sparrowhawks, which ranged from 0.75 to 3.00. However, these estimates of fitness were on an individual basis rather than a habitat basis, and comparisons with our estimates are difficult. If reproductive output is considered the primary driving force in defining habitat fitness potential, then the larger spatial process variation in reproductive output could be considered sufficient evidence that Northern Spotted Owls follow an ideal-despotic distribution. The possibility also exists that habitat fitness potential has been reduced on spotted owl territories because of past changes in the landscape caused by logging. To assess this possibility requires examination of the patch characteristics on territories with different estimated habitat fitness potentials, e.g., assessing the source and timing of disturbance that created other habitats within the mature and old-growth forest matrix.

An ideal-despotic distribution suggests that there is a source–sink relationship among Northern Spotted Owl territories. Territories with habitat fitness potentials >1 act as sources of recruits, whereas territories with habitat fitness potentials <1 act as sinks, in that birth rates by individuals in those territories do not compensate for mortality (Pulliam 1988). However, source–sink models are usually based on discrete habitats. Northern Spotted Owls, and probably a number of other species as well, seem to follow a continuous gradient of habitat quality in which territories may be considered sources at one end of the gradient and sinks at the other end with a number of territories in between that can be relative sources or sinks, or simply balance birth and death rates with $\lambda_H \approx 1$. Regardless, territories at one end of the spectrum are those that contribute surplus recruits to the population, whereas those at the other end may act as sinks if occupied on a regular basis.

An important but unresolved question is: how does habitat fitness potential, λ_H, relate to the overall population rate of change (λ)? If a 1:1 correspondence is assumed, the weighted average of habitat fitness potential that we estimated would be a measure of the overall population rate of change in the absence of temporal variation. In this study, the estimate of λ would be 1.075, the weighted mean of λ_H, which indicates a growing population. On the other hand, the rate of population change estimated using more conventional means was $\hat{\lambda} = 1.009$, which indicates that this same population was stationary over the same time period. The reason for the discrepancy between the two estimates is due to occupancy. For λ_H and λ to be roughly equivalent, all territories need to be occupied. Therefore, to understand the relationship between λ_H and λ, some measure of occupancy on territories needs to be included in some function that also includes λ_H. Such a function might be simply $\lambda = (\lambda_H)(p_o)$, where p_o is some measure of occupancy. However, as discussed previously, we were unable to estimate occupancy appropriately.

Although theoretical models have been developed integrating ideal-free and ideal-despotic distributions with source–sink dynamics (Pulliam and Danielson 1991), they include only discrete habitats and use only reproductive success as a measure of habitat quality. Thus, these models need to be extended to include continuous gradients of habitat quality and estimates of survival.

Sources of variation in Northern Spotted Owl populations

Based on estimated total process variation, apparent survival varied the least, whereas reproductive output varied the most during this study. Two factors, climate and habitat, appeared to have the greatest effect on these two life history traits. However, the effects of these two factors were not similar on apparent survival and reproductive output. Apparent survival exhibited more spatial variation than temporal variation, whereas temporal and spatial variation contributed about equally to total observed variation in reproductive output. Based on our results, spatial and temporal variation appeared to operate independently on reproductive output because of the lack of interaction between climate and habitat covariates. Habitat quality did not appear to buffer the effects of climatic variation on reproductive output of individuals. In other words, temporal variation in reproductive output would be similar if habitat quality were uniformly ''good'' or uniformly ''bad'' among territories. However, temporal and spatial variation did not appear to be independent in their effects on survival, based on the interactions between the climate covariates and the habitat covariates, edge between mature and old-growth forest, and distance between patches of these forests. As habitat quality decreased, the effects of climatic variation on survival increased.

One source of variation that we did not consider was individual variation, which is a function of phenotypic or genotypic differences among individuals (White 2000). Although age effects were accounted for in the models, they contributed little in explaining total process variation. In reality, age effects probably account for little in terms of individual variation, which is more related to individual fitness. A better expression of individual variation would be variation in true individual fitness, those individuals genetically predisposed to surviving better and producing more offspring and, hence, contributing more to future generations. If an ideal-despotic distribution were operating in spotted owls, then habitat quality, as defined by habitat fitness potential, was probably confounded with individual fitness. Individuals with higher intrinsic fitness would be more competitive (despotic) and able to garner the best resources to ensure that their fitness was realized. Partitioning individual fitness from habitat fitness potential requires identification of genetic or phenotypic traits to allow for separation of individual fitness from fitness bestowed on individuals by habitat quality.

Climatic variation and habitat quality

For apparent survival, the best approximating model included interactions between climate and habitat covariates (SOEDG and SODIS) that described the mosaic of mature and old-growth forests and other vegetation types. There appears to be an optimal type of mosaic that defines high-quality spotted owl habitat. In the face of climatic variation, these areas may also provide a more stable prey base by providing more distinct patches of prey populations and, possibly, greater prey diversity if other habitats are a mosaic of different seral stages. Radio-marked Northern Spotted Owls traverse their home ranges less, and hence expend less energy, in areas of older forest mixed with different seral stages than do owls in areas with similar amounts of older forest mixed with clearcuts (Carey and Peeler 1995). The period when climatic variation affects spotted owls is during the early breeding season, when energetic stress is high. Increased movements would only add to an already stressed energetic burden. In addition, spotted owls may exhaust patches of prey through repeated visits (Carey et al. 1992). Thus, dispersed patches of different vegetation types and seral stages within a matrix of mature and old-growth forest may provide a stable prey resource that buffers against the effects of climate on prey populations and, hence, spotted owls. Although speculative, this argument suggests a link in the interaction of climate and habitat quality, with prey abundance and availability as a potential mechanism behind that interaction. This also suggests that habitat maintenance is essential at landscape scales because excessive loss of key landscape habitat components, such as mature and old-growth forest, can exacerbate the effects of unfavorable climatic conditions on survival.

The best approximating model for reproductive output does not support any interactions between climate and habitat covariates. Climate affects reproductive output during the late breeding season. We surmise that climatic effects during this period could inhibit prey populations or the ability of parents to capture prey for their offspring, or could cause direct mortality of young owls. The lack of interaction between climate and habitat supports the idea that increased precipitation during the late breeding season may directly affect survival of young outs before they fledge and are counted during surveys. However, we cannot discount the possibility that, although these particular data during this time period did not support climate–habitat interactions, they might have been present given a longer time period.

Implications for Northern Spotted Owl population dynamics

Dennis and Taper (1994) and Turchin (1995) define a regulated population as one with a long-term stationary probability distribution of population densities. This definition implies some mean level of density around which a regulated population fluctuates with some bounded variance (Turchin 1995). Thus, this definition of a regulated population can be rephrased in terms of rates of population change (λ) as *a population with a long-term mean* λ *of one* ($\bar{\lambda} = 1$) *that follows some probability distribution with variance* σ^2_λ. From this, limitation can be defined as the process that sets long-term $\bar{\lambda} = 1$, and regulation as the process that maintains the population at $\bar{\lambda} = 1$ within σ^2_λ. Density dependence can then be viewed as the dependence of population rates of change on past and/or present population densities (Murdoch and Walde 1989). We were only able to speculate about the role of density-dependent factors with respect to Northern Spotted Owl populations. We did not incorporate density into our analyses, largely because of the problems in detecting density dependence from only 10 yr of field data (see Shenk 1997). The following discussion attempts to integrate simple population dynamics with our empirical evidence on life history traits, their process variation influenced by climate and habitat variation, and their relationship to population rates of change.

Based on estimates of apparent survival and recruitment, the spotted owl population in this study appeared to be stationary ($\bar{\lambda} \approx 1$) during the 10-yr study period. This population was stationary under fluctuating climate conditions and habitat quality that varied spatially, but varied little over time. The stationary nature of the study population suggested that this population was regulated. In addition, temporal process variation in λ for this population was low, suggesting little variation around $\bar{\lambda}$. This evidence suggested a well-regulated population, which may be typical of bird populations (Murdoch 1994), especially raptor populations (Newton 1989*c*).

Habitat may proximally limit spotted owl populations in northwestern California. Here, we use the term *habitat* in reference to the landscape configurations of mature and old-growth forests at the territory scale, which collectively defined the life history traits and habitat fitness potential. Ultimately, the abundance and availability of prey within spotted owl habitat may limit populations, because the habitat covariates most closely associated with survival and reproduction are best explained in terms of prey abundance and availability. Lack (1954, 1966) argues that food supply ultimately limits avian populations. Newton (1980) extends this argument to limitation in raptor populations. Field experiments using food supplementation of raptors support this argument in terms of reproductive output, which increases with increasing available food (Ward and Kennedy 1996, Wiehn and Korpimäki 1997). Unfortunately, empirical evidence is scant concerning the effects of food supply on survival of territory holders. If habitat configurations within Northern Spotted Owl territories are limiting, then both survival and fecundity may be density dependent *if* habitat selection is density dependent, as suggested by an ideal-despotic distribution in spotted owls (Morris 1989). However, this idea needs further empirical examination.

Previously, we argued that survival of territorial individuals determines the magnitude of λ in Northern Spotted Owls, whereas recruitment determines temporal variation in λ above the relative magnitude set by survival. In terms of total process variation, survival varied little, relative to reproductive output, over the course of this study. However, most of the variation in survival was based on habitat variation, whereas variation in reproductive output was based equally on climatic and habitat variation. By affecting apparent survival, habitat quality may determine the magnitude of λ, whereas reproductive output and recruitment may determine variation around λ. If habitat conditions remain unchanged, then density-dependent factors (habitat) control the magnitude of λ, and combined density-independent (climate) and density-dependent factors (habitat) control the variation around λ. However, if habitat conditions change, e.g., from less ''good'' habitat to more ''poor'' habitat, then density-independent factors influence the variation in survival and, hence, variation around λ. In other words, as habitat quality decreases, density-independent factors become more important in determining variation around λ. Thus, there is probably some range of habitat quality where $\bar{\lambda}$ will remain at 1 but variation around $\bar{\lambda}$ will increase. Theoretically, an increase in variation around $\bar{\lambda}$, with a greater proportion of this variation caused by climate, will increase the probability of extinction (Lande 1993). At some point, lower habitat quality will cause the population to be unregulated (i.e., $\bar{\lambda} < 1$), and it will decline, eventually to extinction.

The argument as to whether a single general factor, such as habitat quality or climate, regulates or limits populations becomes moot when interactions are considered (Holmes 1995). These two factors can increase or decrease in importance, depending on changes in the other factor. We believe that understanding the magnitude, strength, and relative importance of different factors under varying conditions provides a deeper understanding of population dynamics.

Acknowledgments

We thank the many people who assisted in the implementation of this project and collection of field data. Pat Ward worked on the initial design and development of the project. Christine Moen, Jennifer Blakesley, John Hunter, and Peter Carlson maintained the continuity in this project over the years by providing scientific contributions, logistic, and field assistance. A project of this scope necessitates a large number of field workers over the years. Antonio Padilla and Colin Jewett contributed greatly to the field effort and donated much of their time and energy over the years. Kevin White, Leon Somme, and Kendal Young also spent a great deal of time in the field on this project. Matt Brunner, Caroline Crowley, David Delaney, Tom Evans, David Fix, Shawna Franklin, Terry Hall, Tom Heinz, Marissa Herrera, Eric Hopson, Marc Kasper, Rich Kostecke, Dave Lamphear, Doug Leslie, Mike Schwerdt, Spencer Smith, Campbell Thompson, Stephanie Waldo, and Jim Woodford also assisted in the field. Gary White at Colorado State University assisted us in using program MARK to analyze the data. Carl Schwarz at Simon Frasier University provided technical advice on POPAN-4. Phil Chapman at Colorado State University assisted with the analyses using mixed-model ANOVA. A number of people provided logistic support and general encouragement for the project. These included Gordon Gould of California Department of Fish and Game, David Solis and John Robinson from Region 5 of the U.S. Forest Service; Jack Kahl, Jeff Mattison, John Brack, Don Kudrna, Larry Cabodi, Debbie Hom, Virginia Wade, Ann Chrisney, Marilyn Fox, and Terry Davis from the Six Rivers National Forest; Jane Bardof, Margaret Lawrence, Cindy Levy, Terry Brumley, Becky Rogers, and Kim Stokely from the Shasta-Trinity National Forest; Tony Hacking, Jan Johnson, Kathy Nickell, and Mark Williams from the Klamath National Forest; Barry Noon, Bruce Bingham, Nancy Tighlman, and Cindy Zabel from Redwood Sciences Laboratory; Lowell Diller and Catherine Hibbard from Simpson Timber Company; Scott Warner, Keith Johnson, and Ted James from Sierra Pacific Industries; Steve Hawks and Jim Decker from the Bureau of Land Management; Peter Steele and Cameron Barrows from the Nature Conservancy; and Mark Andre from the City of Arcata. Pat Kennedy, Jim Nichols, Tanya Shenk, and John Wiens reviewed drafts of parts of this manuscript and provided many useful suggestions for improvements over the course of the analysis. This project was funded by the California Environmental License Plate Fund, California Department of Fish and Game, McIntire-Stennis, Pacific Southwest Forest and Range Experiment Station, Six Rivers National Forest, and U.S. Forest Service Region 5.

APPENDIX A

Biological Background

Biological basis for delineation of life history periods

The *winter stress period* (November–February) and the *heat stress period* (July and August) were defined based on when maximum climatic stresses occurred. The winter stress period averaged the highest precipitation and coldest temperatures during the year, whereas the heat stress period averaged the highest maximum temperatures ≥32°C (Fig. 2). The winter stress period is when female owls may develop fat reserves prior to laying eggs in the spring. Hirons (1982) observed that ovarian follicles failed to develop in Tawny Owl (*Strix aluco*) females that had insufficient fat reserves from the winter. Although individuals do not undergo stresses from rearing young and molting during this period, they may encounter stress from poor hunting conditions during extended periods of rain. Thus, climatic conditions during the winter stress period can affect reproductive output in the following spring, as well as over-winter survival. Extremely hot conditions during the heat stress period, regardless of precipitation, could negatively affect survival in fledged young and ≥1-yr-olds. Although counting of most fledged young occurs before this period, survival of fledged young during this period might affect estimates of recruitment of young birds into the territorial population the following year.

Two periods were defined in which reproduction may require additional energetic demands on individuals. The *early nesting period* (March and April) occurs when owls initiate nesting and incubate eggs, and the *late nesting period* (May) occurs when young are brooded with decreasing frequency until they fledge in late May and early June (Forsman et al. 1984). These two periods can be optimal, given appropriate conditions, for plant growth that optimizes maintenance and production of prey populations. However, severe inclement weather may affect reproductive output during these two periods. In addition, conditions during the early nesting period may affect survival of owls ≥1 yr old, because winter-like conditions can still occur. The last period we considered was the *dispersal period* in September and October, when juveniles disperse from their natal territories and first begin fending for themselves (Gutiérrez et al. 1995). This period is relevant only to recruitment, because juvenile survival affects potential recruitment of these individuals into the territorial population.

Biological basis for development of hypothesized climate models

In terms of direct effects, it is unlikely that cold temperatures alone affect survival of Northern Spotted Owls ≥1 yr old because they have plumage characteristics similar to those of boreal owl species (Barrows 1981). However, young owls have poor thermoregulatory ability while still in the nest (Howell 1964, Wijnandts 1984) and may be negatively affected by cold temperatures, especially in combination with precipitation. Conversely, Northern Spotted Owls may be prone to heat stress. They appear to have a lower upper critical temperature (25.2°C) than do Great Horned Owls, exhibiting heat stress at ~32°C under laboratory conditions and in the wild (Barrows 1981, Ganey et al. 1993).

In terms of indirect effects, precipitation combined with cold temperatures may inhibit the owls' ability to forage successfully at night when they rely primarily on hearing to locate and capture prey (Forsman et al. 1984). Although precipitation does not inhibit nocturnal movements of radio-tagged Northern Spotted Owls (Forsman 1980), it reduces the hunting success of Tawny Owls (*Strix aluco*), presumably by limiting the owls' ability to hear prey movement at night (Hirons 1982). Therefore, precipitation may not inhibit movements of owls, but may inhibit their success in capturing prey. Large prey may also limit their movements during rainy weather (Linsdale and Tevis 1951, Wells-Gosling and Heaney 1984, Gentry et al. 1966), whereas small prey may increase their activity (Gentry et al. 1966, Marten 1973, Vickery and Bider 1981, Scheibe 1984). However, small prey may decrease their activity during low ambient temperatures (Marten 1973, Vickery and Bider 1981, Scheibe 1984). We postulate that hunting success for Northern Spotted Owls is lowest during cold, rainy periods when prey activity and the hearing ability of owls are both suppressed. Hunting success determines both individual survival and reproductive success. Female owls do all of the incubation and early brooding of young, with the male providing food (Forsman et al. 1984). Nest desertion in Tawny Owls is influenced by the inability of the male to provide sufficient food for the female during bad weather (Southern 1970). Conversely, hunting success should be highest during dry, warm conditions and neutral during wet, warm or dry, cold conditions that represent trade-offs between detection ability of owls and activity of prey (Table A1).

We also postulate that (1) wet, cold conditions and severe drought conditions, in general, would negatively effect prey survival; (2) drought conditions, regardless of temperature, would negatively affect prey reproduction and plant production; and (3) only warm, wet conditions would have a positive effect on both (Table A1). Extended rainy periods increase parasitism and disease in *Neotoma* (Linsdale and Tevis 1951), whereas *Peromyscus* has reduced body mass under drought conditions (Nelson 1993). Prey reproduction can be inhibited by both drought conditions and reduced ambient temperatures, which reduce sperm production and litter size (Meyers et al. 1985, Nelson 1993) and delay breeding seasons (Sadleir 1974). Production of forage also affects successful reproduction in prey species because of increased energetic demands during breeding (Bronson 1989). In northern California, the vegetative growing season is restricted to the spring when higher temperatures coincide with adequate water supplies, which are lacking in the summer (Major 1977). Fitter et al. (1995) suggest that ambient temperature may be the most important determinant of flowering in the spring.

TABLE A1. Potential indirect effects of climate conditions on Northern Spotted Owls and their prey that were used to develop statistical models of the effects of climate on life-history traits: 0 indicates a neutral effect, − a negative effect, and + a positive effect.

Climate condition	Hunting success	Prey survival	Prey reproduction	Prey forage production	Net effect
Warm wet	0	0	+	+	+
Cold wet	−	−	−	−	−
Warm drought	+	−	−	−	−
Cold drought	0	−	−	−	−

However, lack of available water also has a direct inhibitory effect on photosynthesis (Larcher 1980). Hypogeous fungi reach higher biomass in mesic conditions (Luoma et al. 1991), whereas tanoak requires relatively high levels of moisture and mild temperatures for production, even though it is adapted to withstand drought conditions (McDonald and Tappeiner 1987). There could also be lag effects of climate on plant production, which in turn could affect spotted owl prey. Overwinter survival and density of small mammals have been positively correlated with forage production in the previous year (Watts 1969, Jensen 1982). For example, acorn production of *Quercus* oaks in California is positively associated with total precipitation during the previous growing season (Kundel 1980). Therefore, life history parameters of Northern Spotted Owls in time $t + 1$ may be indirectly affected by the growing season in time t.

Preface

This report is one of a set of periodic reports produced by the Northwest Forest Plan (the Plan) interagency monitoring program. These reports attempt to answer questions about the effectiveness of the Plan using the latest monitoring methods and research results. The reports focus on establishing baseline information from 1994, when the Plan was approved, and reporting changes that have occurred since then. The series includes late-successional and old-growth forests, northern spotted owl (*Strix occidentalis caurina*) population and habitat, marbled murrelet (*Brachyramphus marmoratus*) population and habitat, watershed condition, government-to-government tribal relationships, socioeconomic conditions, and project implementation. These monitoring reports are also intended to identify potential issues and to recommend solutions for future adaptive management changes and, as noted in the first reporting cycle, to resolve information management issues that inevitably surface during these analyses.

Abstract

Davis, Raymond J.; Dugger, Katie M.; Mohoric, Shawne; Evers, Louisa; Aney, William C. 2011. Northwest Forest Plan—the first 15 years (1994–2008): status and trends of northern spotted owl populations and habitats. Gen. Tech. Rep. PNW-GTR-850. Portland, OR: U.S. Department of Agriculture, Forest Service, Pacific Northwest Research Station. 147 p.

This is the second in a series of periodic monitoring reports on northern spotted owl (*Strix occidentalis caurina*) population and habitat trends on federally administered lands since implementation of the Northwest Forest Plan in 1994.

Here we summarize results from a population analysis that included data from long-term demographic studies during 1985–2008. This data was analyzed separately by study area, and also in a meta-analysis across all study areas to assess temporal and spatial patterns in fecundity, apparent survival, recruitment, and annual rates of population change. Estimated rates of annual population decline ranged from 0.4 to 7.1 percent across federal study areas (weighted average of 2.8 percent). Covariates for barred owls (*Strix varia*), weather, climate, habitat, and reproductive success were analyzed and had varying degrees of association with owl demographic parameters. We now have more evidence that increasing numbers of barred owls and loss of nesting/roosting habitat contributed to demographic declines in some study areas.

We also summarize results from a habitat analysis that used the above data in conjunction with remotely sensed data from 1994 to 2007 to develop "habitat suitability" models and habitat maps. These maps were used to quantify the amount and distribution of owl habitats. We also report on causes of habitat change during this period. On federal lands, nesting/roosting habitat declined by 3.4 percent rangewide, with some physiographic provinces experiencing losses of 10 percent. Dispersal habitat increased by 5.2 percent, but dispersal-capable landscapes declined by 1 percent.

Wildfire remains the leading cause of habitat loss. We developed a rangewide "wildfire suitability" model and map to illuminate the portions of the owl's range where suitable nesting/roosting habitat overlaps with landscapes suitable for the occurrence of large wildfires.

Barred owls and management of owl habitat in fire-prone areas continue to be topics for future monitoring, research, and management consideration.

Keywords: Northwest Forest Plan, effectiveness monitoring, northern spotted owl, geographic information system, owl habitat, habitat suitability, wildfire suitability, demographic study, remote sensing, predictive model, habitat model.

Summary

For the eight federal study areas associated with the Northwest Forest Plan (the Plan) effectiveness monitoring program, the average rate of population decline was 2.8 percent per year. Strong evidence of declines in annual rates of population change were reported for five of the eight individual effectiveness monitoring area study sites, but confidence limits on point estimates for three areas in the center of the northern spotted owl (*Strix occidentalis caurina*) range (southwest Oregon) overlapped lambda = 1.0, suggesting these three populations may not be declining. Rates of population decline were highest in the northern portions of the owl's range (Washington and northern Oregon) where populations are estimated to have declined 40 to 60 percent since the Plan's implementation.

A variety of covariates including presence of barred owls (*Strix varia*), weather and long-term climate cycles, the amount of suitable nesting/roosting habitat on and adjacent to each study area, and the previous year's reproductive success, were included in the analysis of demographic data to explore associations between them and observed population trends. These covariates had varying degrees of association with owl demographic parameters, but at least one vital rate (i.e., fecundity, apparent survival, or population) was declining on all study areas.

The long-term demographic data we continue to collect are the key to understanding the range of factors that are affecting the recovery of spotted owl populations. At present, the invasion of the competitive barred owl and the amount of suitable nesting/roosting habitat are the factors most associated with spotted owl vital rates. Directly managing barred owl encroachment into spotted owl habitats may be beyond the scope of the Plan, but maintaining large blocks of suitable spotted owl habitat will likely play a key role in decreasing negative interactions between the two species and increasing the likelihood of the persistence of spotted owl populations.

On federal lands, we estimated nesting/roosting habitat losses for 1994 through 2007 in California, and 1996 through 2006 in Oregon and Washington at 3.4 percent rangewide. Although rangewide losses have not yet exceeded what was anticipated under the Plan, some physiographic provinces have incurred losses up to 10 percent. This and the fact that most of the nesting/roosting habitat loss occurred within reserved land use allocations, and not within the federal matrix outside of these reserves, raises some concern. But in spite of this paradox, the large, repetitive design of reserves appears to still be functioning as intended. Of the 12 million ac of nesting/roosting habitat remaining, 71 percent occurs on federally administered lands, and approximately 70 percent of this is in reserved land use allocations (not including riparian reserves). Over half of the nesting/roosting habitat occurs in the central (core) portions of the owl's range, within the Klamath Mountain provinces of Oregon and California (27 percent) and the western Cascades of Oregon (26 percent). Not enough time has yet elapsed for us to accurately detect or estimate any significant recruitment of nesting/roosting habitat; however, increases were observed in "marginal" (younger) forests indicating that future recruitment of nesting/roosting habitat is on track to occur, as anticipated, within the next few decades.

In addition to providing potential future nesting/roosting habitat, some younger forests function as dispersal habitat. Forest succession accounted for some dispersal habitat recruitment, especially in the more productive tree-growing portions of the range (i.e., Oregon Coast Range). Partial disturbances of nesting/roosting habitat also accounted for some of this recruitment as well. Loss of dispersal habitat, primarily from wildfires, was observed, but recruitment rates exceeded losses, resulting in a net increase in dispersal habitat of 5.2 percent (rangewide). In spite of this net gain, dispersal-capable landscapes actually decreased by 1 percent within the owl's range because of the spatial distribution of this habitat. Even with this small decrease, the network of large reserves remains fairly well connected, with the exception of the northern portion of the eastern Cascades of Washington and also within the southern tip of the range where some large reserves appear to be isolated (including the Marin County population).

Recent improvements in remotely sensed vegetation and change-detection mapping has resulted in better habitat maps to replace the baseline versions produced for the first monitoring report. Progress in habitat "niche" modeling methods and software has improved our ability to map not only habitat for spotted owls, but also "suitable habitat" for large wildfires. Wildfire remains the leading cause of owl habitat loss. About 3.6 million ac of nesting/roosting habitat remain in landscapes that are naturally prone to large wildfires. Most of this "fire-prone" habitat (85 percent) occurs within the "core" of the owl's range (i.e., the Klamath Mountains and the western Cascades of Oregon). Not all habitat burned is lost to owls, as fire intensity and frequency play a role in the effect of fire on owl habitat use. Our monitoring showed that large wildfires resulted in 30 to 62 percent loss of the nesting/roosting owl habitat within their perimeters.

Wildfire is a natural ecological process under which northern spotted owls have evolved, but the landscapes in which this occurred were heavily altered during the 20th century. Most remaining nesting/roosting habitat is now contained on federal land, and its fragmented condition makes it, and the populations that rely on it, more vulnerable to future large wildfires. Conservation management for northern spotted owls in relation to wildfire will involve understanding (1) where suitable owl habitats overlap suitable habitat for large wildfire; (2) the effect of fuel reduction treatments to reduce fire risk on owl habitat use and demographics; and (3) the relationships of fire frequency, severity, and extent with owl habitat use and demographics.

Chapter 1: Introduction and Background

Raymond J. Davis, Katie M. Dugger, and Shawne Mohoric

In 1994, the Northwest Forest Plan (referred to hereafter as the Plan) amended 19 existing Forest Service and 7 Bureau of Land Management resource management plans within the range of the northern spotted owl (*Strix occidentalis caurina*). An interagency effectiveness monitoring framework was implemented to meet requirements for tracking the status and trends for late-successional and old-growth forests, northern spotted owl populations and habitat, marbled murrelet (*Brachyramphus marmoratus*) populations and habitat, watershed condition, social and economic conditions, and tribal relationships. Monitoring results are reported at 1-year intervals and evaluated at 5-year intervals. The first regional monitoring reports roughly covered the first 10 years of Plan implementation and were documented in a series of General Technical Reports posted at http://www.fs.fed.us/pnw/publications/gtrs.shtml. The first northern spotted owl population and habitat monitoring report was produced in 2005 covering status and trends of populations up to 2003 and habitat up to 2002 (Lint 2005). This report is the second in the series of northern spotted owl effectiveness monitoring reports (Lint et al. 1999) and covers population status and trend up to 2008 and habitat status and trend up to 2007.

The goal of the northern spotted owl monitoring program is to evaluate the success of the Plan in arresting the downward trends in populations and habitats that were largely responsible for the establishment of the Plan. In part, the Plan was designed to maintain and restore habitat conditions necessary to support viable populations of the northern spotted owl on federally administered lands throughout the owl's range (fig. 1-1). The objectives for northern spotted owl effectiveness monitoring are as follows:

1. Assess changes in population trends and demographic rates of spotted owls on federal lands within the owl's range.
2. Assess changes in the amount and distribution of nesting, roosting, foraging and dispersal habitat for spotted owls on federal lands.

The first monitoring effort reporting on status and trends of northern spotted owl populations and habitat (Lint 2005) included a summary of the fourth northern spotted owl meta-analysis (Anthony et al. 2006) and produced a habitat baseline map using the latest technology and best available data at the time. This report covers the first 15 years of implementation under the Plan, including a summary of the fifth northern spotted owl population meta-analysis (Forsman et al. 2011) and the development of new habitat maps based on new vegetation data, analytical methods, and habitat modeling technologies.

Lint (2005) realized that as technology advances, there will be a need to refine or adapt old monitoring methods for new analytical approaches. With the help of leaders in the fields of statistics and wildlife demographics, the analytical methods for conducting the population meta-analysis continue to advance. Barred owl (*Strix varia*), climate, and habitat covariates were included in the latest analysis for the first time in 2009 (Forsman et al. 2011). The habitat covariates used were products from the 10-year report (Davis and Lint 2005). The inclusion of these new modeling techniques and covariates allowed us to investigate relationships between them and owl demographics for the very first time.

Likewise, the habitat analysis has evolved to incorporate new habitat modeling and forest pattern analysis software that can be used for identifying habitat conditions, characterization of change to those conditions, and the recruitment of those conditions through forest succession. Improvements were made to the vegetation data used to characterize owl habitat, including the addition of more variables for habitat modeling and analysis. Most notable, a consistent vegetation data set was produced for the entire range of the northern spotted owl, which has never been available before. This new vegetation data set replaces the two previously used data sets (IVMP and CALVEG) and, along with new modeling software, allowed us to refine the previous baseline habitat map. Therefore the baseline amounts and distribution of owl habitat reported in the 10-year report are replaced by results presented in this report.

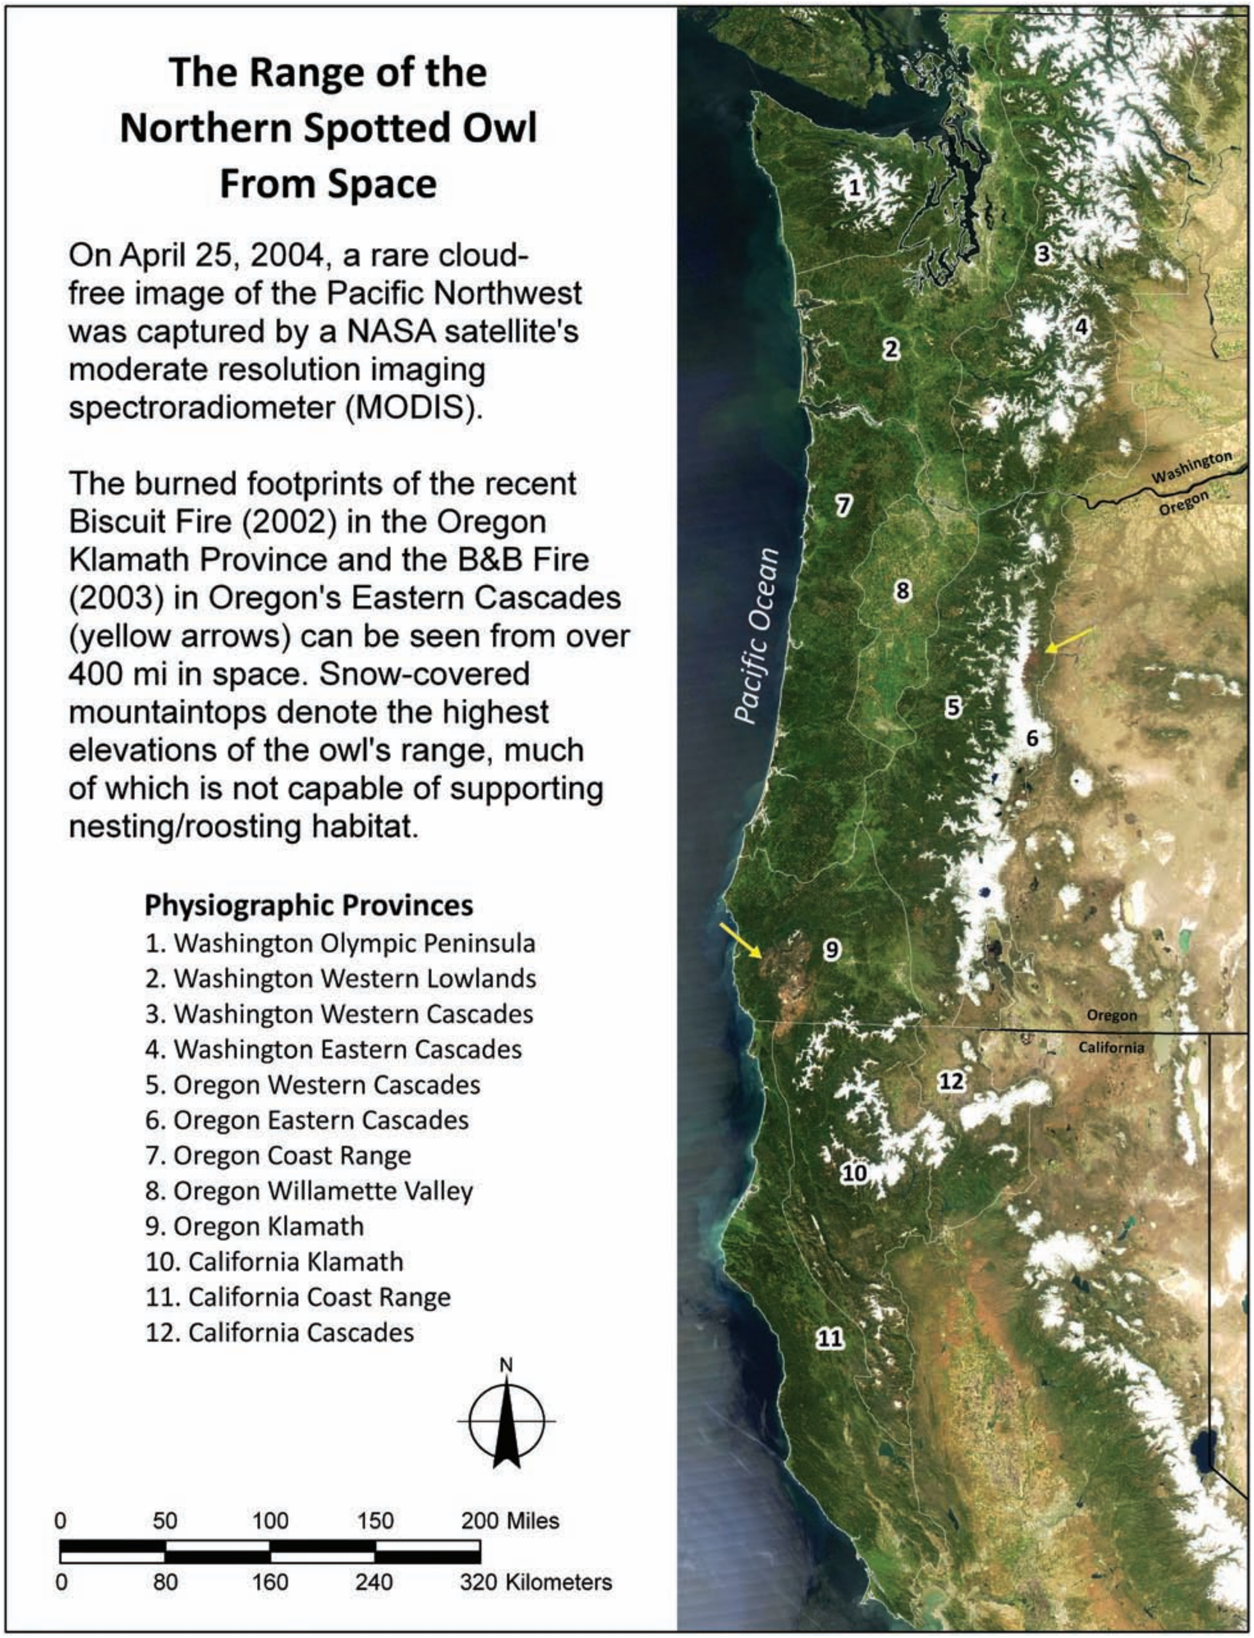

Figure 1-1—The range of the northern spotted owl. NASA = National Aeronautics Space Administration.

Improvements were also made to the remotely sensed data used for estimating habitat changes. These improvements include a finer time sequence of change-detection (annual versus 4- to 5-year intervals) and an improved ability to detect lower intensity disturbances (i.e., thinning, insects, and disease). Another improvement in our ability to detect habitat changes came from the creation of a vegetation data set that contains the same variables as the baseline data set, but for a later period. We called these vegetation data sets "bookends." Our first bookend is from 1994 in California and from 1996 in Oregon and Washington. The other bookend is from 2007 in California and from 2006 in Oregon and Washington. Therefore our habitat maps and our analysis of habitat status and trends cover the period from 1994/96 to 2006/07.

The spotted owl monitoring plan includes two phases of monitoring (Lint et al. 1999). Phase I entails demographic monitoring of individual territorial owls on eight federal study areas to estimate population demographics including survival, fecundity, and rate of population change while also tracking habitat conditions rangewide. The eight federal study areas that are part of phase I occur on federal lands administered by the U.S. Forest Service, Bureau of Land Management, and the National Park Service. They provide population trend data for a representative mix of areas considered key to the success of owl management under the Plan. The scientists who developed the monitoring plan determined that these eight study areas were the minimum number needed to be able to make scientifically credible and defensible inferences of population trends to the broader federal landscape within the owl's range (Lint et al. 1999, Mulder 1997). It is hoped that eventually the demographic monitoring data can be combined with the habitat monitoring data to develop predictive models of owl occurrence and demographic performance based on observed habitat conditions. This would allow for implementation of phase II, which increases emphasis on habitat monitoring and decreases the population monitoring to a minimum of four study areas, which would provide a means to validate the population predictions of the habitat models. Implementation of phase II depends on our ability to relate owl demography to habitat conditions such that we can relate habitat status and trends directly to population status and trends with acceptable confidence. To date, attempts to develop predictive models have had mixed results (Dugger et al. 2005, Franklin et al. 2000, Olson et al. 2004) and have generally been unsuccessful across the range of the owl; however, some progress has been made as noted above and, as technology continues to advance, this remains our goal.

After 15 years, agency managers continue to be proactive and supportive of the monitoring program. As Lint (2005) stated, this support is, "of utmost importance to the future of the effectiveness monitoring program." The Northwest Forest Plan's effectiveness monitoring program (Mulder et al. 1999) has received national and international attention (Gosselin 2009) and has been noted as the largest and most comprehensive regional forest plan monitoring ever conducted (McAlpine et al. 2007). The monitoring data created and the analysis results presented in the 10-year monitoring report have provided valuable information for managers and policymakers in making informed decisions. Examples include northern spotted owl recovery planning (USDI 2008b) and designation of critical habitat (USDI 2008a) and increased emphasis by regulatory and management agencies to reduce risk of owl habitat and old forests from high-severity fire in dry provinces (Spies et al. 2006).

Chapter 2: Population Status and Trend

Katie M. Dugger and Raymond J. Davis

Introduction

The collection of demography data is the foundation of the effectiveness monitoring program for northern spotted owls (*Strix occidentalis caurina*) (Lint et al. 1999), designed to monitor the effect of the Northwest Forest Plan (the Plan) on populations. Demographic surveys for spotted owls following standardized data collection protocols began on some study areas as early as 1985 (northwest California: Franklin et al. 1996a, 1996b) even before the monitoring plan was actually finalized. The first rangewide meta-analysis was conducted in 1991 (Anderson and Burnham 1992), then again in 1993 (Burnham et al. 1996), and every 5 years thereafter (1998: Franklin et al. 1999; 2004: Anthony et al. 2006; 2009: Forsman et al. 2011). This long history of owl surveys and demographic data collection represents the single largest, long-term mark-recapture data set in the world for a threatened species (Courtney et al. 2004), and these data are invaluable for monitoring spotted owls under the Plan.

The goal of the population component of the monitoring program is to determine if the Plan is arresting or slowing the declining trend in northern spotted owl populations on federally administered lands throughout the owl's range. This is accomplished with annual data collection on eight federal study areas associated with the effectiveness monitoring plan (Lint et al. 1999). For the 10-year report (Lint 2005), these eight areas and data from three other independent study areas provided relevant data to address this question on federal lands managed under the Plan (Anthony et al. 2006). After 15 years, we report results from the eight federal demographic study areas and one independent study area. These nine areas are spread throughout the owl's range (fig. 2-1) and data on owl occupancy, survival, and productivity were gathered annually from each to estimate apparent adult survival, reproduction, and annual rate of change of owl populations. Detailed results of the analyses of these data and data from two other, independent study areas within the range of the owl are reported by Forsman et al. (2011). The objectives of the most recent population status and trend meta-analysis were as follows:

- Estimate age-specific survival and fecundity rates and their sampling variances for individual study areas.
- Determine if any trends in adult female survival and fecundity exist across study areas.
- Estimate annual rates of population change (λ) and their sampling variances for individual study areas.
- Determine if the declines in apparent survival and populations, which were documented previously (Anthony et al. 2006), have continued or stabilized.
- Determine whether changes in the amount of suitable habitat, the presence of barred owls (*Strix varia*), or climate explain the observed annual variability in owl vital rates.
- Estimate components of the rate of population change, including apparent survival and recruitment rates that were not done in previous analyses (Anthony et al. 2006, Burnham et al. 1996, Franklin et al. 1999).

Data Sources and Methods

Data from eight demographic study areas in Washington, Oregon, and California were used to estimate status and trends of owl populations on federal lands (fig. 2-1). Although it is not part of the monitoring plan, data from the Rainier study area in Washington were also included because the study area occurs primarily on federal land. The two additional study areas in the latest meta-analysis are the Hoopa on tribal lands and the Green Diamond Resource study area on private timber company lands (Forsman et al. 2011). Because Hoopa and Green Diamond Resources did not include any lands managed under the Plan, they were excluded from this monitoring report, except when meta-analysis results including all 11 study areas are presented.

This monitoring report is based on nine study areas managed under the Plan that include variation in climate, vegetation, and topography and encompass most of the

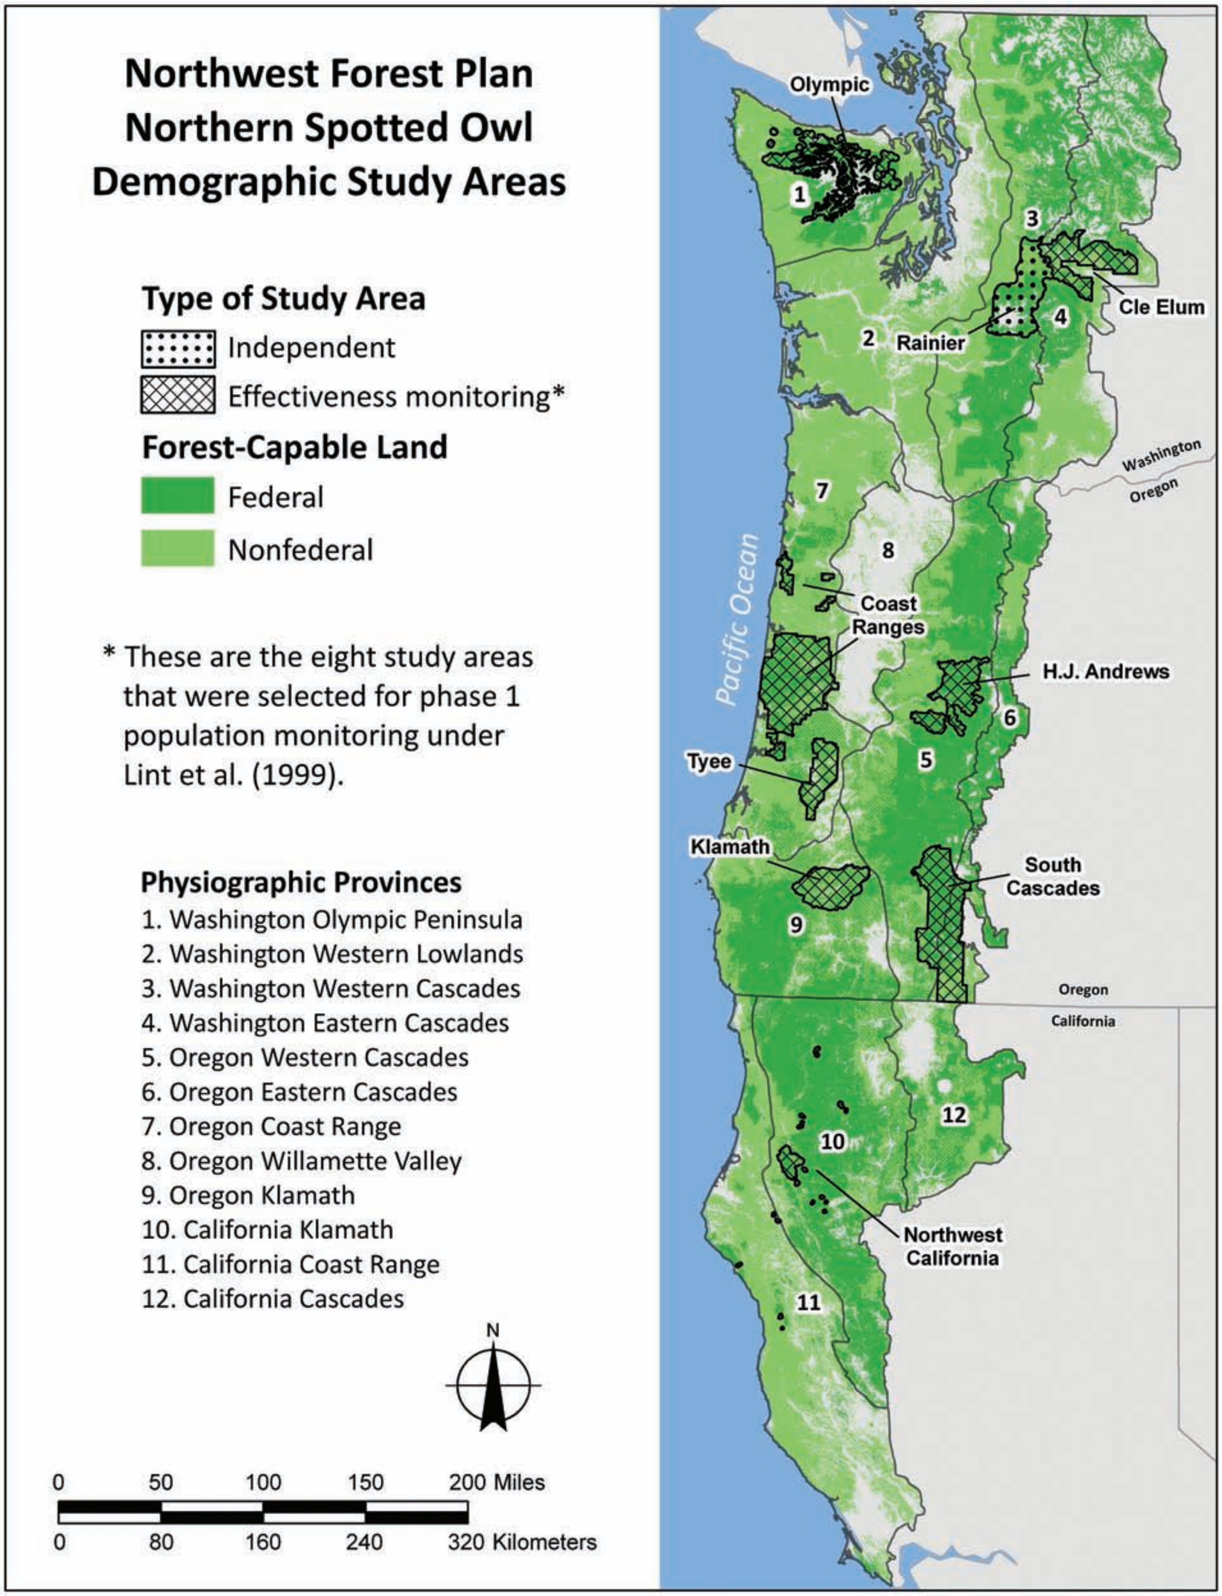

Figure 2-1—Location of nine demography study areas comprising primarily federal lands administered under the Northwest Forest Plan and included in the 2009 northern spotted owl meta-analysis. Source: Forsman et al. (2011).

northern spotted owl's geographic distribution. The forests on all study areas are dominated by conifers or mixtures of conifers and hardwoods, although there are regional differences in species composition (for more details, see Forsman et al. 2011). The nine study areas range from 396 to 1514 mi^2; the median study area size was 691 mi^2, and the mean was 829 mi^2 (table 2-1). These nine study areas encompassed 7460 mi^2 or approximately 8 percent of the owl's range, and the numbers of years included in these data sets ranged from 17 (Rainier) to 24 (Northwest California). Four of these study areas (Olympic, H.J. Andrews, South Cascades, and Northwest California) primarily comprised federal lands administered by USDA Forest Service, the USDI Bureau of Land Management, and the USDI National Park Service (table 2-1). The other five (Cle Elum, Rainier, Coast Ranges, Tyee, and Klamath) included a mixture of federal, private, and state lands intermixed in a checkerboard pattern of ownership (table 2-1).

Field Data Collection

Data on individually identifiable (i.e., banded) owls were collected from the nine demographic study areas annually. During each breeding season (March through August), multiple visits (usually > three per season) were made to owl territories to locate banded owls; confirm band numbers, sex, and age; and band any unmarked owls. In addition, the number of young produced was documented for each territorial owl, and fledglings were banded resulting in a known-age population of spotted owls on each study area. For details on the standardized field methods used to capture, mark, age, sex, and estimate productivity, see Franklin et al. (1996a). These methods resulted in complete capture histories over time of every owl banded during this study and the number of young fledged per territorial female (NYF) located each year. From these data, annual apparent survival (φ) by sex and age, annual productivity (NYF) by age, and the annual rate of population change (λ) were estimated (Forsman et al. 2011).

Data Analysis

During a 9-day period in January 2009 (9^{th} through 17^{th}), a workshop was held at Oregon State University in Corvallis, Oregon, to analyze the data from 11 study areas. This workshop was led by research scientists with internationally recognized expertise in population dynamics, statistics, and the analysis of capture-recapture data. The analyses were conducted under the direct guidance of these scientists. Consistent with the previous four workshops convened since 1991 to analyze spotted owl demographic data, all participants adopted formal protocols for error-checking data sets and for the development of a priori model sets for each parameter of interest (Anderson et al. 1999). Thus, the data were collected and prepared in a consistent manner among study areas, and there were no analyses of additional models after post hoc examination of initial results (i.e., all data sets were analyzed the same way). Detailed results from this workshop (summary presented here) are reported in Forsman et al. (2011), and these analyses represent a retrospective, observational study, which assesses the strength of association between owl vital rates and a variety of explanatory covariates rather than addressing direct cause-effect relationships.

Error Checking

Crew leaders from each study area compiled survival, fecundity, and rate of population change data sets in a consistent manner, following specific instructions provided by workshop organizers. When digital files were completed, data entry was error checked by independent members of the workshop organizing team. The capture-history files for estimation of survival and annual rate of population change were error checked by randomly drawing 10 capture histories from each study area file and comparing them to paper copies of the field data that supported each of these capture histories. Fecundity data entry was error checked in a similar way, with 10 records of reproductive success for a specified female in a given year compared to paper copies of the field data forms. If errors were found in the first round of checking, the errors were corrected and the process was repeated with another sample of 10 records. If errors were found in the second round of data checking, the entire file was returned to the crew leader and principal investigator for review and correction. This sequence of error checking and correction was continued until no errors were found

Table 2-1—Descriptions of nine demographic study areas associated with land managed under the Northwest Forest Plan

Study area	Physiographic province	Years	Land-owner class	Ecological region	Study size	Number of banded owls				Total encounters[b]
						S1[a]	S2[a]	Adults[a]	Total	
					mi²					
Washington:										
Cle Elum[c]	Eastern Cascades	1989–2008	Mixed	Washington mixed conifer	689	31	32	148	211	1,170

in 10 randomly drawn records, although it is possible that a low level of data entry error might still persist. Copies of error-checked records and field data forms submitted to confirm these records were archived, and all crew leaders signed statements before submitting data for analysis certifying the accuracy of their data.

Estimating Survival

Cormack-Jolly-Seber open population models (CJS) (Franklin et al. 1996a, Lebreton et al. 1992) in Program MARK (White and Burnham 1999) were used to estimate apparent survival of owls each year. Because survival estimates from CJS models cannot separate losses of individuals who died from losses owing to permanent emigration, these models estimate apparent survival, which incorporates the annual site fidelity of individuals (true survival x site fidelity = apparent survival). Spotted owls show high annual site fidelity (Forsman et al. 2002), so permanent emigration does not seriously bias model estimates, and apparent survival is believed to be very close to true survival (Anthony et al. 2006, Forsman et al. 2011). The general approach used to generate survival estimates from capture-recapture data on individual study areas was as follows:

- Decide on a set of a priori models for analysis and the order in which models will be run.
- Evaluate goodness-of-fit of the data to the general CJS model and estimate an over-dispersion parameter (c-hat = $\hat{c}$) using the median c-hat approach in Program MARK.
- Use the estimated c-hat to adjust covariance matrices for over-dispersion and to obtain quasi-Akaike's information criteria ($QAIC_c$) for model selection.
- Run all models for capture probability and apparent survival developed in the pre-analysis a priori model set.
- Select appropriate models for inference based on $QAIC_c$ model selection results (Burnham and Anderson 2002).

Several covariates expected to affect survival, including age, sex, the cost of reproduction, the proportion of territories where barred owls were detected each year, and climate covariates, were also included in the analysis. The nature (positive or negative) of these effects was hypothesized a priori, and the appropriate models reflecting these effects were included in the initial model sets prior to analysis.

The meta-analysis of all 11 study areas combined was conducted in a similar fashion, but in addition to study area, time trends, the cost of reproduction, and the barred owl covariate, models also included land ownership, ecological region, latitude, climate, and habitat change.

Estimating Fecundity

All analyses of reproductive rate were based on the annual number of young produced per territorial female (NYF), but to be consistent with previous reports (Anthony et al. 2006, Forsman et al. 1996, Franklin et al. 1999), estimates from these models were presented as "fecundity," where fecundity is the average annual number of **female** young produced per female owl (NYF/2). This adjustment assumes a 1:1 sex ratio at birth, which has been supported by previous genetic analyses of blood collected from juveniles (Fleming et al. 1996). Models were developed a priori to investigate the effects of age, general time variation, a variety of time trends, the proportion of owl territories where barred owls were detected each year, and an even-odd year effect, which has previously been shown to reflect a temporal cycle in spotted owl reproduction (i.e., Anthony et al. 2006). In addition, climate and habitat covariates were included in the analysis. The general approach used to generate fecundity estimates was as follows:

- Decide on a set of a priori models for analysis and the order in which models will be run.
- Determine whether spatial variance (the random effect of territory) should be included in the modeling process.
- Use Proc Mixed in SAS (SAS Institute Inc. 2008) to fit all a priori models to the annual averages of NYF using a regression model based on a normal distribution.
- Select appropriate models for inference based on $QAIC_c$ model selection results (Burnham and Anderson 2002).

There was no consistent pattern regarding the best model for fecundity among study areas, so a nonparametric approach was used to estimate mean NYF by age class. The mean NYF was computed for each year and age class. Then these means were averaged across years within each age class. The estimated standard error was computed as the standard error of the average of the averages among years. This method gave equal weight to all years, regardless of the number of birds actually observed, and it did not force a model for changes over time.

As was done for survival, a meta-analysis of fecundity with all 11 study areas combined was conducted, and in addition to the covariates included in the individual study area analysis, land ownership, latitude, climate, and ecological region were also included. Analysis details and meta-analysis results are reported in Forsman et al. (2011).

Estimating Annual Rate of Population Change and Realized Population Change

The reparameterized Jolly-Seber method (Pradel 1996) was used to estimate annual rates of population change (λ_{RJS}) in Program MARK using capture-recapture data. A parameterization was used to generate annual estimates of λ (λ_t) for each study area, which allowed for decomposition of λ into two components, apparent survival (φ) and recruitment (f), where:

$$\lambda_t = \varphi_t + f_t$$

Apparent survival (φ_t) reflects both survival of territory holders within study areas and site fidelity at time t (year), so both death and permanent emigration are included in this parameter. Recruitment (f_t) is the number of new owls in the population at time t+1 per animal in the population at time t and reflects both individuals born on the study area that become established territory holders, and immigration of recruits from outside the study area. Thus, the estimate of λ_t accounts for all of the losses and gains in the study area populations during each year and results in minimum bias in estimation of the annual rate of population change (Anthony et al. 2006).

In addition to an analysis of annual population change for each individual study area, a meta-analysis was conducted with all 11 study areas combined, where landownership, latitude, climate and weather, and ecological region were also included. Analysis details and meta-analysis results are reported in Forsman et al. (2011).

Estimates of realized population change (Δ_t) were also computed and reflect the proportional change in estimated population size relative to population size in the initial year of analysis, and were computed following the methods of Franklin et al. (2004). On each study area, annual estimate of realized population change was calculated as:

$$\widehat{\Delta}_t = \prod_{i=x}^{t-1} \hat{\lambda}_i$$

where x was the year of the first estimated λ_t. For example, given three, year-specific lambdas of say 0.9 in 1993, 1.2 in 1994, and 0.7 in 1995, the realized population change would be 0.9 x 1.2 x 0.7 = 0.756. This value means that at the end of 1995, the population was 75.6 percent of the starting population in 1993. Thus, estimates of realized population change clearly illustrate the long-term, cumulative trends in annual population changes.

Results

The following is a summary of the demographic analysis of apparent survival, fecundity, annual rate of population change, and realized population change for the northern spotted owl reported by Forsman et al. (2011). These analyses are the most long-term and comprehensive to date across the range of the owl; however, although the 11 study areas included in this analysis covered a large portion of the owl's geographic range, they were not randomly selected. Thus, results cannot be considered representative of owl populations throughout its entire range and cannot be used to assess demographic trends on nonfederal lands because only two study areas on nonfederal lands were included in the analysis. However, Forsman et al. (2011) believed their results to be representative of most owl populations on federal lands as they include nine large study areas, with comprehensive geographic coverage and a variety of landownership and management strategies. Thus, the results from the nine study areas associated with federal land managed under the Plan can be used to make inferences to populations on those lands.

Survival

For the nine individual study areas, the number of banded owls included in the survival analysis were 615 1-year-olds, 668 2-year-olds, and 2,910 adults (>3 years old) with 19,680 total encounters across all individuals and age classes (table 2-1). The number of recaptures in this data set was 4.5 times the number of initial captures.

In general, survival was similar between sexes (except for Olympic where survival was higher for males) and higher for adults compared to subadults (table 2-2). Factors including time and time trends, the proportion of territories where barred owls were detected each year, reproductive rate (fledglings per pair) in the previous year, and weather had varying effects on survival depending on the study area. Mean annual estimates of model-averaged apparent survival of female owls ranged from 0.529 to 0.794 for 1-year-olds, 0.674 to 0.864 for 2-year-olds, and 0.819 to 0.865 for adults (≥3 years old) (table 2-2). Most notably, survival was declining on all but the Klamath study area, and in some cases, the declines occurred primarily in the last 10 years or so (Coast Ranges, H.J. Andrews, Tyee, South Cascades). Declines were most evident in Washington and strongest in the last 5 years for the Cle Elum and Rainier study areas. The Klamath study area was the only one for which no trend in survival was observed, although large amounts of annual variation in adult survival were observed (see fig. 5b in Forsman et al. 2011).

For the Rainier and Olympic study areas in Washington, survival was negatively associated with high rates of reproduction in the previous year, but this effect was not evident on any of the other study areas. In the meta-analysis

of all 11 study areas, the negative cost of reproduction on survival was an important covariate and a consistent effect across all study areas. The analyses of individual study areas supported the negative effect of barred owls on survival, but the effect was variable among study areas: decreased survival was associated with higher proportions of territories where barred owls were detected for Rainier, Coast Ranges, and H.J. Andrews, with weaker evidence found for the Olympic and Northwest California, and negligible evidence of a barred owl effect for Cle Elum, Tyee, and Klamath study areas. The results of the meta-analysis support much stronger negative effects of barred owl presence on spotted owl survival. The model with an additive barred owl effect ranked higher compared to the model with an interaction between barred owl presence and study area, supporting the importance of a consistent barred owl effect across all study areas, rather than an effect that varies in magnitude among areas.

The effects of climate, weather, and the amount of suitable owl habitat on survival were only investigated during the meta-analysis. There was some support for decreasing time trends in survival and a negative relationship between early nesting season precipitation and survival, but the amount of suitable habitat had no effect (Forsman et al. 2011). In addition, there was also some support for differences in survival among ecological regions, with the lowest survival rates reported for study areas in Washington mixed-conifer regions and highest survival for the Coast Ranges. The meta-analysis suggested several factors affected survival, but none of the covariates explored in this analysis explained a substantial portion of the variation among years and study areas (between 0.0 and 5.7 percent only).

Fecundity

The analysis across all 11 study areas by Forsman et al. (2011) included 11,450 observations of the number of young produced by territorial females, and 90 percent of those observations were from adult females (>3 years old). The younger age classes were observed breeding much less frequently (3.8 percent for 1-year-olds, 6.1 percent for 2-year-olds), and age had a strong effect on productivity (Forsman et al. 2011). Mean fecundity was highest for adults (0.330, SE = 0.025), lower for 2-year-olds (0.202, SE = 0.042), and nearly negligible (0.07, SE = 0.015) for 1-year-olds (Forsman et al. 2011).

Fecundity differed greatly by study area, and adult fecundity was highest on Cle Elum (0.553, SE = 0.052) and lowest in the Coast Ranges (0.263, SE = 0.04) (table 2-3). There was considerable annual variation in fecundity, but the patterns in variation were not consistent among study areas. A cyclic, even-odd-year effect where fecundity was high in even years and low in odd years was still important for some study areas (Forsman et al. 2011), but has generally become less evident since the last analysis (Anthony et al. 2006). Overall, fecundity was declining in four areas (Cle Elum, Klamath, South Cascades, Northwest California), stable in two areas (Olympic, Tyee), and increasing in three areas (Rainier, Coast Ranges, H.J. Andrews) (table 2-4).

The effects of several covariates on owl fecundity were also reported by Forsman et al. (2011). The proportion of owl territories on each study area where barred owls were detected at least once during a breeding season had a negative effect on fecundity for three study areas (Coast Ranges, Klamath, South Cascades), a positive effect on fecundity in one study area (H.J. Andrews), and no effect on the other five areas. There was also evidence that low temperatures during the early nesting season had negative effects on fecundity in three study areas (Rainier, Coast Ranges, South Cascades); late nesting season temperatures had a negative effect on fecundity on one study area (Tyee); and high precipitation during the early nesting season had negative effects on fecundity in three study areas (Cle Elum, Coast Ranges, Northwest California). Support for a negative effect of barred owls and effects of climate and weather on fecundity was generally weak. In Oregon, increased fecundity on four of five study areas (Coast Ranges, H.J. Andrews, Tyee, South Cascades) were associated with higher annual estimates of the amount of suitable habitat associated with each study area; however, more suitable habitat resulted in decreased productivity on the Klamath study area (Forsman et al. 2011). There was little indication of any association between the amount of suitable habitat and fecundity on the Washington study areas, and this association was not

investigated for California study areas because comparable maps to develop the covariate were not available (Forsman et al. 2011).

Annual Rate of Population Change

Estimates of the annual rate of population change (λ) on the nine study areas ranged from 0.929 to 0.996 (table 2-4). There was strong evidence that populations on the Cle Elum, Rainier, Olympic, Coast Ranges, H.J. Andrews, and Northwest California study areas declined during the study (table 2-4, fig. 2-2), with particularly low estimates of λ for Cle Elum and Rainier, which suggested population declines of 6.3 and 7.1 percent per year, respectively (table 2-4). Point estimates of λ for the Tyee, Klamath, and South Cascades study areas were all <1.0, but 95-percent confidence intervals (CIs) included 1.0 (table 2-4), suggesting populations may be stationary. The weighted mean estimate of λ for all the study areas included in the analysis by Forsman et al. (2011) was 0.971 (SE = 0.007, 95-percent CI = 0.960 to 0.983), which indicated that the average rate of population decline was 2.9 percent per year during the study. The weighted mean estimate of λ for the eight federal effectiveness monitoring areas (excluding Rainier) was 0.972 (SE = 0.006, 95-percent CI = 0.958 to 0.985), which indicated an estimated decline of 2.8 percent per year.

Results from the meta-analysis on the annual rate of population change indicated that both survival and recruitment differed by ecological region, with the highest survival in the Oregon Coast Douglas-fir region and lowest survival in Washington mixed-conifer region (Forsman et al. 2011). Recruitment was highest in the Oregon/California mixed-conifer region and lower elsewhere (Forsman et al. 2011). A negative association between barred owl detections and survival in the rate of population change analysis was also evident and consistent with results from the meta-analysis of survival (see above). A weak association between sur-

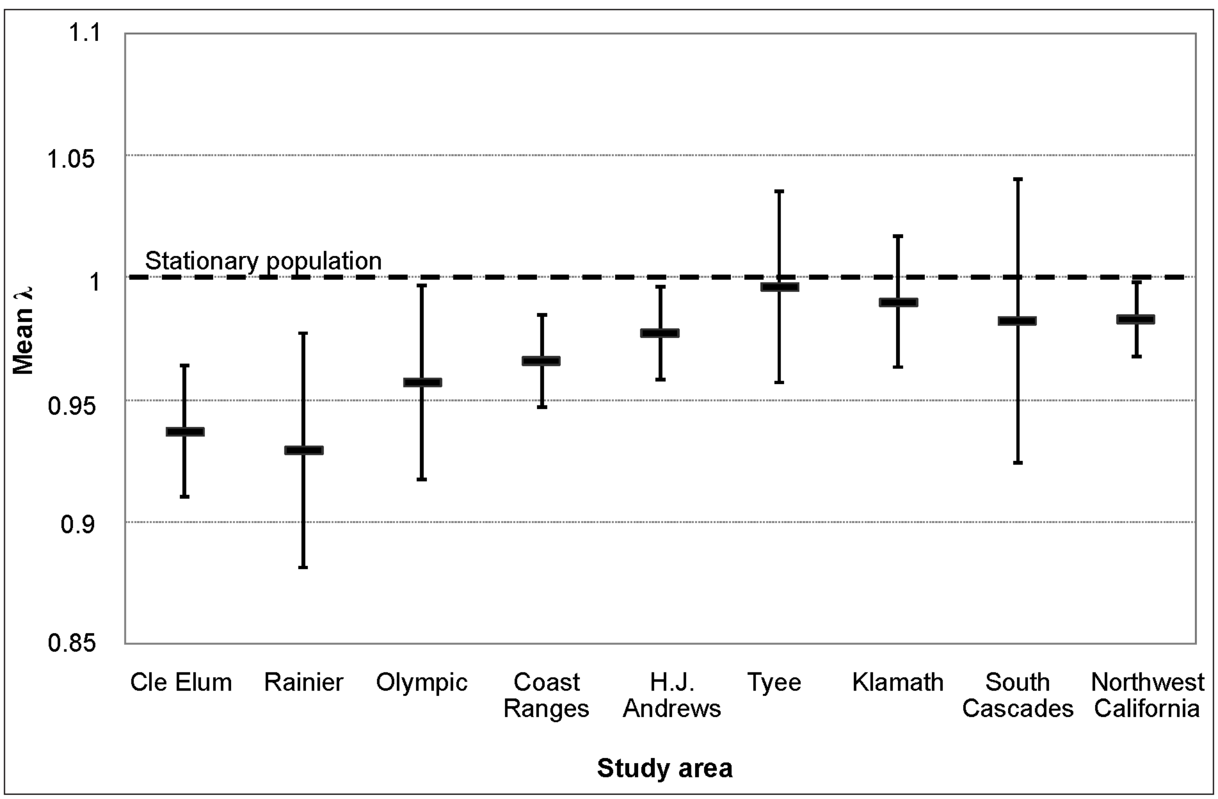

Figure 2-2—Estimates of mean annual rate of population change (λ), with 95-percent confidence intervals for northern spotted owls in nine study areas associated with lands managed under the Northwest Forest Plan in Washington, Oregon, and California. Source: Forsman et al. (2011).

vival and the Pacific Decadal Oscillation was also evident, with higher survival observed during warmer phases of this regional climate cycle. No other climate or weather covariates were important. Estimates of recruitment were higher on study areas comprising primarily federal lands (Olympic, H.J. Andrews, South Cascades, Northwest California) compared to mixed or private ownerships. Recruitment was also higher when the proportion of suitable owl habitat was higher within study areas, but was lower in association with higher proportions of suitable habitat outside study area boundaries.

Realized Population Change

Estimates of realized population change reflected the trend in the proportion of the population remaining each year, based on annual changes in λ in relation to the population at the beginning of the study (Forsman et al. 2011). Populations in Washington and northern Oregon (Olympic, Rainier, Cle Elum, Coast Ranges) declined by 40 to 60 percent during this study (fig. 2-3), and there is some evidence that populations on the H.J. Andrews and Northwest California study areas were also declining (20 to 30 percent) although 95-percent CIs around estimates of realized population change overlapped 1.0 slightly (fig. 2-3). There was less evidence that populations on South Cascades, Tyee, and Klamath areas were in decline (5 to 15 percent), but many point estimates of realized population change for these areas were less than 1.0 even though 95-percent CIs broadly overlapped 1.0 (fig. 2-3).

Discussion

These demographic results are a summary of Forsman et al. (2011) and they represent the fifth meta-analysis of demographic data from northern spotted owls (Anderson and Burnham 1992, Anthony et al. 2006, Burnham et al. 1996, Franklin et al. 1999). The second meta-analysis of demographic rates of northern spotted owls was conducted in 1993 and included 11 study areas (Burnham et al. 1996, Forsman et al. 1996). At that time, owl fecundity rates varied among years and with owl age, and exhibited no increasing or decreasing trend over time (Burnham et al. 1996). Survival rates were dependent on age, and there was a decreasing trend in adult female survival. The annual rate of population change was <1.0 for 10 of 11 areas examined, with an estimated average rate of population decline of 4.5 percent per year (Burnham et al. 1996). By 2004, owl fecundity was relatively stable among the 14 study areas examined, survival rates were declining on 5 of the 14 areas, and populations were declining on 9 of 13 study areas for which there were adequate data to estimate λ (Anthony et al. 2006). However, the annual rate of decline was less, as mean λ for the 13 areas was 0.963, indicating populations were declining 3.7 percent annually during the study (Anthony et al. 2006).

Declines in fecundity, survival, and rate of population change were observed across most study areas in this most recent analysis by Forsman et al. (2011). Over the last 15 years, populations on all 11 areas included in the recent meta-analysis declined on average 2.9 percent per year (Forsman et al. 2011). This is a lower rate of decline than the 3.7 percent reported in the last meta-analysis (Anthony et al. 2006), but the rates of decline are not directly comparable between analyses. The current analysis represents a different time series than past efforts, and data collection on two of the study areas included in past analyses was discontinued (Wenatchee, Warm Springs Reservoir), so these areas could not be included in the most recent analysis (Forsman et al. 2011). In addition to the Rainier study area, apparent survival rates of owls were declining on seven (Cle Elum, Olympic, Coast Ranges, H.J. Andrews, Tyee, South Cascades, Northwest California) of the eight study areas associated with the Plan (table 2-4) and fecundity was also declining in four of these populations (table 2-4) (Forsman et al. 2011). In Washington and northern Oregon, the number of declining populations and the rate of decline raises concern about the long-term sustainability of the owl throughout its range (Forsman et al. 2011).

The reasons for declines in spotted owl populations were not readily apparent in any of the previous meta-analyses (Anthony et al. 2006, Burnham et al. 1996, Franklin et al. 1999). The analysis done by Forsman et al. (2011) incorporated covariates to investigate the influence of barred owls, weather and climate, and habitat on fecundity, survival, and rate of population change. As a result, we now

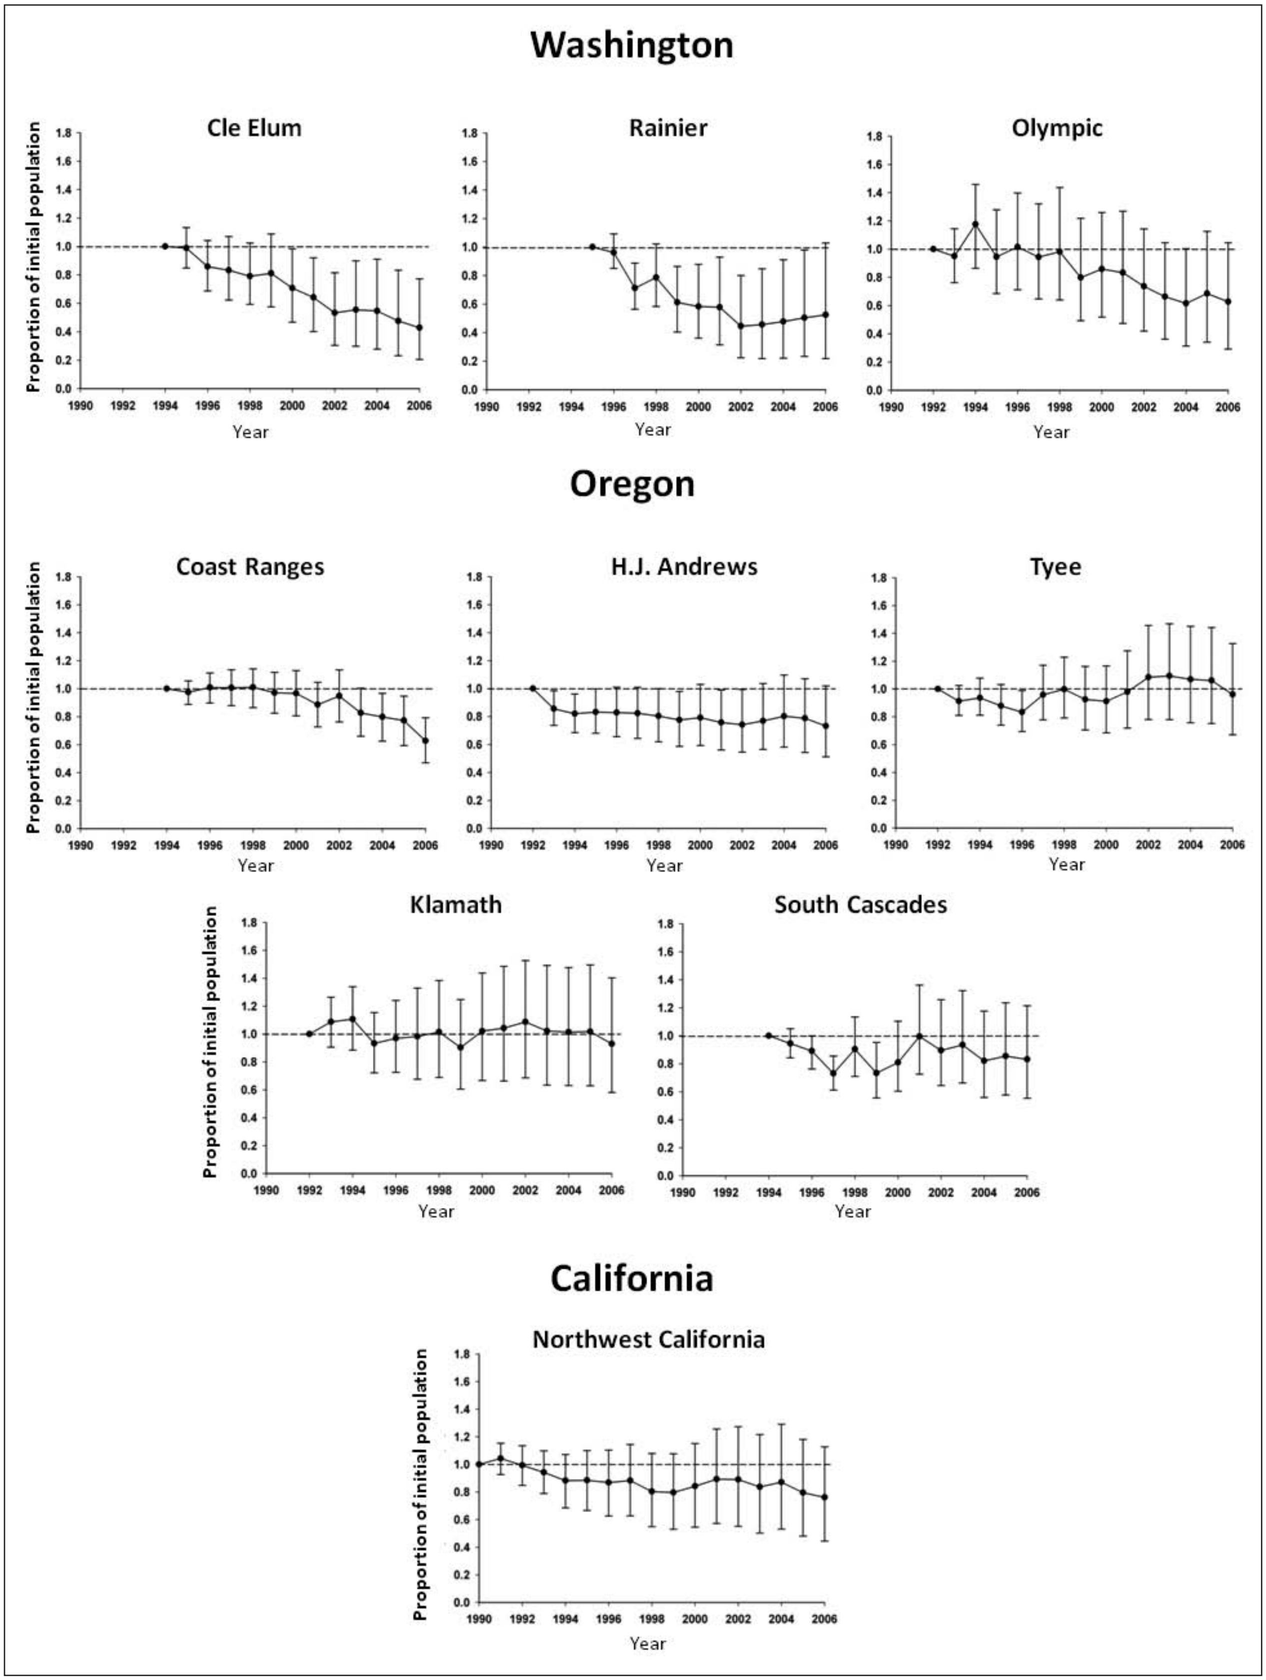

Figure 2-3−Estimates of realized population change, Δ_t, with 95-percent confidence intervals for northern spotted owls on nine study areas associated with lands managed under the Northwest Forest Plan in Washington, Oregon, and California, 1990–2006.

have some evidence that increasing numbers of barred owls and loss of habitat contributed to demographic declines reported in some study areas (Forsman et al. 2011). The presence of barred owls appeared to be the strongest and most consistent negative factor relating to spotted owl survival, but the strength of the response was variable among study areas. Forsman et al. (2011) concluded that although their results do not represent cause-effect relationships, they certainly suggest that barred owl invasion into the range of the spotted owl is at least partly to blame for the continued decline of the owl on federal lands. However, recovery of habitat lost over the last century is a slow process and likely continues to negatively impact owl populations.

From the perspective of evaluating the effectiveness of the Plan on the conservation and recovery of the owl, the relationship between demographic rates and habitat are of particular importance. Because of the differences in the vegetation data used to develop habitat models for the 10-year report, as discussed in chapter 3 of this report, the development of the habitat covariate in California was not possible, and its effect on demographic rates could only be investigated for Washington and Oregon (see Forsman et al. 2011 for details). From this analysis, there was evidence that the percentage cover of suitable owl habitat had a positive influence on recruitment of owls in the meta-analysis of λ (Forsman et al. 2011); however, this relationship was not strong or prevalent for all demographic parameters or among all study areas.

Based on the meta-analysis of λ, there was some evidence that apparent survival was related positively to the percentage cover of suitable habitat in the Cle Elum, Coast Ranges, H.J. Andrews, and Tyee study areas in Washington and Oregon (Forsman et al. 2011). Also, a positive relationship between recruitment and the percentage cover of suitable owl habitat within the study area in the meta-analysis of λ was also found (Forsman et al. 2011). Recruitment was also highest on federally owned lands where the amount of suitable habitat was highest compared to private lands (Davis and Lint 2005). One possible explanation for this result is that more suitable habitat within the study areas provided areas where nonterritorial owls could survive until they were able to recruit into the territorial population.

Summary

After 15 years of population monitoring, we continue to observe significant annual declines in spotted owl populations (2.9 percent all ownerships, 2.8 percent federal ownership) (Forsman et al. 2011). Our ability to monitor the trend in owl populations is improving with newer technologies, the inclusion of explanatory covariates, and more years of data. We now have some evidence to support the suggestions of Anthony et al. (2006) that possible causes for declines in owl survival and populations may include high densities of barred owls and loss of habitat. However, a lot of uncertainty remains, and we are just beginning to understand the effects of these two factors on owl demography. We also must continue to stress the caution put forth in the Plan for projecting current estimates of population decline into the future.

At its implementation, the Plan's assumption was that owl populations across the range would continue to decline for the first three to five decades, eventually stabilizing at lower levels as losses of habitat lessen and habitat is restored in the network of large reserves scattered throughout its range. Since the Plan's inception, the rate of habitat loss has certainly lessened, and here we report an overall habitat decline of 3.4 percent on federal lands in the last 15 years (see chapter 3 in this report), which is less than the anticipated rate of habitat loss of 5 percent per decade. We also report an overall 2.8 percent annual population decline on federal lands, with higher declines in the northern portions of the range and stationary populations in the central portion of the range as first noted by Anthony et al. (2006). These stationary populations were also not expected at the Plan's implementation (Lint 2005). Although habitat is being maintained, the restoration of habitat under the Plan is still a few decades away. Forest succession is a slow process, but there are suggestions that it can be accelerated through well-designed silviculture (Garman et al. 2003, Muir et al. 2002). We were not yet able to accurately measure recruitment of nesting/roosting habitat with current technologies; however, we were able to detect recruitment of the younger forests that serve as dispersal habitat (see chapter 3 in this report). We speculate that declining spotted owl populations will not begin to stabilize across the range at least until nesting/roosting habitat begins to increase significantly. And although habitat is a key element in the conservation of spotted owls (Lint 2005), it may no longer be the primary factor affecting population stability in either the short or long term. The rapidly increasing trend in barred owl populations has produced an unanticipated and confounding influence, as these species may compete for resources.

The answer to the question, "Will the Plan reverse the declining population trend and maintain the historical geographic range of the northern spotted owl?" still eludes us. Five more years of monitoring has shed more light on the subject, but a definitive answer will require more long-term monitoring to better understand the temporal and spatial variability in owl demographics and the factors that affect owl vital rates. Until then, we believe that habitat maintenance and restoration, as currently envisioned under the Plan, remains essential to the owl's recovery. However, additional conservation measures (i.e., barred owl control) that were not envisioned under the Plan may ultimately be needed to recover the species in the face of the barred owl expansion into the Pacific Northwest.

Chapter 3: Habitat Status and Trend

Raymond J. Davis and Katie M. Dugger

Introduction

The first rangewide northern spotted owl (*Strix occidentalis caurina*) habitat map was developed for the Forest Ecosystem Management Assessment Team (FEMAT) in 1993. It was constructed through a combination of digital maps derived from satellite imagery and maps derived from aerial photo interpretation. The team used the best available data and geographical information system (GIS) technologies at that time to represent owl habitat conditions at the start of the Northwest Forest Plan (the Plan), which we call the "baseline." However, the authors acknowledged that the map was an estimate and had not been assessed for accuracy (FEMAT 1993). Six years later, the northern spotted owl effectiveness monitoring plan concluded that this map lacked the spatial resolution and accuracy needed for a baseline spotted owl habitat map for monitoring purposes (Lint et al. 1999). They proposed the development of a new rangewide baseline habitat map to "provide the landscape-scale view of habitat conditions at different resolutions."

Having a good baseline habitat map is essential to the effectiveness monitoring program because it provides a snapshot in time of what conditions were like when the Plan was implemented. Without an understanding of baseline conditions, we would not be able to answer the primary question of whether owl habitat and dispersal habitat are being maintained and restored under the Plan. The first rangewide baseline habitat monitoring map was developed by Davis and Lint (2005) for the 10-year monitoring report (Lint 2005). The data sources and methods used to develop that map are fully described in Davis and Lint (2005) and are not repeated in this report. Limitations in the first baseline map were noted by Davis and Lint (2005) and Raphael (2006) and are reviewed in the following discussion.

The Northwest Forest Plan effectiveness monitoring program was in its early stages of development at the time of the 10-year reporting analysis. A consistent rangewide vegetation data set as described in Lint et al. (1999) did not exist. Instead, two distinctly different vegetation data sources covered the owl's range: Interagency Vegetation Mapping Project (IVMP) data (Oregon and Washington) and Classification and Assessment with Landsat of Visible Ecological Groupings (CALVEG) data (California) (Davis and Lint 2005, Moeur et al. 2005). The choice of vegetation variables provided by these two sources was limited and included only tree size class and cover attributes, which were not mapped consistently between the two products. Other habitat mapping "core elements" discussed by Lint et al. (1999), such as stand age and tree species data, were not available, resulting in omission of important habitat relationship variables in the models used to create the first baseline map. To compensate for lack of tree species data, Davis and Lint (2005) used elevation as a variable in their habitat modeling and also built a "habitat-capable" GIS layer, largely based on a rangewide elevation isopleth that would "mask out" subalpine forests, in which spotted owls avoid nesting. There was no way to "mask" pine-dominated forests or to include evergreen hardwoods, which are important components of owl habitat in the southern physiographic provinces. As a result, where tree size and cover conditions were otherwise similar to those used by nesting and roosting territorial owls, the models classified them as suitable, even when they probably were not because of tree species composition.

Another problem was the coarse spatial resolution and lack of continuous attribution in the CALVEG data (Davis and Lint 2005). This resulted in poorer estimates of habitat in the California physiographic provinces and habitat maps that were not directly comparable to the Oregon and Washington maps. The lack of a consistent rangewide habitat map resulted in our inability to fully model associations between spotted owl demography rates and habitat during the 2009 population meta-analysis (Forsman et al. 2011).

Additional limitations of the 10-year report's baseline owl habitat map (Davis and Lint 2005) included the use of the median algorithm in the BioMapper habitat modeling software (Hirzel et al. 2002), which was the only algorithm available at the time (Davis and Lint 2005). This algorithm assumed species distribution along the environmental factors was normal (see fig. 3-8 on page 36 in the 10-year report); however, in reality, this is not always the case, and nonnormal relationships resulted in the overestimations of habitat suitability. In general, profile models like BioMapper are known to sometimes overpredict habitat suitability (Engler et al. 2004). To compensate for this, Davis and Lint (2005) provided a habitat map with a continuous scale from 0 to 100, where a value close to zero signified that an individual map unit (pixel) had little in common with the conditions found where territorial owls are present, and those with values close to 100 had much in common with sites having territorial owl presence. During this initial effort, a threshold value that designated a cutoff between "suitable" and "not suitable" habitat was not chosen. Instead, Davis and Lint (2005) reported on status and trend of the spectrum of habitat suitability (HS) divided into equal-interval bins, and areas with HS >40, which "had characteristics similar to areas where territorial owls have been found."

Based on our latest work (presented here), we now conclude that the baseline habitat map developed for the 10-year report did overestimate owl habitat suitability in portions of the range. Overestimations occurred within pine-dominated forests of the eastern Cascades for reasons discussed above, and, as noted by Raphael (2006), habitat suitability scores greater than 40 were achieved in stands as young as 30 years in the Coast Range of Oregon and 50 years in Oregon western Cascades, providing further evidence of profile model overpredictions. Based on visual comparisons of the former baseline maps and the new one, we also believe that the use of the coarser scale CALVEG data in the 10-year habitat modeling resulted in considerably more habitat suitability >40 estimated for California.

Since the 10-year report, much progress has been made in developing a consistent rangewide vegetation data layer, with a larger suite of vegetation attributes to be used as "core elements" for habitat mapping, including tree species information (Ohmann and Gregory 2002). These new rangewide vegetation data are produced by the Landscape Ecology, Modeling, Mapping, and Assessment group (LEMMA) based at the Pacific Northwest Research Station in Corvallis, Oregon (link to Web page: http://www.fsl.orst.edu/lemma/). Detailed attributes of forest composition and structure were mapped for all forests in the Plan area for two "bookend" dates. The bookend dates were 1996 and 2006 in Washington and Oregon, and 1994 and 2007 in California. This marks the first application of using multiple satellite imagery dates to create "bookend" vegetation maps for habitat monitoring purposes (Ohmann et al. 2010).

In addition to improved vegetation map products, the science of habitat modeling has evolved since the 10-year report. Species distribution and habitat suitability modeling has been the subject of much current research and discussion in ecology (Elith et al. 2006, Guisan and Zimmermann 2000, Hirzel and Le Lay 2008), so we spent a substantial amount of time reviewing modeling options and testing several types of software used for habitat modeling before deciding on the approach presented here.

One thing we have observed through these efforts is that regardless of the methods used, the map products are visually similar at the rangewide scale (fig. 3-1). Therefore, it is important to test the map's accuracy with actual spotted owl nesting and roosting location data. This is one area where the population monitoring and habitat monitoring efforts connect, as we used different subsets of the demographic data to first train and then test the accuracy of our habitat model mapped predictions.

The use of the new rangewide vegetation data set and the latest habitat modeling software has resulted in an improved baseline habitat map that has tested well with actual owl pair location data (including independent data sets). These improvements included better discrimination of habitat in the eastern Cascades, where pine-dominated forests mostly occur, and the use of the "habitat-capable" layer from Davis and Lint (2005) was no longer required for habitat modeling with the inclusion of a subalpine forest type variable. We use this new baseline map (1994/96) and the other bookend map (2006/07) for conducting our habitat status and trend analysis.

The development of bookend maps was an innovative advancement in our monitoring methods, but aspects of it remain to be tested. Given its novelty, we restricted our use of the 2006/07 bookend to only inform us on habitat changes within areas that were identified as having experienced a disturbance by the LandTrendr data. It is important to make sure that the bookend maps used for later analyses are generated with the same data sets and methods, and tested so that the detection of change from one to the other

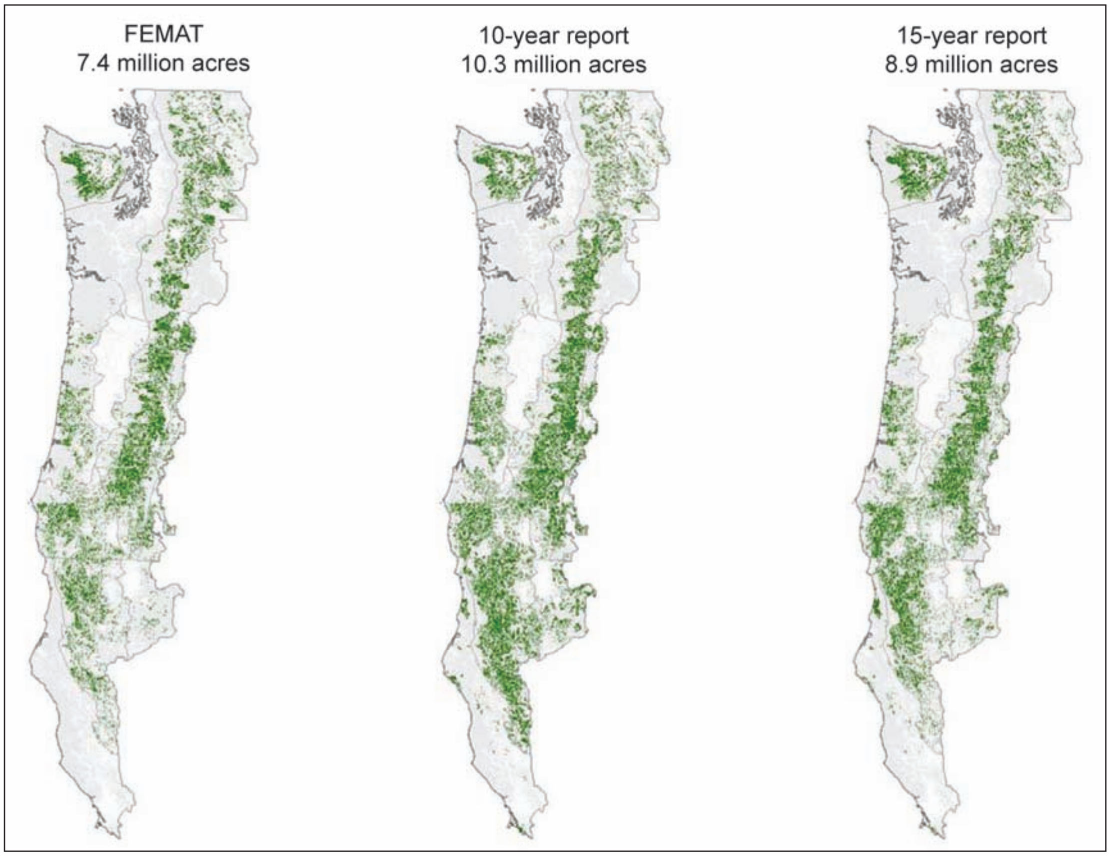

Figure 3-1—Baseline maps are representative of habitat at the implementation of the Northwest Forest Plan. They evolve with new mapping technology. Even so, at the range scale, the general spatial patterns of habitat between them are similar. FEMAT = Forest Ecosystem Management Assessment Team.

is a fair comparison of "real" change and not one caused by analytical or data differences. In future monitoring cycles, we anticipate more advancements in both vegetation data mapping and habitat modeling science; therefore, we anticipate that future modifications will be made to the baseline map, including the use of 1994 satellite imagery for the entire range. This is appropriate as the status and trend analysis is based on the use of the best available vegetation and change-detection data and technologies.

Habitat Monitoring Under the Plan

Under the monitoring plan, habitat status and trends are to be estimated approximately every 5 years after the baseline map was developed because it was believed that changes in forest vegetation conditions would not be discernable from the remote sensed vegetation data on more frequent intervals (Lint et al. 1999). The intent of habitat monitoring is to determine if assumptions made during the development of the Plan are holding true. Testing the assumption that habitat will not decline faster than predicted in the final environmental impact statement (USDA and USDI 1994) is of particular interest. The initial list of assumptions is as follows (Lint et al. 1999):

1. Habitat conditions within late-successional reserves (LSRs) will improve over time at a rate controlled by successional processes in stands that currently are not habitat. However, this is not expected to produce any significant changes in habitat conditions for several decades.
2. Habitat conditions outside of reserved allocations will generally decline because of timber harvest and other habitat-altering disturbances, but the vegetation structure across the landscape will continue to facilitate owl movements.

3. Catastrophic events are expected to halt or reverse the trend of habitat improvement in some reserves; however, the repetitive design of reserves should provide resiliency, and not result in isolation of population segments.

Central to these questions is the federal network of reserved land use allocations designed to support groups of reproducing owl pairs across the species' range. These reserves include LSRS, adaptive management reserves, congressionally reserved lands, managed late-successional areas, and larger blocks of administratively withdrawn lands. It is also important to monitor the lands between these reserves because they provide for recruitment of new owls into the territorial populations (see chapter 2, this report) and are important for dispersal and movement of owls between larger reserves. These dispersal habitats occur in a combination of matrix, adaptive management areas, riparian reserves, small tracts of administratively withdrawn lands, and other small reserved areas such as 100-ac owl core areas. To understand whether the Plan is contributing to the conservation and restoration of owl habitat, the condition and trends of owl habitat must be regularly assessed. The specific questions that were addressed in the 10-year report and that will be addressed here as well include:

1. What proportion of the total landscape on federal lands are owl habitat and dispersal habitat?
2. What are the trends in amount and changes in distribution of owl habitat, particularly in large, reserved blocks?
3. What are the trends in amount and distribution of dispersal habitat outside of the large, reserved blocks?
4. What are the primary factors leading to loss and fragmentation of both owl habitat and dispersal habitat?

Following the approach of Davis and Lint (2005), the condition of owl habitat will be reported at three broad geographic scales: (1) the physiographic province, (2) the state, and (3) the geographic range of the owl. However, because of changes that have occurred in federal land use allocations since the 10-year report (fig. 3-2), we will no longer report status and trends within every land use allocation. Instead, we will report by broad federal land use allocations representing "reserved" and "nonreserved" landscapes (fig. 3-3), which we feel is a more consistent and appropriate scale for monitoring. Because the "large block" reserves (see fig. 3-13, page 44 in the 10-year report) make up about 90 percent of the reserved landscape, we now consider our reporting of status and trend in the reserved landscape as one entity, whereas in the 10-year report we separated them. Although the effectiveness monitoring is focused to address questions about the Plan, its developers realized that the status and trends of the subjects being monitored are often influenced by conditions on the surrounding nonfederal lands. Therefore, we will report on habitat conditions on nonfederal lands at the state and range scales because these were included in the 10-year monitoring synthesis report by Raphael (2006).

As stated in the 10-year report, our objective was to produce maps of forest stands (regardless of patch size and spatial configuration) that showed the level of similarity to stand conditions known to be used for nesting and roosting by spotted owls. Forest stands with conditions most similar to what is used by nesting and roosting owl pairs are what we will refer to as "nesting/roosting habitat" throughout this document. We will also report on forest stand conditions that are known to be used by dispersing owls, which we refer to as "dispersal habitat."

Methods and Data Sources

Land Use Allocation Data

An updated map of the Plan's land use allocations (LUA) was produced in 2002 for the 10-year monitoring reports (Huff et al. 2005, Lint 2005, Moeur et al. 2005). It updated the original 1994 version, which was mapped with older GIS technology and had a 40-ac resolution. This first update corrected some mapping inconsistencies, but more importantly, incorporated allocation changes that occurred between 1994 and 2002. Although this map was considered an improvement from the earlier version, some limitations still remained (Davis and Lint 2005, Huff et al. 2005). The major limitations were the inability to map riparian reserves

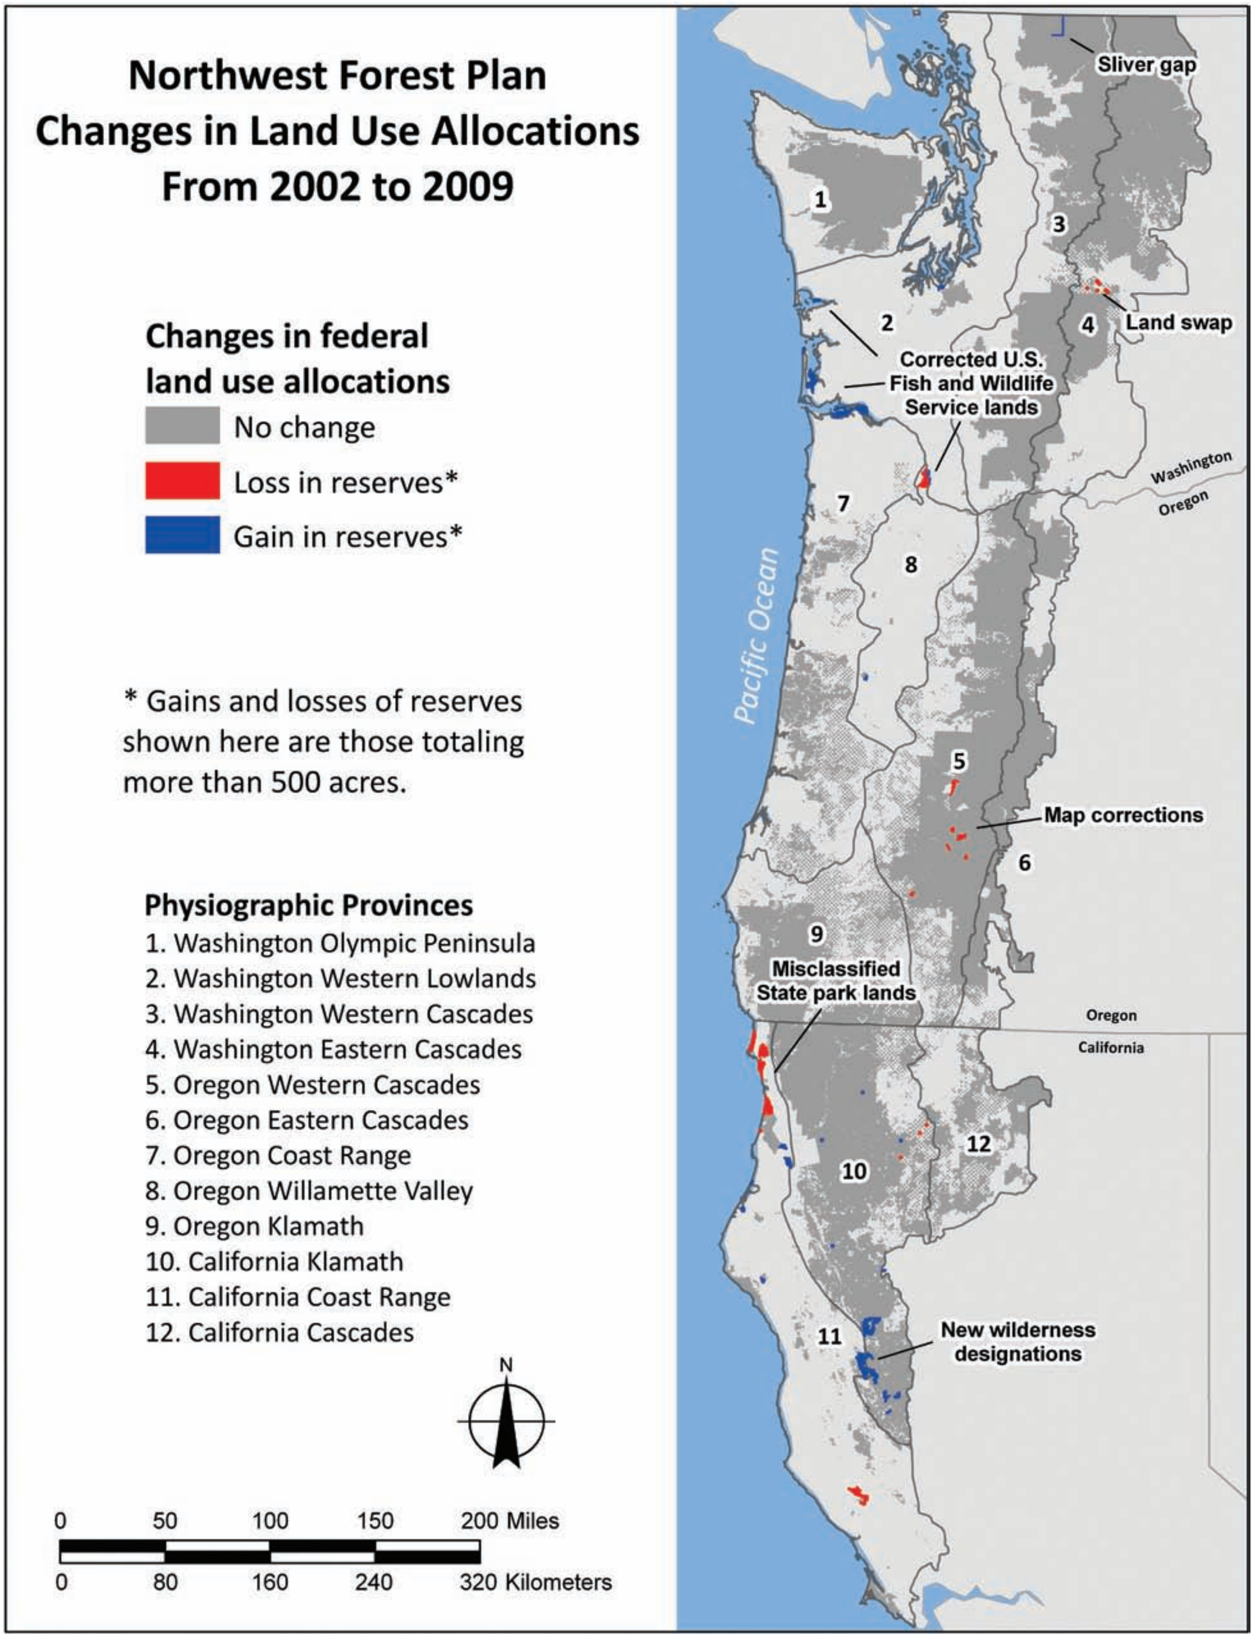

Figure 3.2—Changes made to the land use allocations since the 10-year report (Lint et al. 2005).

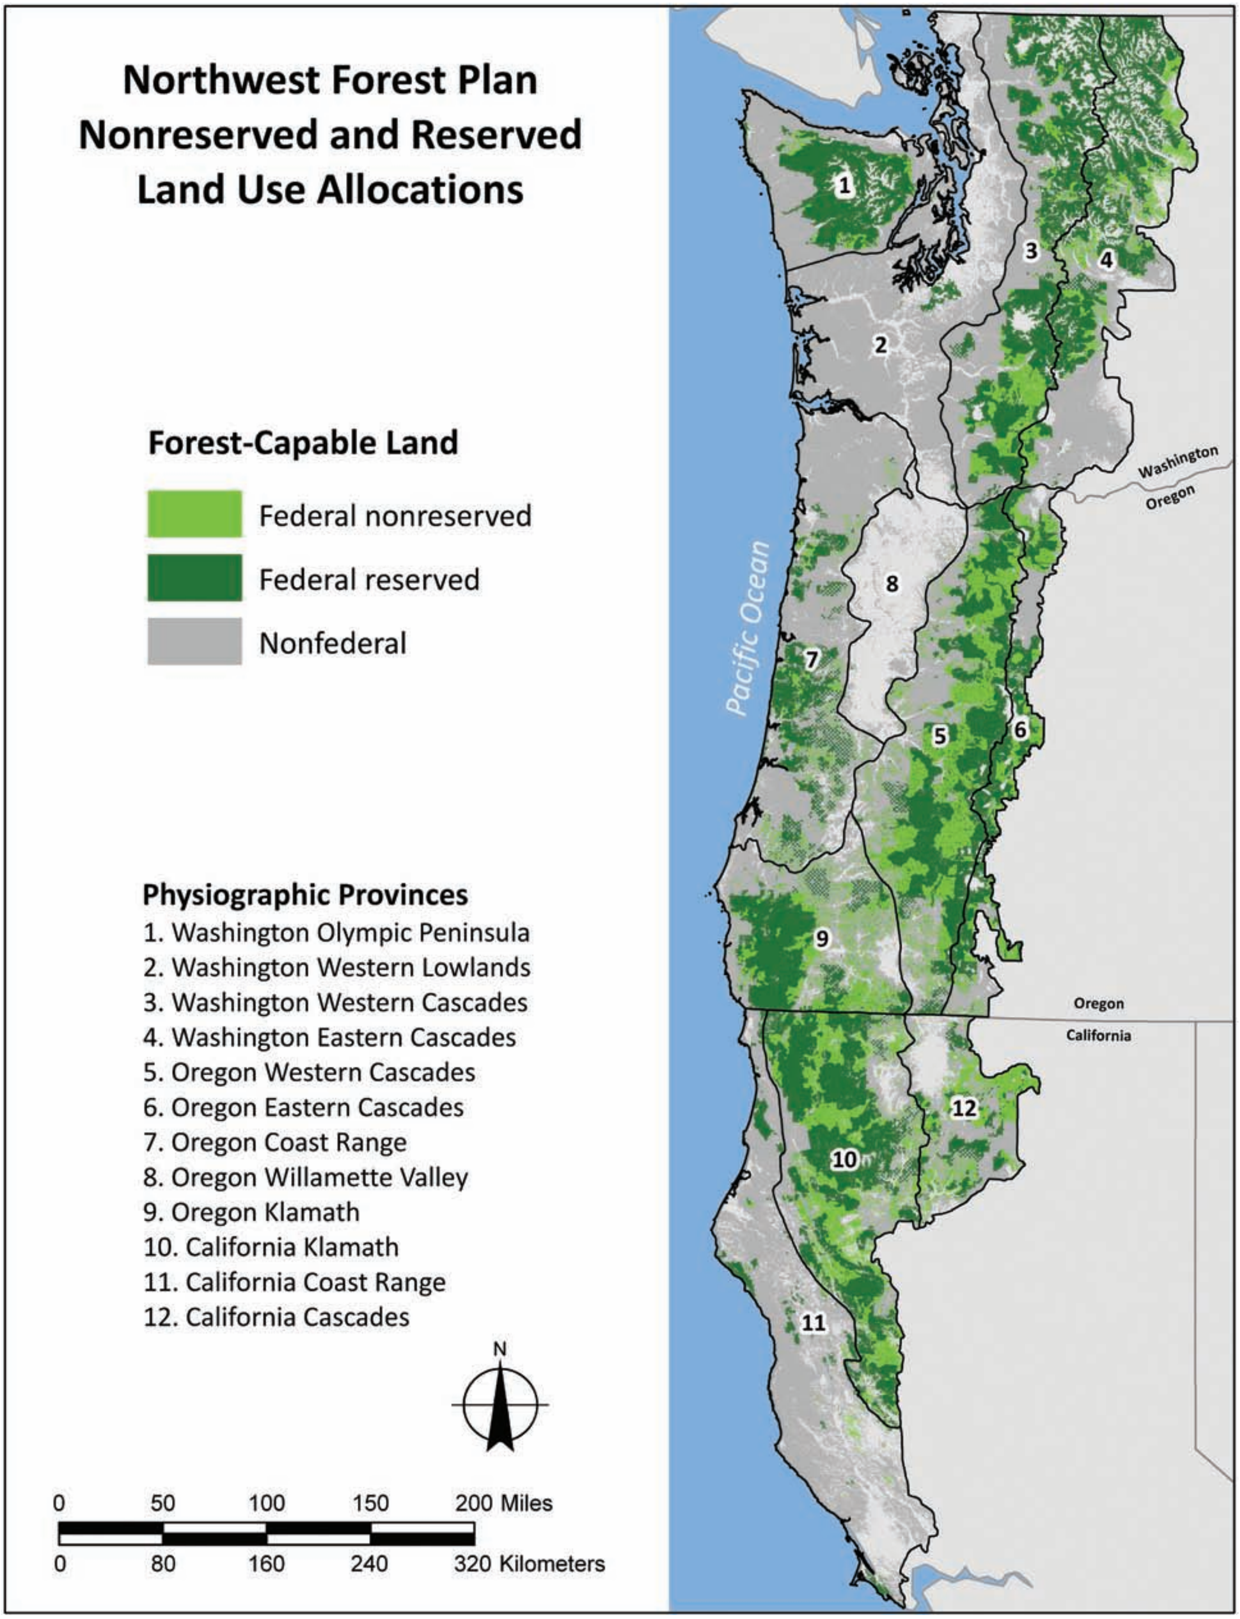

Figure 3-3—Federally administered lands within the range of the northern spotted owl.

(which can cover significant amounts of land where stream densities are high) and inconsistencies in how administratively withdrawn areas were delineated. Errors that remained after the 2002 update included the misidentification of a state-owned park in the redwood region of California as federally owned National Park Service land and inaccurate or missing boundaries of national wildlife refuges, mainly in Washington and Oregon. Other minor mapping issues included edge matching inconsistencies that caused "sliver gaps" and inconsistent attribution of large water bodies.

A second update of LUAs performed in 2009 (fig. 3-2) produced a new version that is used for this 15-year report. The new version incorporates major LUA changes that occurred between 2002 and 2009, and it also corrects the errors identified above. Minor issues with inconsistent mapping of administratively withdrawn areas still remain, and a small amount (<1 percent) of federally administered lands are awaiting official LUA designations and are identified as "not designated" in the 2009 map. Riparian reserves still remain unmapped because, as Moeur et al. (2005) noted, "…at the Plan scale, they cannot be reliably distinguished from matrix because of a lack of consistency in defining intermittent stream corridors and varying definitions for riparian buffers."

The Plan allowed for land exchanges involving LSRs if they provide benefits equal to or better than current conditions, such as to improve area, distribution, and connectivity of the LSR system (USDA and USDI 1994). It also acknowledges that future changes would occur for the administratively withdrawn allocation. At the end of the 15-year monitoring period, we note a net increase of about 25,000 ac in reserved allocations, and a net decrease of about 17,000 ac in nonreserved allocations. Most of the changes that occurred were designations of otherwise reserved allocations into 237,000 ac of congressionally designated reserves, and most of this (83 percent) occurred in northern California. Because some of the changes included land exchanges or acquisitions, the increase in reserved allocations and decrease in nonreserved allocations are not equal.

Land use allocations will continue to change, and we will continue to update this map with the intent of improving it for each monitoring effort. For monitoring purposes, we archive the previous versions and report vegetation and habitat changes for all monitoring modules within the reference frame of the most up-to-date allocation map. Major LUA changes that are important for us to note include changes that cover thousands of acres and involve gains or losses of reserved allocations. We will discuss these changes in relationship to the standard and guidelines within the record of decision (USDA and USDI 1994). Given the most recent information, the latest changes in reserved allocations (fig. 3-2) have resulted in a slightly increased area and improved distribution and connectivity of the reserved allocation system.

Vegetation Data

The vegetation data used for habitat modeling and mapping were developed through a method for predictive vegetation mapping using direct gradient analysis (Gauch 1982, ter Braak 1986) and nearest-neighbor imputation (Moeur and Stage 1995) to assign detailed forest vegetation plot information to every pixel in a GIS raster map. The combining of these methods to develop vegetation maps was termed "gradient nearest neighbor" (GNN) and is thoroughly described in Ohmann and Gregory (2002). The GNN maps developed in the Pacific Northwest have previously been applied to broad-scale vegetation mapping efforts across a wide range of forest ecosystems (Ohmann et al. 2007, Pierce et al. 2009). Forest attributes from regional inventory plots are assigned to map pixels where data are missing, on the basis of a modeled relationship between the detailed forest attributes from plots and a combination of spatial predictor variables derived from Landsat satellite imagery, climate variables, topographic variables, and soil parent materials. The assumption behind GNN methods is that two locations with similar combined spatial "signatures" should also have similar forest structure and composition. Plot data are from regional forest inventory plots: Forest Inventory and Analysis (FIA) periodic inventories on nonfederal lands, FIA annual inventory on all ownerships, and Current Vegetation Survey inventories. The GNN data used for habitat modeling and mapping covers the entire breadth of the owl's range from Washington to northern California for two points in time. We call these two data sets “bookends” because the changes in habitat that we analyzed and report on occurred between them. The satellite imagery from which GNN was created covers the period from 1994 to 2007 in California and 1996 to 2006 in Oregon and Washington. The on-the-ground plot data used to create the vegetation maps covers the period 1991 to 2000 for bookend 1, and 2001 to 2007 for bookend 2. The GNN products are 30-m (98.4-ft) grids that were specifically developed for mid- to large-scale spatial analysis (Ohmann and Gregory 2002).

The primary challenge was to develop GNN model-based maps for the two bookend dates that minimized spectral differences owing to different image dates that might produce false vegetation changes. To achieve this, the GNN models used Landsat imagery that was geometrically rectified and radiometrically normalized through time using the LandTrendr algorithms (Kennedy et al. 2007). A full description of the GNN bookends methodology can be found in Moeur et al. (2011).

The accuracy assessment for GNN continuous variables was based on the correlation of observed plot values against predicted (modeled) values. Ohmann et al. (2010) used a modified leave-one-out cross-validation approach that yields results similar to those of a true cross-validation approach, but probably slightly underestimates the true accuracy. The accuracy assessments are based on pooled plots for each modeling region. Canopy characteristics are usually the most easily determined via space-borne remote sensing instruments, and the most accurate GNN variable was conifer canopy cover, with an average plot correlation of 0.74 (±1 standard deviation [SD] = 0.07). Inferring vegetation characteristics underneath the canopy is more difficult, and the correlation coefficients for the structural and age vegetation variables we chose to use ranged from 0.38 to 0.82, with an average plot correlation of 0.63 (±1 SD = 0.12). The accuracy assessment for the species composition variables is based on Cohen’s kappa coefficient, which is a measure of agreement between predicted and actual conditions (in this case dominant tree species), taking into consideration agreement occurring by chance (Cohen 1960). We combined several species to produce “forest type” basal area variables as shown in appendix A. The average kappas for these species groups, or forest-type, variables ranged from 0.30 to 0.46, with an average kappa of 0.40 (±1 SD = 0.07). Oak woodland was the most accurate species group, followed by subalpine, evergreen hardwoods, and pine.

Change-Detection Data

A new approach to monitoring landscape vegetation change was implemented to map forest disturbances in the owl’s range. Landsat-based detection of trends in disturbance and recovery (LandTrendr) produces yearly maps of forest disturbance using a new analysis of annual Landsat Thematic Mapper satellite imagery (Kennedy et al. 2010). In general, LandTrendr detects spectral trajectories from Landsat time-series stacks and correlates them to land surface changes. The time series of Landsat imagery that was assembled for the Plan area was processed using basic atmospheric correction, cloud screening, and radiometric normalization to separate imagery noise (i.e., cloud cover, smoke, snow, or shadows) from actual vegetation change. Predictions of vegetation cover change were then evaluated using a statistical model of vegetation cover developed from photointerpreted plots (Cohen et al. 2010). The results of this evaluation found that LandTrendr detected vegetation disturbances as well as or better than two-date change-detection methods, and that it detects with reasonable robustness a range of other dynamics such as insect-related disturbance and growth (Kennedy et al. 2010). Errors in LandTrendr predictions were generally confined to very subtle change phenomena (Kennedy et al. 2010). In summary, LandTrendr improved the temporal frequency of disturbance maps used for monitoring, better separates subtle changes from background noise, and detects a wider range of vegetation change phenomena than was possible with previous technologies (Kennedy et al. 2010, Moeur et al. 2011).

We used the LandTrendr data to verify habitat losses between our bookend maps and to attribute the most likely cause of habitat loss (fig. 3-4). The data covered the entire analysis area and period (1994–2007) and provided information by 30- by 30-m pixels on initial year of disturbance. LandTrendr classified the cause of disturbance (vegetation cover loss) into three types: (1) timber harvest, (2) insect

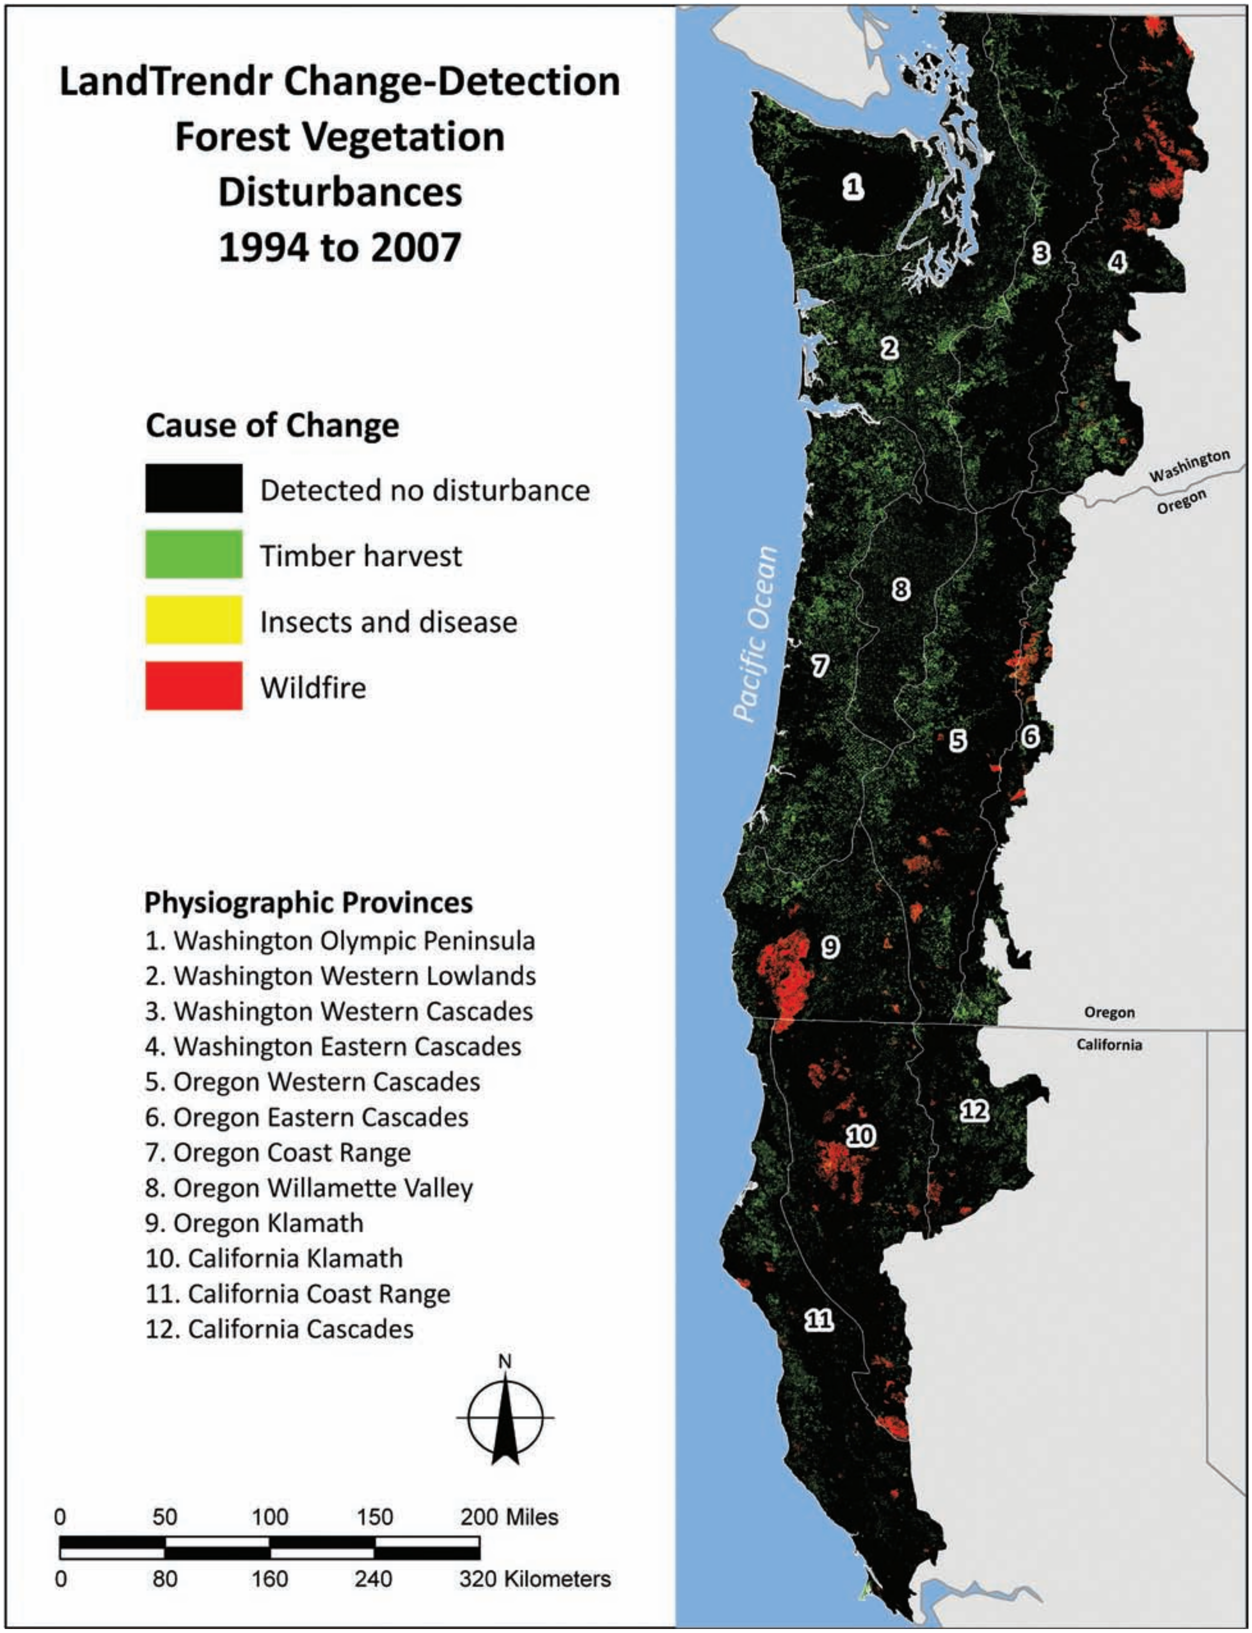

Figure 3-4—LandTrendr change-detection data (Kennedy et al. 2010).

and disease (can also include pathogens and other nonabrupt processes), and (3) wildfire. Fire locations were identified based on fire perimeter GIS data from Monitoring Trends in Burn Severity (MTBS[1]) data, Geospatial Multi-Agency Coordination (GeoMAC[2]) data, and other sources (i.e., individual forest data). The remaining short-term disturbances were assigned "harvest" as the probable cause of disturbance, although wind may account for a small percentage.

Spotted Owl Presence Data

The owl survey data collected under the effectiveness monitoring program are important not only for population monitoring (chapter 2, this report), but also for monitoring suitable habitat. The owl pair location data (presence only spatial data) from demographic study areas are collected annually and are spatially very accurate. This made such data ideal for habitat suitability modeling; thus, we used them as the foundation for training our habitat models. However, the results of our preliminary model testing indicated that using only demographic study area data was problematic for modeling habitat in some modeling regions. Confining our model training data to the demography areas produced a "geographically clumped" distribution of model training points within the boundaries of our larger modeling regions. This clumping violated the basic assumption of habitat modeling methods that require independence and sampling without bias for presence data (training data) from the modeling region (Gillison and Brewer 1985, Phillips et al. 2009, Williams et al. 2002). We therefore matched our modeling regions to the boundaries of the demographic study areas, trained the habitat model to those areas, and then extrapolated the model results to the larger geographic regions. This produced mixed results, with some models testing well, while others could not be projected (extrapolated) successfully when the larger geographic area did not contain all the environmental variables that were used for habitat modeling. Our solution was to supplement the owl location data from demography study areas with the owl presence location from the broader geographic areas surrounding them to reduce sampling bias issues and produce a training data set that was better distributed within the modeling region. To do this we used the data set used for the 10-year report (Davis and Lint 2005).

The first step in this process was to conduct a nearest neighbor distance analysis on owl pair site centers from study areas within each modeling region (app. B). We used the average nearest neighbor distances calculated from the 50-percentile harmonic cores (to remove outlier sites) from each of the study areas as a minimum distance parameter for randomly selecting a number (equal in size to the demographic study area data) of northern spotted owl pair sites from the 10-year report training data set (Davis and Lint 2005) that was outside of the study area boundaries. Both the demographic study area sites and the random selection of owl pair locations outside of them were combined to form the habitat suitability model training data set. This provided a well-distributed and nonclumped training data set for each modeling region.

We also attempted to match the date of our training data to the date of the satellite imagery used to create the vegetation data set that provided habitat variables for modeling. And finally, because we suspected interspecific competition between spotted owls and barred owls (*Strix varia*) to potentially confound the spotted owl/habitat use relationship, we used activity centers from the study areas based on surveys done between 1994 and 1996 because barred owl densities were lower than in 2006 and 2007. Our training data outside of the study area cover a broader period that roughly frames that period as discussed in Davis and Lint (2005).

Habitats, the Niche Concept, and Habitat Modeling

Understanding where animals live and the myriad factors associated with how and why they make the choices as to where to live has been the subject of extensive research (Stauffer 2002). As stated by Morrison et al. (1992), "an

[1] Data accessible thru the Forest Service's Remote Sensing Applications Center (RSAC) Web site http://www.fs.fed.us/eng/rsac/.

[2] Geospatial Multi-Agency Coordination Group or GeoMAC, is an Internet-based mapping application originally designed for fire managers to access online maps of current fire locations and perimeters in the conterminous 48 states and Alaska. Data are available at http://www.geomac.gov/.

animal's habitat is, in the most general sense, the place where it lives." This seems simple enough: an animal can only live in an area that meets its basic needs for resources (food, water, nest sites, etc.), includes competitors and predators with which it can coexist, and in climatic extremes it can withstand (Morrison et al. 1992). This is maybe best articulated within the niche concept, which has a long evolution in the science literature (see Morrison et al. 1992 for review) and has become a useful construct for conceptualizing and quantifying wildlife-habitat relationships. The multivariate, or n-dimensional, niche as defined by Hutchinson (1957) lends itself well to current attempts to model wildlife-habitat interactions, as it allows us to conceptualize all the complexities associated with how and why animals choose where they live. A species potential or "fundamental" niche includes a subset of all the environmental conditions required for a species long-term survival; however, this "fundamental niche" can be further restricted by predators and competitors resulting in a "realized niche" (Hutchinson 1957). This realized niche reflects a subset of the conditions found in the fundamental niche and is the set of environmental conditions that characterize the space a species actually occupies (Hutchinson 1957) and is reflected in the observed distribution of a species.

Many types of species distribution models are available for estimating a species' realized niche (and producing a geographic distribution map of it) using species presence data that are correlated to environmental data of relevance to the species occurrence. For the 10-year report (Davis and Lint 2005), we used modeling software called BioMapper (Hirzel et al. 2002). However, species distribution modeling is a rapidly evolving field of study, so before conducting the spotted owl habitat modeling, we conferred with some of the species distribution modeling software developers (A. Hirzel and S. Phillips) and evaluated various habitat modeling methods (i.e., BioMapper: Hirzel et al. 2002; MaxEnt: Phillips et al. 2006, Phillips and Dudík 2008; Mahalanobis distance method: Jenness 2003; resource selection functions: Manley et al. 1993). We also ran comparison tests between BioMapper (all algorithms) and MaxEnt using "virtual species" data sets provided by Dr. Alexandre Hirzel (the developer of BioMapper) with known species occurrence and distributions. The details of these tests are not provided in this report; however, our conclusions were similar to those of Braunisch and Suchant (2010) who found that BioMapper and MaxEnt produced models with similar accuracy, but that MaxEnt performed better when trained with systematically sampled data that were well-distributed within the modeling region. However, BioMapper outperformed MaxEnt when the model results were extrapolated to areas outside of the model training data area (Braunisch and Suchant 2010). In summary, our tests found that as long as species presence [training] data were fairly well distributed within a modeled region, MaxEnt outperformed the other modeling methods, and we selected it as the habitat modeling tool for this reporting cycle. Several other comparisons between MaxEnt and a number of other habitat modeling approaches are available in the scientific literature, and in most cases, distribution models generated by MaxEnt performed as well or better than the other methods (Baldwin 2009).

Other notable factors associated with our selection of MaxEnt included its user-friendly interface, its ability to run replicated models for testing purposes and to provide information on the importance of the environmental variables used for modeling, and most importantly, its ability to "project" or "transfer" model results. Model transferability is the term given for applying the results of a model that is calibrated for specific location or period, to a different geographic location or period (Turner et al. 1989). The concept is based on the idea that calibrated model parameters from one area or time may provide useful information in estimating conditions in a different time or place. In our situation, we attempted to transfer our models, which were trained in 1994/96 to the same geographic location, but in a different period—2006/07. Model transferability is a fairly new concept, and one that is rarely assessed (Randin et al. 2006). Issues with MaxEnt projections documented by Braunisch and Suchant (2010), our model testing, and the current literature advise for caution in its use and interpretation (Jiménez-Valverde et al. 2009, Peterson et al. 2007, Phillips 2008).

Habitat Modeling Process

MaxEnt uses a machine learning process and a suite of potential response functions to estimate the most uniform distribution (maximum entropy) of the "average" environmental conditions at known species locations compared to what is available across the modeled area (background) (Phillips et al. 2006). The modeling process does not require an a priori specification of a set of models, but instead fits training data (presence locations of owl pairs) to environmental covariates using various combinations of response functions (features) such as linear, quadratic, product, hinge, and threshold structures. However, the use of all feature types may lead to model overfitting depending on the sample size of the training data (Phillips et al. 2006); therefore, the "auto feature" (default) restricts the model to simpler features, such as linear, quadratic, and hinge, for smaller sample sizes (Elith et al. 2011). In our preliminary model tests, overfitting seemed to occur from the use of the threshold feature, which requires a minimum of 80 training samples and produced sharp jumps (both up and down) in the variable response curves. Modeling with just the hinge feature produces models with simpler or smoother functions and is generally a useful simplification that can reduce overfitting (Phillips 2010). Our final selection incorporated a combination of linear, product, and hinge features because most of our hypothesized variable responses fit those choices. We considered using the quadratic feature; however, during our model testing, MaxEnt applied this feature to variables in which the response function did not make ecological sense (i.e., tree diameter). This was most apparent in modeling regions where the variables had outlier values at the extreme high end of the distribution histogram. The inclusion of the hinge and product features compensated for the omission of the quadratic feature, because in combination, they can conform to a quadratic shape. We also selected the "auto features" option, which allows MaxEnt to further limit the subset of response features from those we selected above by retaining only those with some effect.

Other techniques can be used to control overfitting the data, such as reducing the number of parameters in the model. To do this, MaxEnt provides a "regularization feature" that performs a function similar to Akaike's information criterion (Akaike 1974) by penalizing the complexity of the model. The regularization multiplier affects the fit of the model training data to the modeling variable empirical means. A smaller value results in a tighter fit but potentially leads to overfitting the model to the data. The default setting of 1.0 is believed to be an appropriate setting for most modeling efforts (Phillips and Dudík 2008). A higher regularization multiplier setting reduces the number of model parameters, allowing for a more spread out fit around the mean, and simplifies the model.

Observing the statistical performance on test (versus training) data is the best approach to final model calibration (Phillips 2010). We therefore evaluated our model's performance beginning with the model test gain, which indicates how different the testing data are from the background data. It is similar to "deviance" as used in generalized linear modeling (Phillips et al. 2006) and higher gains indicate larger differences between occurrence location environmental conditions and average background environmental conditions. The exponent of gain produces the mean probability value of predicted species occurrence compared to a random location selected from the surrounding modeled landscape. Or in other words, an average testing gain of 0.80 indicates that the model predicted owl occurrence 2.2 times what would be expected by chance. In addition, observing the differences between model testing gain and regularized training gain can be used to control model overfitting, as a large difference between the two is an indication of model overfitting (Phillips 2010).

Using more than just one evaluation statistic to evaluate habitat model performance is highly recommended (Liu et al. 2005), so in addition to gain, we evaluated the area under the receiver operating curve (AUC) statistic to determine model accuracy and fit to the testing data (Fielding and Bell 1997). The AUC statistic is a measure of the model's predictive accuracy, and it was originally developed for evaluations using presence and absence data, producing an index value from 0.5 to 1 with values close to 0.5 indicating poor discrimination and a value of 1 indicating perfect predictions. The AUC values can be interpreted similarly to the traditional academic point system where values between

0.9 and 1.0 indicate an excellent model (A), 0.8 to 0.9 is good (B), 0.7 to 0.8 is fair (C), 0.6 to 0.7 is poor (D), and AUC values between 0.5 and 0.6 represent failure (F), or models that don't predict much better than a random guess. An example of this interpretation in the field of niche-based species distribution models can be found in Araújo et al. (2005) and Randin et al. (2006). In our situation, MaxEnt uses 10,000 randomly selected background locations (map pixels) instead of true absence data, so it is not possible to achieve an AUC value of 1.0 (Wiley et al. 2003). However, interpretation is similar, with higher AUCs indicating better model predictions (Phillips et al. 2006). Specific to our case, AUC values represent the percentage of times a spotted owl nest site location would have a higher habitat suitability value than a randomly selected location from the modeling region.

Our third measure of model performance was the continuous Boyce index (CBI) as described by Hirzel et al. (2006). This index and methodology is designed specifically for testing habitat suitability models produced from presence-only data. The index is based on the Spearman rank correlation coefficient (R_S) that compares the ranks of modeled species occurrence with the area available to "binned" modeled prediction ranks (Boyce et al. 2002). A good model would predict an increasing ratio of the percentage of species occurrence to the percentage of the modeled landscape in each model bin as the bin values increase. An R_S of 1.0 indicates a strong positive correlation (Boyce et al. 2002).

We produced 10 bootstrapped random replicates for each modeling region using 25 percent of the training data held out to test the model. We reviewed the jackknife graphs for mean test gain and AUC from these replicates, which are produced by MaxEnt. These graphs illustrated the contribution that each variable made to the overall model (Phillips et al. 2006). Based on these graphs, we dropped variables that significantly increased mean test gain and AUC when excluded. Once this decision was made, a final check for model overfitting (see above) was conducted. This process entailed increasing the regularization multiplier by increments of 0.5 from the default setting of 1.0 (once the final list of variables was agreed to) to minimize the difference between the regularized training gain and test gain, while maximizing the test AUC and CBI using the held-out testing points.

The final models used for reporting status and trends are the average summary statistic model outputs from these replicates. MaxEnt also produced other summary statistic grids, such as the standard deviation for each cell within the modeling region. We used these maps to calculate a 95-percent confidence interval (CI) for each cell and produced upper and lower limit maps based on it. These summary maps were used to generate histograms of the model predictions uncertainty for each model region and for each bookend (app. C). The maps produced are also useful to see where within the modeling region the model predictions are less robust.

Environmental Variables

The environmental variables that influence the spotted owl's distribution in the Pacific Northwest have been well studied, and a wealth of information exists in the literature on important vegetation characteristics associated with owl habitat use. As previously noted, we were restricted to only a few basic factors (i.e., tree diameter, canopy cover) for the habitat modeling done in the 10-year monitoring cycle (Davis and Lint 2005); however, the GNN map products provided us a more extensive "menu" of forest vegetation variables to consider. Our initial selection of vegetation characteristics and environmental variables for habitat modeling was based on three things: (1) habitat relationship information in the literature or expert knowledge, (2) on-the-ground plot accuracies of the variable, and (3) correlations between the covariates. We chose not to use any GNN structural or age variables that had plot correlations less than 0.3 for an individual modeling region and <0.5, averaged across all modeling regions. For species composition variables, we chose not to include any variables that had kappas <0.2 for individual modeling regions or <0.3, averaged (as a species group) across all modeling regions. In cases where variables were highly correlated (Pearson correlation >0.7) with each other we dropped the variable with the lower plot accuracy.

From our initial list of GNN variables, we dropped basal area of conifers ≥20 in diameter at breast height (d.b.h.) because it was highly correlated with the mean stand conifer diameter, stand height, and the diameter diversity index, but had the lowest plot accuracies. We also dropped the standard deviation of d.b.h. of all live trees for similar reasons. We also did not include total canopy cover or stand density index variables because both had high correlations with conifer cover, which had the highest plot accuracy of all GNN variables. We considered, but did not use any GNN variables for snags and down wood because of low plot accuracies for those types of variables.

We ended up with a consistent set of five variables that reflected forest structure and one forest age variable that we included in all of our modeling regions. The accuracy of the variables we used is shown in appendix A (table A-2), along with Pearson correlations between covariates we selected for habitat modeling. We also developed five forest species composition variables (i.e., subalpine, pine, evergreen hardwoods, oak woodlands, and redwoods) and included them as appropriate for each modeling region (app. A, table A-2). For instance, we did not include a subalpine variable in the California Coast Range modeling region, because none exists in that area. Likewise, we did not include the redwood variable in the western Washington/Olympic Peninsula modeling region. The final list of variables used in each modeling region is provided in appendix C.

Modeling Regions

Based on recommendations from the 10-year report (Davis and Lint 2005), we developed habitat modeling regions that removed some administrative boundaries (i.e., state lines) and framed areas based more on ecological rather than sociopolitical divisions. Our modeling regions were modified versions of the standard physiographic provinces developed in FEMAT (1993) and used for reporting monitoring results (fig. 3-5). Our intent was not to further split the existing delineations into smaller areas, but to combine the existing delineations based on two things: (1) ecological similarities between physiographic provinces and (2) occurrence and distribution of spotted owl location data being used for model training and testing. We used the ecological region (a.k.a. geographic region) information from the population monitoring work (app. A in Anthony et al. 2006, Forsman et al. 2011) to combine some provinces and Environmental Protection Agency level III ecoregions (Omernik 1987) to guide final delineations of modeling regions. Modeling regions were only used for habitat modeling purposes, but we still report on habitat status and trend conditions within the physiographic provinces to maintain consistency with previous reports.

Within these modeling regions, our modeling background (the area for which MaxEnt compares the combinations of environmental variables that underlay owl locations to the broader area that is available for use) was based on a "habitat-capable" mask that we generated specifically for habitat modeling purposes. The GNN environmental data are modeled from detailed field plot data from forest-capable areas only, and a non-forest-capable "mask" is provided by GNN using ancillary land class data from the Gap Analysis Program (GAP) and National Land Cover Data (NLCD) data sets (Vogelmann et al. 2001). The GAP data are based on multiseason satellite imagery (Landsat ETM+) from 1999 to 2001 used in conjunction with other data sets (i.e., elevation, landform, aspect, etc.) to model the distribution of ecological systems (Comer et al. 2003) and land cover classes at a 1-ha (2.47-ac) resolution. However, upon review, the GNN mask included inconsistent masking of urban areas and roads, and also did not mask out areas that we felt were not capable of developing into habitat (i.e., subalpine parklands and steppes). Therefore, we used the "unmasked" GNN data set and applied our own customized mask specific to our purposes. The mask we developed included the use of the "impervious layer" from NLCD (Herold et al. 2003) to consistently exclude areas that have been converted into non-habitat-capable conditions (i.e., urbanized areas, major roads, etc.) and refined the developed open space designations. We then modified the existing GNN mask classes to exclude a few additional land classes or ecological systems that we felt were not habitat capable. Isolated areas less than 2/3 ac (pixel map noise) of both mask and nonmask were removed. The intent of our mask was to frame our modeling area such that it contained lands capable of producing closed-canopy forests that could

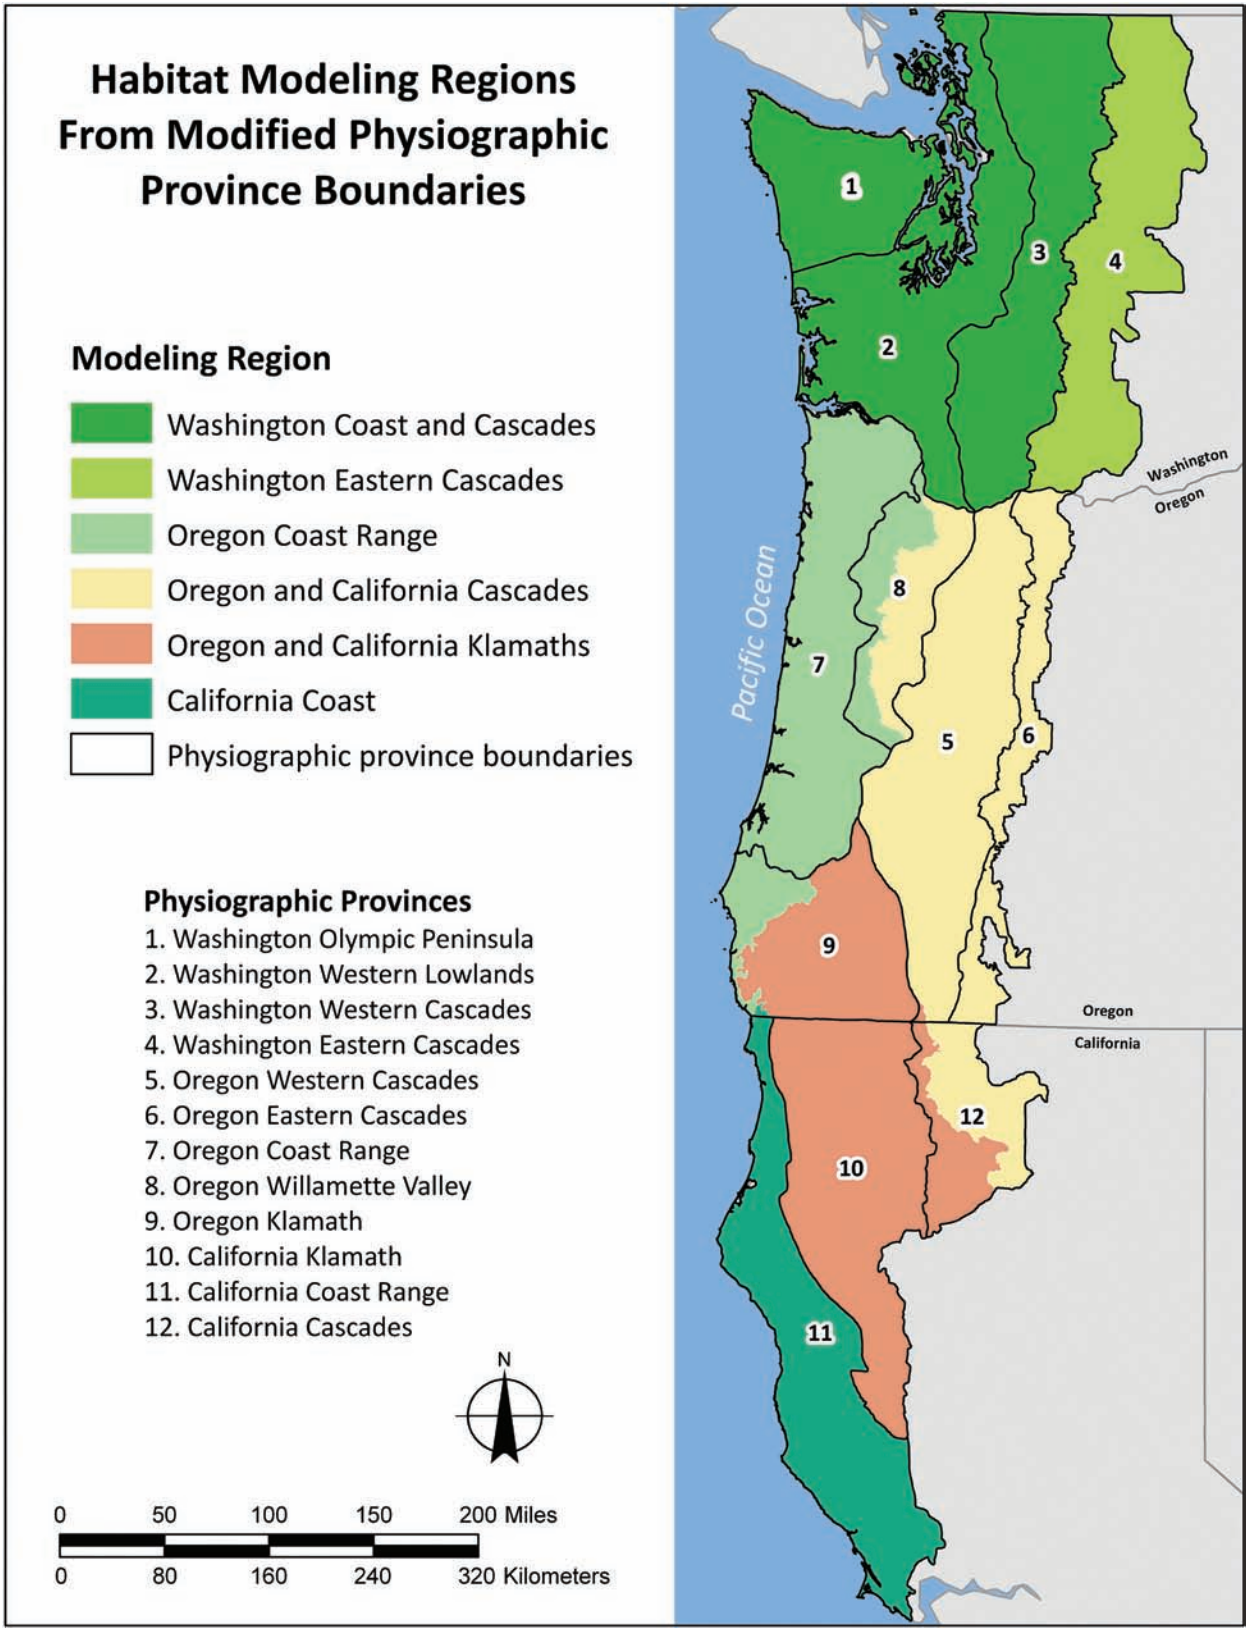

Figure 3-5—Modeling regions used for modeling northern spotted owl habitat.

be potentially suitable for spotted owl nesting, roosting, foraging, or dispersal; however, we suspect that this mask contains areas, especially in the higher elevations, that might not actually be capable of developing habitat under the current climate.

Habitat Map Development and Evaluation

The MaxEnt model output is a logistic probability estimate of a site's suitability for species presence based on environmental conditions from where the species are found, and their differences from the surrounding background environmental conditions within the modeling region (Phillips and Dudík 2008). In our case, the environmental predictor variables used were based on stand-level structural and forest-type species conditions associated with nesting and roosting use by spotted owls. Therefore, our raw model output maps show a scale of nesting/roosting suitability (from low to high) for forested stands based on the stand structure and species composition conditions described by the GNN data. The mapped logistic probability values will be higher where these stand-level conditions are more similar to the conditions observed where we have documented nests and territorial pair centers (i.e., the training data). A mapped logistic probability of 0.5 represents the "average" condition where the species occurred (Phillips 2008).

Our charge is to develop habitat maps that work well and to then measure and report on amounts and distribution of habitat. The latter requires that we select a threshold from the probability values described above to represent "suitable" owl nesting/roosting habitat for summarization purposes. In the 10-year report, we used the area-adjusted frequency (AAF) curves (Boyce et al. 2002) associated with the habitat suitability output from BioMapper to evaluate our habitat models. These curves are among the few diagnostic measures designed specifically for measuring the accuracy of habitat models based on presence-only data (Hirzel et al. 2006). But in addition to model evaluation, these curves also provide information that can be used to reclassify habitat models into discrete habitat classes (Hirzel et al. 2006). To conform to the new terminology, we now refer to AAF curves as "continuous predicted versus expected (P/E) ratio curves" (Hirzel et al. 2006). The continuous P/E curves provide three indications of a model's performance (Hirzel et al. 2006):

1. For replicated model runs that use held-out testing methods (i.e., bootstrap or jackknife), the variance along the curve gives information about the model's robustness along its range of probabilities. Smaller variances indicate more reliable prediction points. Large variances indicate the range of prediction values that are the least robust. This information allows a better understanding of the model's strengths and weaknesses.
2. The shape of the curve provides clues about the model's predictive power. The Spearman rank correlation coefficient (R_s) is used to help us judge the shape of the curve and the model's performance. For fluctuating curves, each time the curve dips as the ranks increase, R_s decreases. A higher R_s indicates a consistently increasing larger proportion of species presence (versus available) being predicted as the model prediction output increases. This is indicative of a good model; however, note that one can get the same R_s for many different-shaped curves (i.e., linear, exponential, and sigmoid), and curves with flatter slopes can have the same ranks as curves with steep slopes. According to Hirzel et al. (2006), a perfect model would have a linear P/E curve that monotonically increases as probability increases because a perfectly straight line allows for an infinite number of classes along the scale of probability (i.e., "resolution"). A wavy line lowers the resolution because classifying the line depends on these changes in the shape and slopes. For exponential models (like MaxEnt), an exponentially increasing curve is indicative of a good model.
3. The maximum y-axis value reached by the P/E curve reflects how much the model differs from chance expectation, or deviation from randomness. This score reflects the model's ability to differentiate the species niche characteristics from those of the modeled region. Caution is needed because this maximum value is sensitive to the species niche breadth within the context

of the modeled region. In other words: Does the species just use a small percentage of what is available in the modeled region or is its habitat use more generalized within the modeling region? If there is abundant habitat available in the modeling region that is being used by the species, the model will usually produce a flatter curve with lower P/E values. Also, the selection and resolution of the environmental variables used for modeling can influence the maximum P/E value.

Once the habitat model evaluation process has been completed, the P/E curve provides a method for classification of a model into discrete habitat classes (Hirzel et al. 2006). The point along the model prediction axis (x-axis) where the curve crosses P/E = 1 along the y-axis (fig. 3-6) is the threshold where the model predicted species occurrence is higher than would be expected if there were no selection (i.e., habitat use was random). This threshold is often used to classify habitat models into binary maps, where logistic probability values greater than the P/E = 1 threshold represent "suitable" habitat (Hirzel et al. 2006). We also note that in our case, the P/E = 1 threshold was similar to the "maximum specificity and sensitivity threshold"[3] (Phillips and Dudík 2008) for all model regions. We provide these and additional thresholds, that are commonly used, in appendix C. We also note that the 10-percentile threshold (app. C) is equivalent to where we reported that 90 percent of the owl training data occurred in the 10-year report habitat models (see fig. 3-11 and table 3-4 in the 10-year report).

We further divided the continuous scale of probability of occurrence from our habitat models into four habitat classes that represent from the least to the most suitable habitat conditions (fig. 3-6). This was done to produce histograms (app. F) similar to the five-class histograms used to profile the continuum of habitat suitability in the 10-year report (Davis and Lint 2005). As in the 10-year report, tracking the changes in these habitat profiles (app. F) is expected to provide useful information for visualizing where habitat may be recruited (first two habitat classes) via forest succession over the next few decades. The only difference between the two reports is that the classes in the 15-year report are based on commonly used thresholds and have more biological meaning. These habitat classes are defined as follows:

- Unsuitable—MaxEnt logistic output from zero to the mean value between zero and the P/E = 1 threshold. This habitat class represents the lowest suitability class and owls will normally avoid using it for nesting and roosting.
- Marginal—MaxEnt logistic output from the mean value between zero and the P/E = 1 threshold to the P/E = 1 threshold. This habitat class represents a condition approaching what owls will nest and roost in. Occasionally, these habitat characteristics are associated with nesting and roosting owls; however, this could be due to occurrence of legacy habitat features such as large trees, extreme rarity of suitable nesting/roosting habitat, or perhaps interspecific competition with barred owls.
- Suitable—MaxEnt logistic output from the P/E = 1 threshold to 0.5. A MaxEnt logistic output value of 0.5 represents the "average" environmental condition associated with the owl training data. This habitat class represents habitat conditions where the probability of owl presence is higher than expected by random chance and up to average conditions associated with nesting and roosting.
- Highly suitable—MaxEnt logistic output from 0.5 to the highest output from the habitat model. This habitat class represents the most suitable, or "above average," conditions used by nesting and roosting territorial owl pairs.

In some of the modeled regions, the 10-percentile threshold occurs within the "marginal" habitat class indicating some owl nesting/roosting use of younger, mid-aged stands as noted by Thomas et al. (1990) who stated that as forests develop along the continuum from young to old, they gradually become more suitable for spotted owl nesting/roosting. To show this continuum of conditions, and to help interpret what these habitat classes represent on the ground,

[3] Minimizes omission (false absence predictions) and commission (false presence predictions) errors.

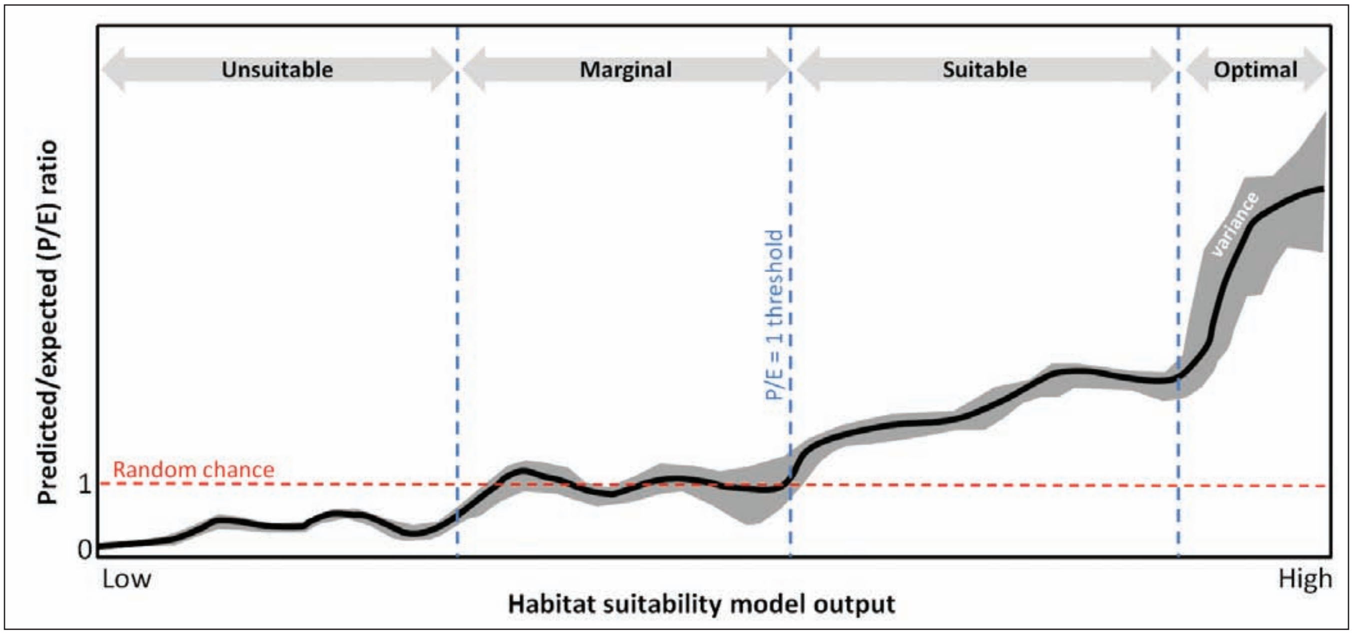

Figure 3-6—The predicted versus expected ratio curve (modified from fig. 6 in Hirzel et al. 2006).

we also provide average stand structure and age attributes (table 3-1). It appears that the lowest class of habitat includes early- to mid-successional forests and the highest suitability class includes the oldest and most structurally complex forests (table 3-1). However, we stress that these simple combinations of forest attributes do not fully describe habitat, and it is the complex interaction between them that does.

Nesting/Roosting Habitat

The importance of mature or late-successional forests for nesting, roosting, and foraging of owls in the Pacific Northwest is clear (see reviews in Thomas et al. 1990), with numerous studies documenting both selection of these habitats by owls (Carey et al. 1990, Forsman et al. 1984, Glenn et al. 2004, Gutiérrez et al. 1984, Hamer et al. 1989) and now more recent research linking greater amounts of older forest in owl territories to owl fitness (i.e., increased survival and/or reproductive success) (Dugger et al. 2005, Franklin et al. 2000, Olson et al. 2004). High-quality owl habitat was described by Thomas et al. (1990) and generally includes older, multilayered, structurally complex forests characterized by large-diameter trees, high amounts of canopy cover, numerous large snags, and lots of downed wood and debris.

Although late-successional and old-growth forests are often equated with spotted owl habitat, they are not always the same. As noted by Thomas et al. (1990), the redwood zone in northwestern California is unique in terms of owl habitat development. In that portion of the owl's range, the structural conditions that constitute nesting/roosting habitat develop quicker, with suitable conditions occurring in 40 to 60 years on some sites and superior conditions in 80 to 100 years. Habitat development is not a mechanistic process, and there is considerable variability in predictions of habitat (Courtney et al. 2004). As can be seen in table 3-1 and appendix C, the transition from unsuitable to suitable conditions is more complex than a simple increase in a stand's average tree diameter and canopy closure. In addition, species composition is also important; for instance, late-successional/old-growth ponderosa pine forests do not function as nesting/roosting habitat, nor do older subalpine forests.

We consider our "suitable" and "highly suitable" habitat classes, as described above, as nesting/roosting habitat. It is important to emphasize that our maps are not attempting to predict owl occupancy or other demographics across the landscape, but rather describe stand-level habitat characteristics that are associated with owl pair use that

Table 3-1–Average (± standard deviation) habitat variable values (gradient nearest neighbor) for nesting/roosting habitat classes in each modeling region

Model region	Habitat class	Habitat suitability	Conifer cover	Average conifer d.b.h.[a]	Large conifers (≥30-in d.b.h.)	Diameter diversity	Average stand height	Average stand age

[a] d.b.h. = diameter at breast height.

approximates a species' realized niche within a specific environmental space (Phillips et al. 2006).

Dispersal Habitat

Dispersal habitat is used by juvenile owls moving away from natal areas or by subadults and adults moving between territories (Forsman et al. 2002). Spotted owls are capable of dispersing long distances, and gene flow from one portion of the range to another can occur in a few generations (Forsman et al. 2002). The network of large reserves established under the Plan appeared suitable for maintaining interconnected populations of spotted owls (Lint et al. 2005); however, concern remained for disjunct small populations that are isolated by large nonforested areas or expanses of young managed forests (Forsman et al. 2002).

Thomas et al. (1990) predicted that much of the forested area between owl conservation areas would be suitable for passage by dispersing spotted owls as long as at least 50 percent of the landscape was forested with conifer stands with an average d.b.h. of ≥11 in with at least 40 percent canopy closure. This definition of a dispersal-capable landscape became known as the "50-11-40 rule" (Thomas et al. 1990) and was based on information of habitat conditions for dispersing juvenile owls (Miller 1989). Older forest habitat is more frequently used for natal dispersal, but closed-canopy (>60 percent cover) younger forests are also used, whereas younger open-canopied (<40 percent cover) forests are generally avoided (Miller et al. 1997). Dispersal distance is also negatively associated with the amount of clearcut forest in the landscape, and large urban and agricultural areas appear to be barriers to dispersal (Forsman et al. 2002, Miller et al. 1997). Spotted owls use a wide variety of forest habitats for dispersal and will traverse very fragmented landscapes (Forsman et al. 2002), but little information exists on how the amount or fragmentation of habitat influences dispersal. The results of the latest meta-analysis suggest that recruitment into the territorial breeding population may depend on the presence of sufficient amounts of high-quality dispersal habitat, enough to ensure survival of dispersing owls until they recruit into the territorial population (Forsman et al. 2011).

We did not use presence locations and MaxEnt to model dispersal habitat. Instead we developed dispersal habitat maps for both bookend periods using simple GIS queries of our GNN variables for conifer d.b.h. ≥11 in and conifer cover ≥40 percent, similar to what was done in the 10-year report (Davis and Lint 2005). We also included both suitable habitat classes from our nesting/roosting habitat models, because owls obviously disperse through nesting/roosting habitat. We then analyzed the status and trend of this habitat within federal reserved and nonreserved LUAs, as well as nonfederal lands.

To detect changes in amounts of dispersal habitat that might affect owl movement across the landscape, we conducted a landscape-scale analysis using a spatial framework based on Forsman et al. (2002). Only 8.7 percent of dispersing individuals moved more than 31 linear mi and only "large expanses" of nonforested or younger forested areas appear to pose significant barriers to this movement (Forsman et al. 2002). We used this distance to define the radius (15.5 mi) for a circular analysis window within which we quantified the percentage of dispersal habitat for both bookend periods and included all landownerships. This distance is also comparable to the root-mean-square dispersal distance (a measure of gene flow) estimated by Barrowclough et al. (2005). We then overlaid linear owl dispersal paths from the 10-year report (Lint et al. 2005) on the baseline version to measure underlying percentages of dispersal habitat in the landscape through which they dispersed (fig. 3-7). The mean percentage of dispersal habitat for both juvenile and nonjuvenile owls was 55 percent. We combined results across age classes and used the 10-percentile value (40 percent) from all owl dispersal paths as a threshold to create binary maps from the roving window analysis maps. Thus, the binary maps show where there appears to be enough dispersal habitat at the landscape scale (≥40 percent within a 15.5-mi radius) to accommodate 90 percent of known owl movements. We call this footprint the "dispersal-capable landscape" and used it to identify potential disconnects or bottlenecks for owl movement between large block reserves. We also identified areas across the range of the owl where the footprint shrank or expanded between our bookends.

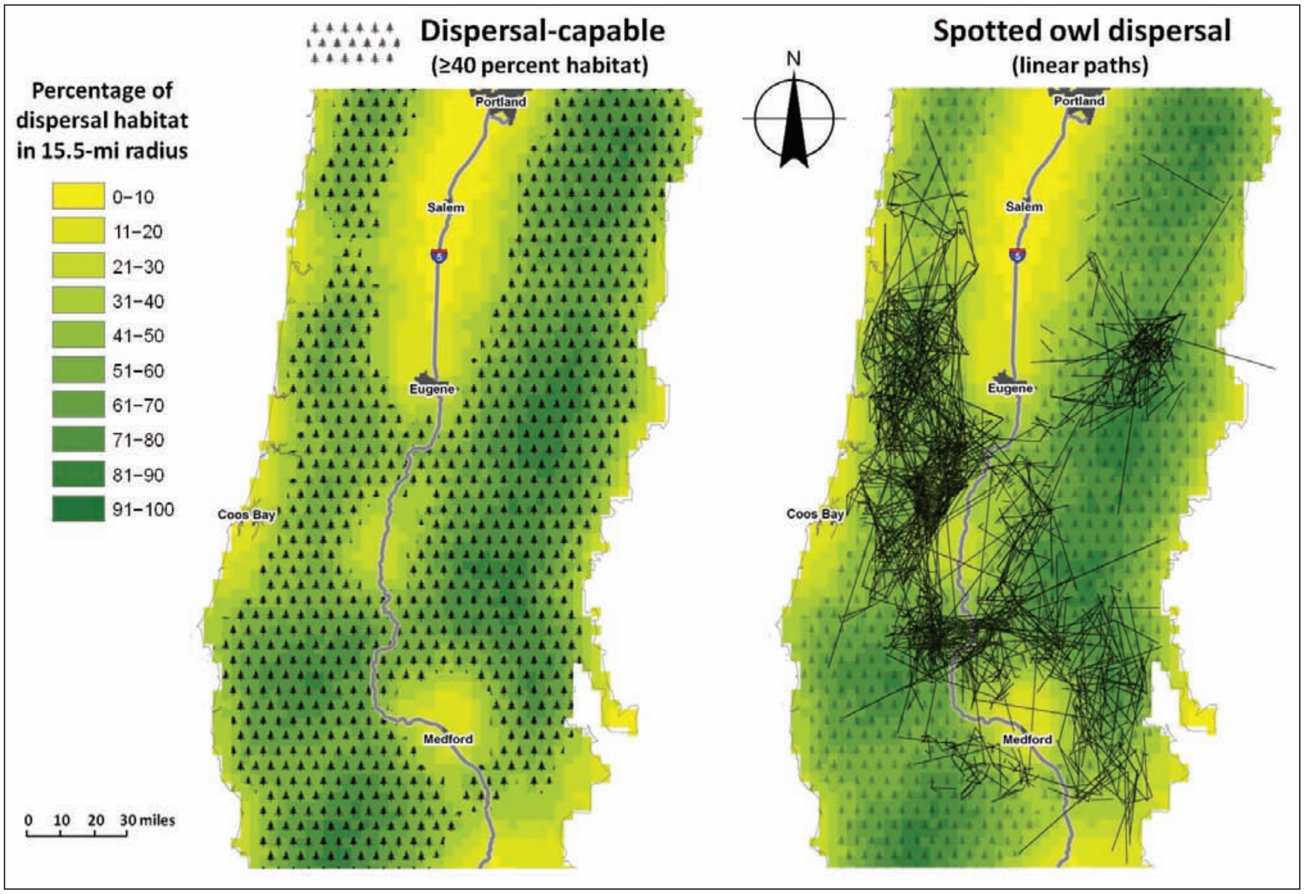

Figure 3.7—Juvenile and nonjuvenile dispersal straight-line paths from Lint et al. (2005) in relation to the amount of dispersal habitat within a 15.5-mi radius that was based on information from Forsman et al. (2002) where only 8.7 percent of dispersing individuals moved more than 31 linear mi.

Habitat Fragmentation

Although large blocks of contiguous, high-quality habitat provide the best configuration for long-term persistence of owl populations (Thomas et al. 1990), smaller blocks or patches of owl habitat can also be important as dispersal habitat (Forsman et al. 2002). These smaller patches help to maintain connectivity between the larger blocks of habitat that will eventually develop in the reserve system designed under the Plan. At the time of the owl's listing, habitat fragmentation was believed to be a stressor for spotted owls because it is associated with habitat loss, and was also thought to improve habitat conditions for spotted owl predators, such as the great horned owl (*Bubo virginianus*) (Carey et al. 1992). There is no clear evidence of indirect effects of fragmentation through predation, but it remains as a possible threat (Courtney et al. 2004). A compilation of the recent research on this subject shows that habitat fragmentation can affect occupancy and other demographic factors, and may result in isolated populations and interruption of gene flow (Courtney et al. 2004).

In a general sense, habitat can be divided into two broad landscape morphological categories: (1) core habitat, which occurs only in larger habitat patches and is some distance away from the patch edge (sometimes referred to as "interior habitat"); and (2) edge habitat, which occurs along the margins of larger habitat patches surrounding the core habitat or occurs in patches that are too small to contain core habitat.

It is not clear how habitat fragmentation affects owl demographics; however, survival and reproduction are higher on owl territories with more old-forest habitat centered on the nest tree or activity center (Dugger et al. 2005, Franklin et al. 2000, Olson et al. 2004). Edge habitat also appears to be important to spotted owls in some portions of their range, probably as a source of prey (Franklin et al. 2000, Olson et al. 2004; but see exception in Dugger et al. 2005).

Here we define core habitat as the internal portion of a stand of nesting/roosting habitat that is farther than 100 m from the stand edge. Edge habitat is defined as all noncore nesting/roosting habitat and is always adjacent to non-habitat. We do, however, distinguish between two types of edge habitat: (1) core-edge habitat, which is the amount of nesting/roosting habitat adjacent to and surrounding core patches (i.e., the edges of large habitat patches), and (2) all other edge habitat that is not directly adjacent to core habitat (i.e., small, isolated habitat patches). In juxtaposition, core and core-edge habitat reflect more contiguous habitat blocks, whereas large amounts of non-core-edge habitat occur in landscapes that are highly fragmented, with patch sizes too small to contain core habitat.

We used GUIDOS v1.3 (Soille and Vogt 2009) to conduct a morphological spatial pattern analysis (MSPA) on 100-m (2.47-ac)-resolution binary raster (grid) maps of nesting/roosting habitat for both 1994/96 and 2006/07 to assess status and trend in habitat configurations. GUIDOS was specifically developed for analysis of forest spatial patterns extracted from satellite images (Soille and Vogt 2009, Vogt et al. 2007). It produces simple-to-interpret maps of core and edge patterns from binary raster maps, and the outputs are pixels with specific core or edge classifications (fig. 3-8). From this product, we conducted an area analysis that quantifies the area represented by both types of pixels (“core” or “edge”); thus, in our analysis, edge is not quantified as a perimeter. Specifically, edge habitat only occurs within 1 pixel width, or 100 m (328 ft), from a nonhabitat pixel, and, therefore, core habitat pixels are greater than 328 ft from nonhabitat pixels. This distance is similar to that used by Franklin et al. (2000) and Zabel et al. (2003) to define their core habitat. Using 100-m (2.47-ac)-resolution maps requires a patch of contiguous habitat to be greater than 22 ac before it can contain core habitat. Therefore, the combination of core plus core-edge pixels shows patterns of habitat patches that are at least that large. All patches of nesting/roosting habitat smaller than that are essentially

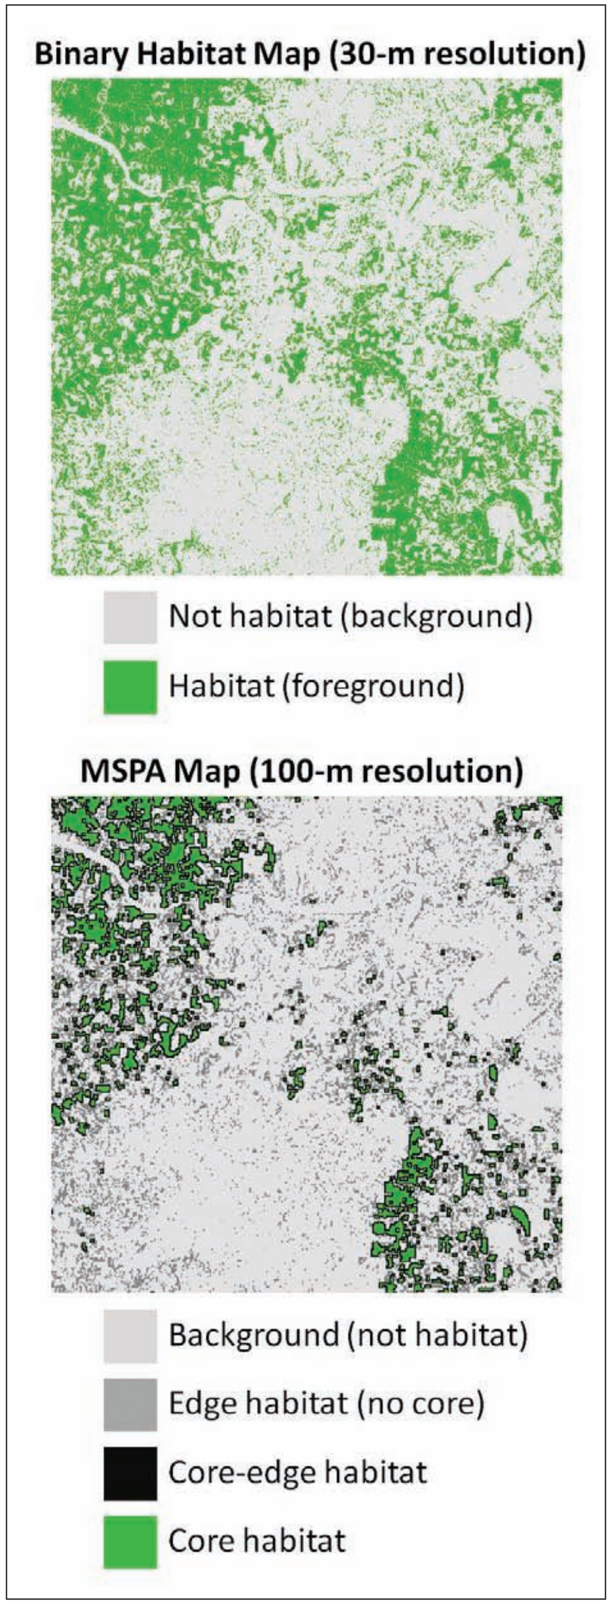

Figure 3-8—Example of the morphological spatial pattern analysis (MSPA) on binary maps of nesting-roosting habitat.

edge habitat. We report on the status and trend of core habitat and changes in the percentage of the sum of [core] + [core-edge] habitat to all nesting/roosting habitat. This percentage can serve as an index of landscape habitat fragmentation, as the higher the percentage, the more contiguous the habitat is within the landscape and the lower the percentage, the more fragmented the habitat (fig. 3-8).

Results

Habitat Suitability Modeling

Our final habitat models and map products (fig. 3-9) represent the mean from 10 bootstrapped replicates. We decided to use the means as our product, because the P/E curves that are generated for the means provide the users with valuable information on how to interpret the model (see the "Habitat Map Development and Validation" section and fig. 3-6). We also provide the summary statistic maps (i.e., 95-percent CI) to supplement this interpretation with area-specific information as discussed in the methods section.

Performance of bookend 1 (1994/96) models was fair to good (i.e., C+ to B+ grades) with AUCs ranging from 0.78 to 0.88 and Spearman rank correlation coefficients >0.9 ($P < 0.001$) (app. C). Our lowest performing models occurred in the Oregon and California Klamath and California Coast modeling regions, and our best models were in the Washington Coast and Cascades and Oregon Coast modeling regions. We suspect this is because of the rich vegetative diversity in that area that (1) confounds remotely sensed data development and (2) produces a more complex "definition" of habitat because of the complex variable interactions. Regardless of the reason, the model AUCs for these regions were 0.78 and 0.81, respectively, and therefore provide useful information (Swets 1988).

Our projected models (bookend 2, 2006/07) were tested using the 2006/07 owl location data sets not used for model training. Spearman ranks based on the continuous Boyce index (Hirzel et al. 2006) ranged from 0.63 to 0.98. The best model projection [extrapolation] occurred in the Oregon Cascades modeling region, followed in order by the Oregon Coast Range ($R_S = 0.95$), western Washington and Olympic ($R_S = 0.93$), and, surprisingly, the Klamath Mountain modeling region ($R_S = 0.92$). The poorest model projections occurred within the Washington Cascades modeling region ($R_S = 0.74$) and California Coast Range ($R_S = 0.63$). During this testing process, we noted interesting differences between the average habitat suitability values where spotted owls in the demographic study areas occurred in 1994/96 compared to where they occurred in 2006/07 (fig. 3-10). We observed consistently lower than average habitat suitability values in 2006/07 compared to 1994/96; however, 95-percent CIs overlap between periods. We speculate that spotted owls might be using lower quality habitat in 2006/07 because they are being displaced from higher quality habitats by barred owls, whose density has increased steadily since the late 1990s (Forsman et al. 2011). The potential for displacement of spotted owls by barred owls in the current bookend is the reason we trained our models using the 1994/96 spotted owl locations. However, given the aforementioned issues on model projection [extrapolation], these results, based on our bookend 2 models, should be interpreted with some caution.

Nesting/Roosting Habitat

We estimate a rangewide gross loss of about 298,600 ac[4] of spotted owl nesting/roosting habitat on federal lands (app. D). This amounts to about 3.4 percent of what was present in 1994/96 (bookend 1). Most of the loss (79 percent) occurred within the reserved allocations, which amounted to about 3.7 percent of the reserved areas under the Plan, whereas nonreserved allocations experienced a 2.7 percent loss of habitat. Wildfires remain the primary cause of habitat loss, accounting for about 90 percent of the loss in reserved allocations (203,900 ac), and about half of the loss in nonreserved allocations (32,600 ac). Timber harvesting accounts for about 45 percent of the loss in nonreserved allocations (37,400 ac) and 7 percent within reserved allocations (16,600 ac), and insects and disease outbreaks account for about 3 percent of the loss in all allocations (fig. 3-11). Relative to the baseline maps, and based on

[4] Acres are rounded up to the nearest 100 ac.

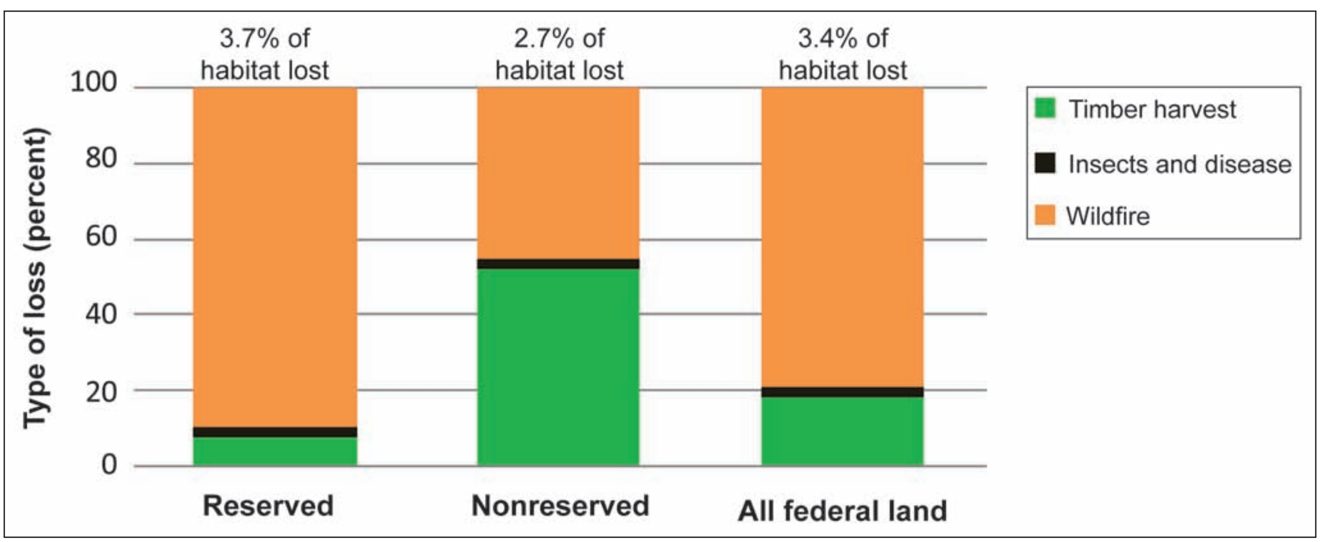

Figure 3-11—Causes of nesting/roosting habitat loss on federally administered lands.

LandTrendr change-detection data, the physiographic province that experienced the greatest loss of habitat was the Oregon Klamath province because of the large Biscuit Fire that occurred in 2002. In general, the Klamath and eastern Cascades physiographic provinces experienced the largest percentage losses of habitat related to wildfires (fig. 3-12); however, in terms of absolute acreage of habitat lost, the Oregon Klamath ranked first (93,600 ac), California Klamath ranked second (71,600 ac), and the Oregon western Cascades ranked third (28,900 ac) (app. D). Most of the habitat loss in the Oregon western Cascades occurred in the southern half of that province.

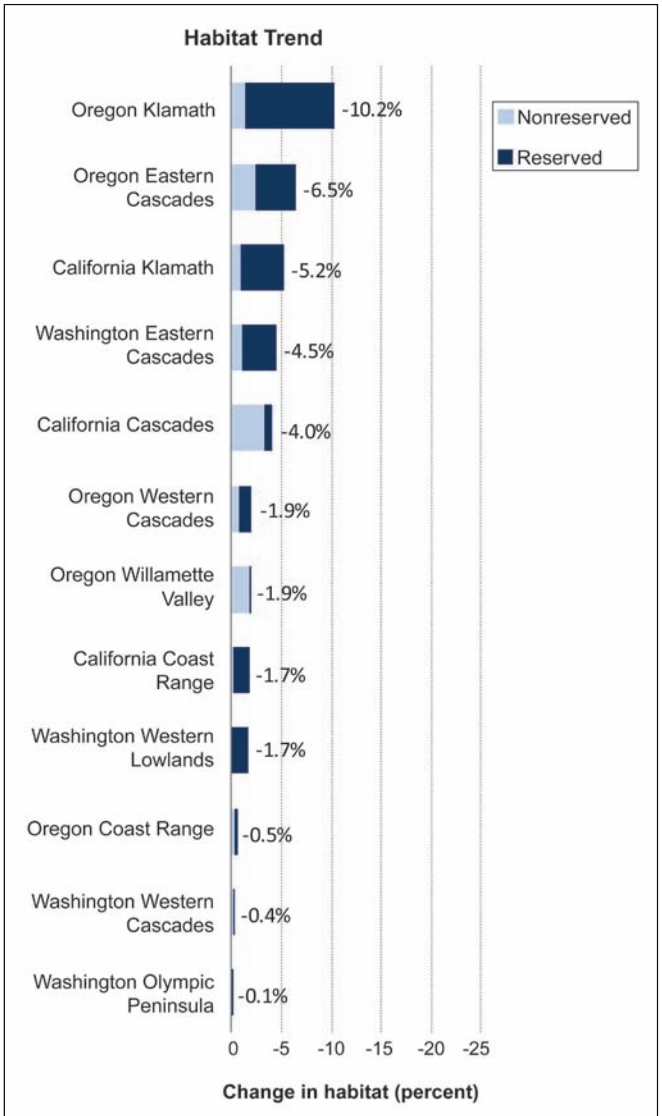

Figure 3-12—Nesting/roosting habitat trends (based on the LandTredr analysis) from 1994/96 to 2006/07 by physiographic province for reserved and nonreserved federal lands.

Because wildfires appear to be the number one cause of habitat loss, we conducted a more indepth analysis of the 20 largest wildfires that occurred within the owl's range between 1996 and 2006 (years with satellite data across the range). Table 3-2 lists these fires in descending order of estimated acres of owl habitat lost. Overall, these 20 fires accounted for almost 200,000 ac of habitat lost. The percentage of owl habitat lost within their fire perimeters differed among the east and west Cascades (Washington and Oregon) and the Klamath Mountains (Oregon and California) physiographic provinces (fig. 3-13). The percentage lost per fire in the Klamath Mountains and the west Cascade provinces were not significantly different (overlapping 90-percent CIs); however, percentage of habitat loss per fire was notably higher in the eastern Cascades. However, in terms of the amount of nesting/roosting habitat burned by these 20 fires, the vast majority of acres lost occurred in the Klamath Mountains (143,000 ac), followed by the east side of the Cascades (36,000 ac) and the western Cascades (20,000 ac).

Based on Climate, Ecosystem, and Fire Applications (CEFA) program data (Brown et al. 2002) and wildfire perimeter data (MTBS and GeoMac), wildfires burned an estimated 2.6 million ac within the owl's range between 1994 and 2007, which frames our analysis period. From our observations, it is clear that wildfires do not remove all owl nesting/roosting habitats within their perimeters. Fires of low to moderate severity can alter this habitat, but do not necessarily result in its loss. The commonly used term to define this effect is "habitat degradation." We estimated owl habitat degradation, as the number of acres that changed from the "highly suitable" to the "suitable" habitat class between our bookends (1994/96 to 2006/07). For habitat degradation, our analysis showed the reverse trend from what we observed for habitat loss (fig. 3-14). These results suggest that wildfires in the east Cascades have been more destructive (higher amount of habitat loss, lower amount of degradation) and that wildfires in the west Cascades and Klamath Mountains were less severe, producing a mosaic of fire effects indicative of a moderate-severity regime.

Table 3-2—Estimated fire effects on northern spotted owl nesting/roosting habitat from the 20 largest wildfires between 1996 and 2006

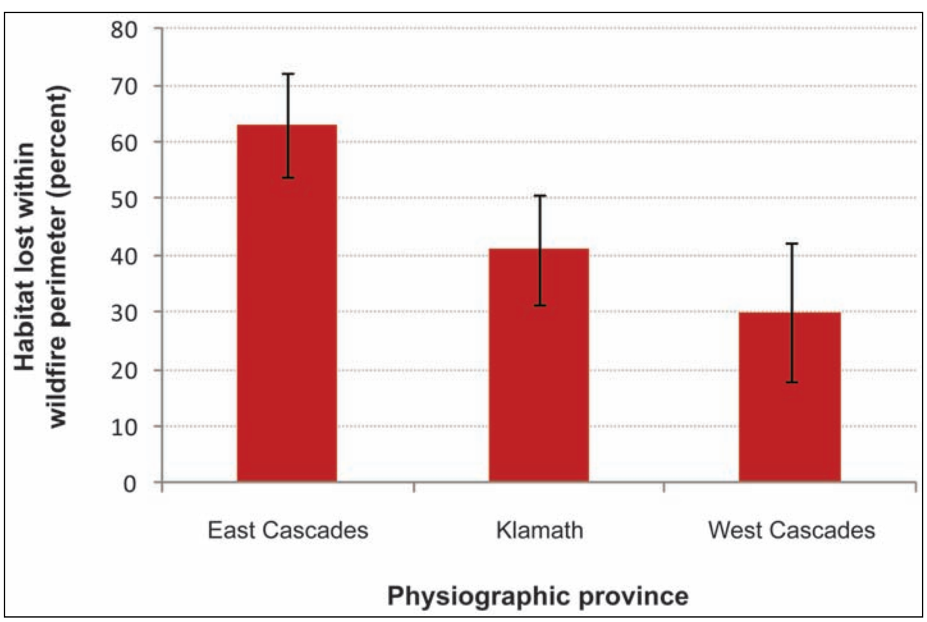

Figure 3-13—Provincial differences in nesting/roosting habitat losses from the fires in table 3-2.

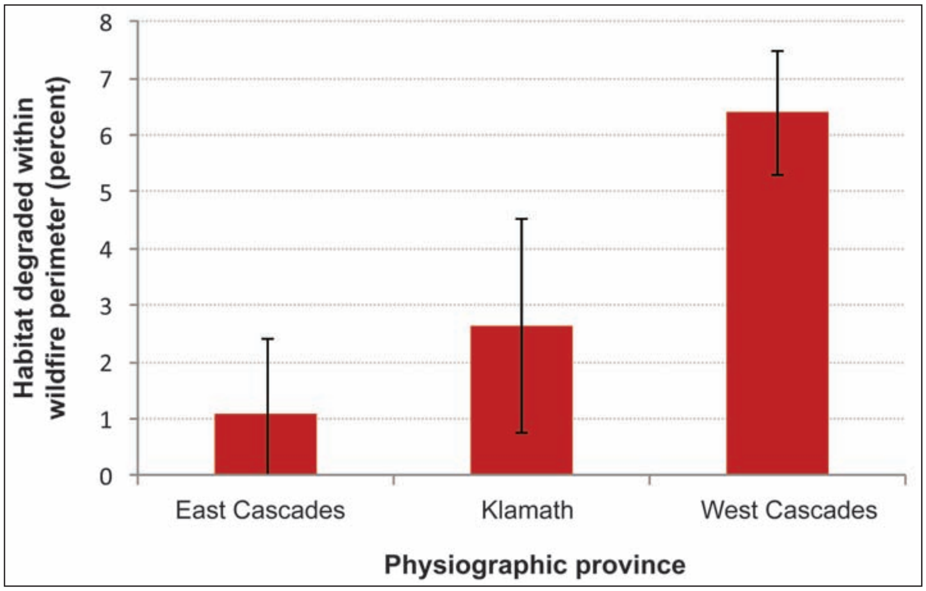

Figure 3-14—Provincial differences in nesting/roosting habitat degradation from the fires in table 3-2.

For this report, we were cautious in our use of the new GNN/LandTrendr data for measuring gains in nesting/roosting habitat. Although the products we used for our analysis (and other remote sensing approaches) have demonstrated their ability to detect both losses and gains in forest cover (Coops et al. 2010; Hais et al. 2009; Kennedy et al. 2007, 2010; Staus et al. 2002), the underlying measurements from passive optical satellite sensors (i.e., those that take pictures of sunlight reflected from the Earth's surface) place constraints on the subtlety of coniferous forest change that can be reliably captured over a short period (i.e., 10 to 12 years). Disturbances that result in substantial removal or reduction of vegetation cover (usually abrupt changes) are easier to discern during change-detection than minor disturbances that cause more subtle change, or gradual disturbances that occur over a longer period, such as insect and disease disturbances. Vegetation recovery can also be more difficult to detect (depending on the type of vegetation and timeframe), as it usually recovers gradually over a longer period. Increases in tree bole diameter and forest canopy cover happen at a faster rate in younger coniferous forests than in older forests, however, and the satellite-measured signal changes faster as well. Within the 10- to 12-year period of this investigation, mapping of such changes in early successional, pre-canopy-closure conditions are relatively robust (Kennedy 2010). Much more subtle, however, are the satellite signals associated with the structural changes as forests progress to maturity and old age. Moreover, small-scale forest canopy gap dynamics cannot be directly observed with the sensors used in our analysis (Frolking et al. 2009). Rather, all structural changes associated with maturing forests often must be inferred from changes in the spectral signal caused by proxy effects, such as within-canopy shadowing. Therefore, it is difficult to distinguish at a given location small changes in forest structure (and any associated variables, such as age) from background random noise caused by differing sun angles, atmospheric effects, and phenological differences, particularly when the interval of change is short (as for the 10- to 12-year period here) (Kennedy 2010).

During our analysis, we conducted visual and GIS examinations of our nesting/roosting habitat maps and variable maps using aerial imagery and noted that commercial thinning of young plantations created suspicious changes in some of our habitat modeling variables in the bookend 2006/07 data set. For instance, in some modeling regions, stand age increased by three to five decades, or density of large conifer (>30 in d.b.h) increased by as much as three to four trees per ac, which is not likely within the timeframe of our analysis. We suspect that canopy shadowing increased owing to the thinning and may have caused some stands to appear older than they actually were, thus making them appear as habitat when the modeling results from the 1994/96 bookend were extrapolated (projected) to the 2006/07 bookend.

We also conducted an analysis of the regional inventory plot data, similar to what was done in the 10-year report (Davis and Lint 2005), to determine if there were significant gains of forest stand conditions that were similar to spotted owl nesting/roosting habitat (see table 3-5, page 47 in Davis and Lint 2005). The results of this analysis did not show any significant gains in "habitat classes" between the initial plot measurement and the remeasurement data, which roughly covers the same periods as our bookend models (app. H). In addition, the net changes between the bookend models were well within the 95-percent CIs between periods; therefore, it is not possible to state with certainty that we observed "real" net changes in nesting/roosting habitat between our bookend maps (app. C). For these reasons (plus the need for caution when transferring or projecting models discussed earlier), we focused on habitat losses, which are more accurately detected with current technologies and were verified by LandTrendr change-detection data. For the next round of monitoring (20-year report), we hope to use LandTrendr for verification of both nesting/roosting habitat losses and gains.

Dispersal Habitat

Although we were cautious in our interpretation of gains in nesting/roosting habitat, we feel that the GNN/LandTrendr data were better suited for detecting gains in younger forests (as described above), such as dispersal habitat, plus we did not develop and then project (extrapolate) a dispersal habitat model from one period to another as we did for nesting/roosting habitat (i.e., no model transferability issues). Examination of the bookend changes in the two variables that were used to define dispersal habitat (d.b.h. and conifer cover), and visual examination of the dispersal habitat maps overlaid on high-resolution color aerial imagery showed realistic changes that one might expect in a 10-to 12-year timeframe.

Rangewide, we report an estimated gross loss of about 417,000 ac of dispersal habitat, most (82 percent) from wildfire (341,800 ac). The causes for dispersal habitat loss were similar to those for nesting/roosting habitat losses, with wildfire being the main cause in reserved allocations and about half of the loss in nonreserved allocations (fig. 3-15). Timber harvesting accounts for the other half of the loss in nonreserved allocations, and insects and disease account for a small percentage of loss in all allocations (fig. 3-15). However, these losses were offset by a 1.26-million-ac gross gain in dispersal habitat on federal land from forest

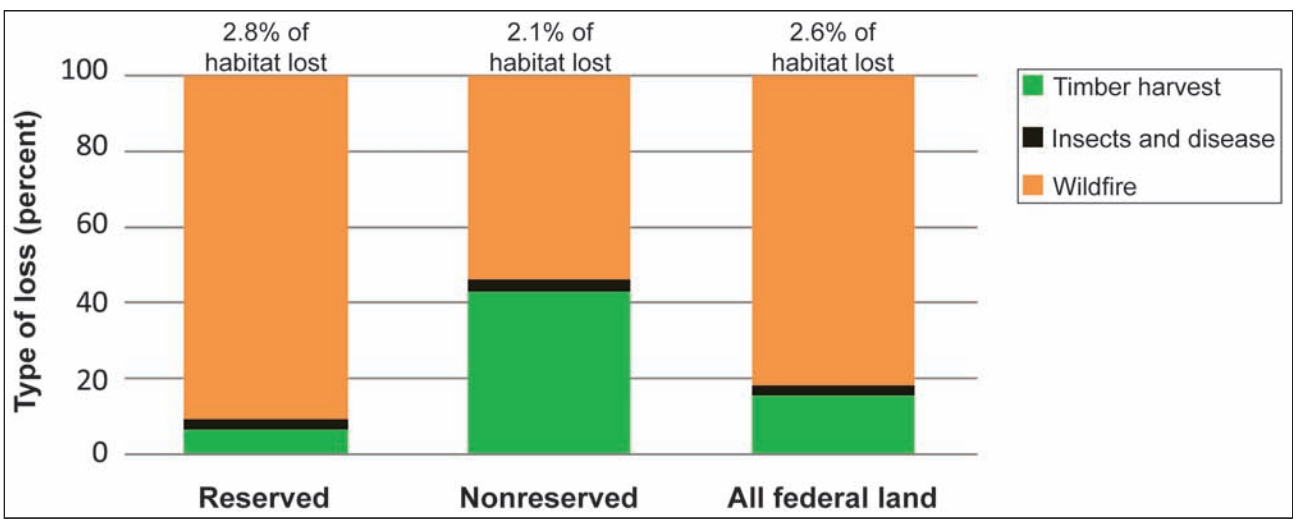

Figure 3-15—Causes of dispersal habitat loss on federally administered lands.

succession, resulting in a 5.2-percent overall net gain of dispersal habitat coverage across the owl's range (app. E). In general, the gains in dispersal habitat were higher in federal nonreserved allocations than in reserved allocations. Only the Oregon Klamath experienced a net decrease in the amount of dispersal habitat (-2.6 percent) owing to the large Biscuit Fire, which removed more dispersal habitat than was recruited for this period (app. E). The biggest net gain (13.1 percent) in federal dispersal habitat occurred in the Oregon Coast Range, which has some of the most productive forests in the owl's range. An example of this recruitment is clearly seen in the maps from 1996 and 2006 for the large Oxbow Fire of 1966 (fig. 3-16). In 1996, this area was forested with stands just about 30 years of age. Based on tree diameter growth data for fully stocked, site class 1, Douglas-fir (*Pseudotsuga menziesii* [Mirb.] Franco) forests, stands of this age have an average d.b.h. of 9 in and can put on 3 in of diameter growth in one decade (McCardle et al. 1961), thus crossing the threshold from nondispersal to dispersal habitat in a relatively short timeframe. However, not all sources of gain for dispersal habitat come from forest succession. Sometimes disturbances, such as a moderate-severity wildfire, can alter (i.e., opening up the canopy) suitable nesting/roosting habitat, making it unsuitable for nesting and roosting, but still suitable enough for owl dispersal (see table 3-1).

At the landscape scale, we detected a 5-percent gross loss of dispersal-capable landscape, mostly around the periphery of the federal forests. We suspect this may be due to regeneration timber harvesting occurring in dispersal habitats on nonfederal lands that border federal lands. Large wildfires on federal lands played a role in this decrease in the eastern Cascade provinces and the Oregon Klamath Mountain province. We also detected a 4-percent gross gain in dispersal-capable landscapes along the periphery of some federal forests caused by forest succession in younger forests, resulting in an overall net decrease of 1 percent in dispersal-capable landscape area (fig. 3-17).

The most noticeable change in dispersal-capable landscapes, that we detected, occurred in the northeastern portion of the Washington eastern Cascades; the losses of dispersal-capable landscape caused by large wildfires in

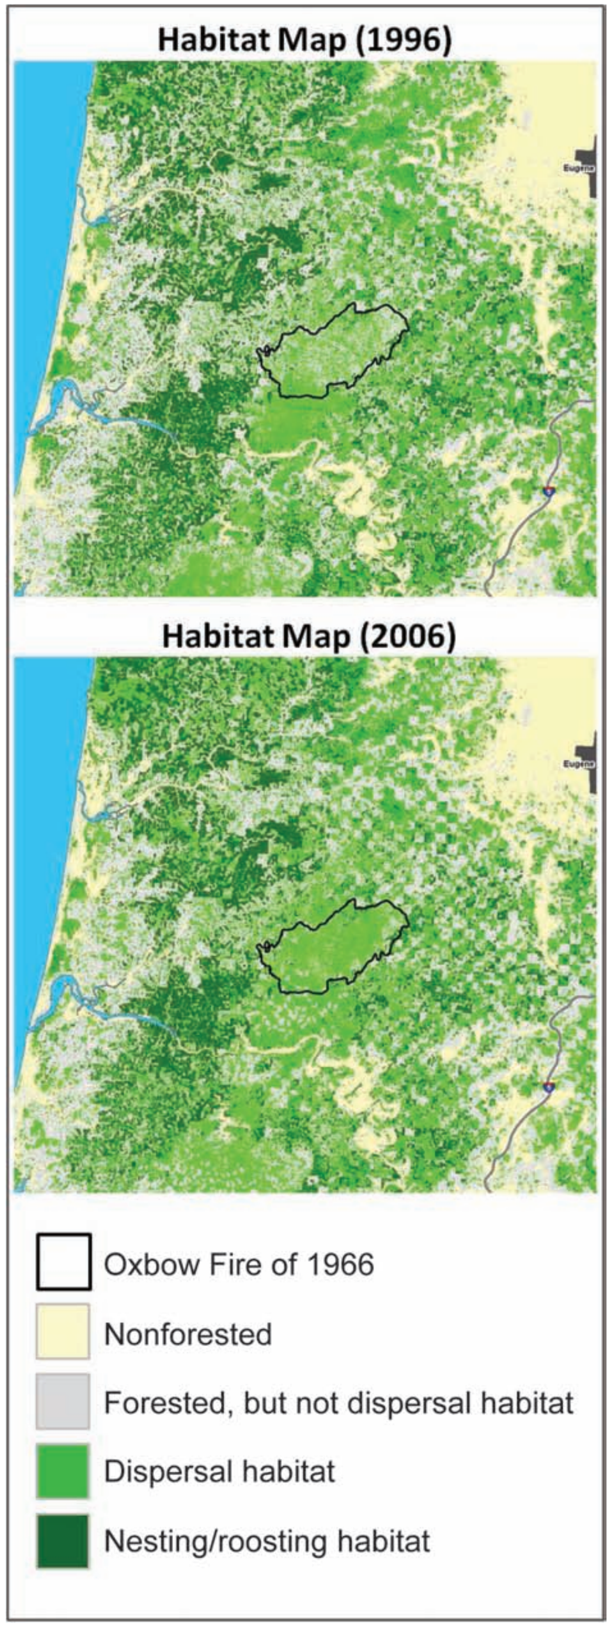

Figure 3-16—Recruitment of dispersal habitat in the Oxbow Fire (1966) in the Oregon Coast Range.

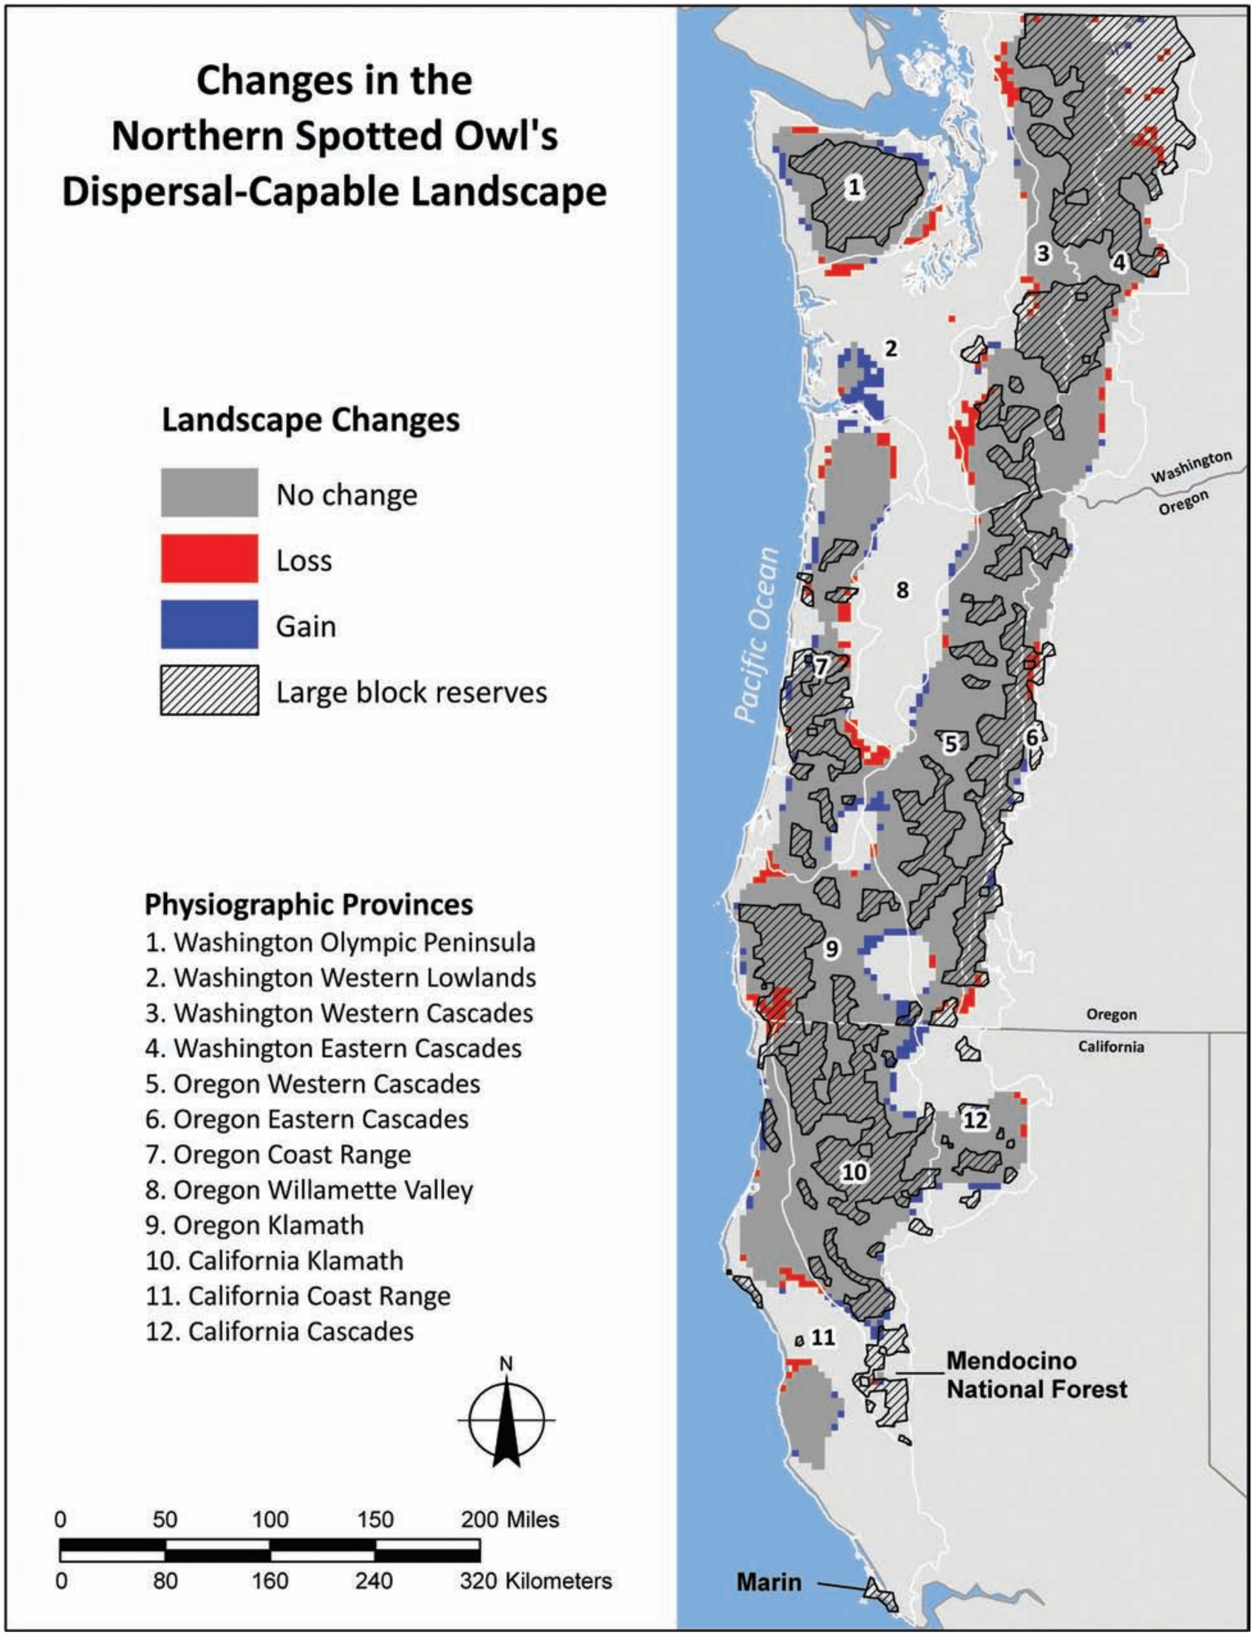

Figure 3-17—Changes in dispersal-capable landscapes across the owl's range.

that area may have isolated some of the large LSRs established at the Plan's implementation (fig. 3-17). This may also be the case for the LSR just to the east of the B&B Fire where it appears that there has been a 3- to 6-mi contraction of dispersal-capable landscape in that area. Overall, the large reserved network still appears to be well connected, with the exception of three areas. Of primary concern are the federal reserved lands on the Olympic Peninsula, which are separated from the Cascades by about 75 mi of landscape with poor dispersal conditions (fig. 3-17). These federal lands are also separated from federal reserves that occur about 90 mi to the south in the northern Oregon Coast Range physiographic province. The federal reserves in the most northern part of the Oregon Coast Range are the second area of concern. It appears that regeneration timber harvesting on nonfederal land may be narrowing the dispersal connection to the rest of the Coast Range's large federal reserved allocations. Finally, the southernmost large reserves, which are mainly located on the Mendocino National Forest in the California Klamath Mountains physiographic province, appear to occur in poor dispersal landscapes, and the Marin County northern spotted owl population, in particular, appears isolated at the extreme southern tip of the owl's range (fig. 3-17).

Habitat Fragmentation

At the range scale, core habitat accounted for about 19 and 29 percent of baseline nesting/roosting habitat within nonreserved and reserved allocations, respectively, indicating that reserved allocations contain larger patches of suitable habitat. Between 1994/96 and 2006/07, the amount of core habitat on federal lands decreased by 6 percent at the range scale, with 4.6 percent of this decrease occurring in reserved allocations. The largest decrease (-20.6 percent) occurred in the Oregon Klamath province and was largely owing to the Biscuit Fire (fig. 3-18). The percentage loss of core habitat by physiographic province shown in figure 3-18 generally follows the same pattern among provinces as for nesting/roosting habitat loss (fig. 3-12); however, percentage of loss is larger for core habitat, because it is a subset of nesting/roosting habitat and confined to a smaller portion of the landscape.

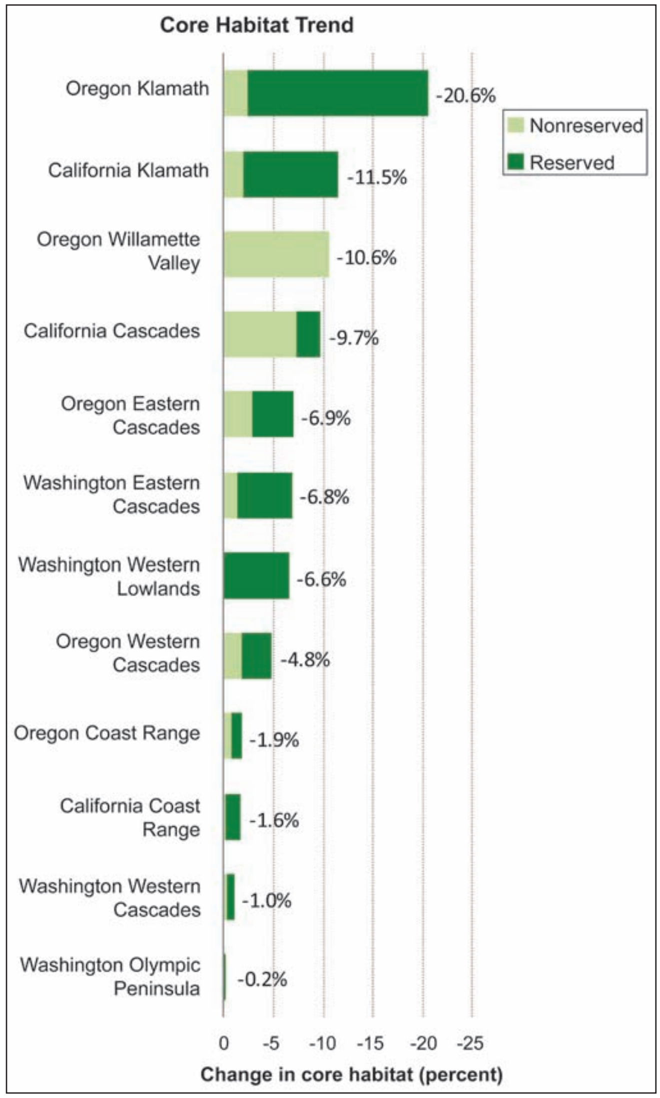

Figure 3-18—Nesting/roosting "core" habitat trends from 1994/96 to 2006/07 by physiographic province for reserved and nonreserved federal lands.

The combination of core and core-edge habitat constituted about 50 percent of the baseline nesting/roosting habitat in nonreserved allocations and 61 percent in reserved allocations at the range scale, indicating that reserved allocations contain more contiguous habitat than nonreserved allocations (table 3-3). We report an average rangewide decrease of 1 percent in these ratios, signifying a small but measureable increase in habitat fragmentation. The largest decreases occurred within the federally reserved portions of the Klamath provinces in Oregon (-4.3 percent) and California (-2.7 percent) and California Cascades (-3.1 percent), again because of wildfires (table 3-3).

Table 3-3–Habitat fragmentation status and trends based on the percentage of nesting/roosting habitat in core and core-edge habitat

	Reserved			Nonreserved		
Physiographic province	**1994/96**	**2006/07**	**Trend**	**1994/96**	**2006/07**	**Trend**
			Percent			
Washington Olympic Peninsula	72.76	72.75	-0.01	33.22	32.86	-0.36
California Coast Range	68.77	68.81	0.04	46.64	47.19	0.55
Oregon Western Cascades	68.77	67.72	-1.05	59.51	58.39	-1.12
Oregon Coast Range	62.83	62.53	-0.30	39.41	37.77	-1.64
Oregon Klamath	61.69	57.35	-4.34	38.51	36.80	-1.71
Washington Western Cascades	59.23	59.06	-0.17	49.77	49.44	-0.33
Washington Eastern Cascades	55.69	54.39	-1.30	50.89	50.20	-0.69
Oregon Eastern Cascades	55.00	55.04	0.04	48.94	47.28	-1.66
California Cascades	51.70	50.67	-1.03	48.30	45.16	-3.14
California Klamath	49.01	46.31	-2.70	42.22	41.14	-1.08
Washington Western Lowlands	31.34	30.28	-1.06	0.00	0.00	0.00
Oregon Willamette Valley	25.74	25.93	0.19	27.83	26.13	-1.70

Note: Physiographic provinces are listed in order of least- to most-fragmented federal reserved land allocations based on the status in 1994/96. Negative trend values indicate increased fragmentation.

Discussion

Substantial progress has been made in 5 years to overcome some of the previous limitations of habitat monitoring (Davis and Lint 2005). Most importantly among these advancements is the development of a consistent set of vegetation data that now covers the entire range of the owl. As suspected by Davis and Lint (2005), the finer resolution (in both spatial scale and attributes) of this new vegetation data resulted in lower, but more accurate, estimates of the amount of northern spotted owl habitat in California. In addition, the development of bookend maps (using the same vegetation and modeling techniques) has increased our ability to detect trends of habitat losses and gains. For the first time, we can estimate not only habitat losses, but also habitat degradation—where habitat is altered by a disturbance, but still remains suitable for owl nesting and roosting. The new LandTrendr change-detection data (Kennedy et al. 2010) were critical for verifying the habitat losses we detected with the bookends and also for assigning a cause for the habitat changes.

Although we were able to detect, measure, and report on nesting/roosting habitat loss and degradation, we were not able to detect and measure its recruitment during the 10- to 12-year timeframe of our analysis data. The expectation was that validation of habitat development would be part of the new habitat suitability maps developed by the interagency monitoring program (Courtney et al. 2004). However, validation of habitat development is a difficult task, and the transition of a forest age class or size class into the next higher class does not always equate to recruitment of owl habitat (Courtney et al. 2004). As seen from the combinations of vegetation variables we used for habitat modeling (app. A and table C-1 in app. C), the definition of nesting/roosting habitat is not a simple combination of one or two attributes. In reality, it is much more complex, and the transition of habitat from unsuitable to suitable likely happens over multiple decades (Courtney et al. 2004). This was not the case for the younger forest types through which owls can disperse. We cautiously accounted for gains in dispersal habitats after examination of the dispersal habitat maps on aerial imagery and through GIS analysis of changes in the tree diameter and canopy cover variables that were used in its definition.

So, although Raphael et al. (1994a, 1994b) and Lint et al. (1999) did not expect to see any significant gains in nesting/roosting habitat for a few decades, an examination of our habitat histograms (app. F) shows some gains in the "marginal" suitability class, which is similar to dispersal habitat (see table 3-1). Within the next three decades, the transition of habitat from the marginal suitability class to the suitable habitat class may be detectable given current remote sensing technology. In addition, the use of light detection and ranging (LIDAR) imagery, which is able to map forest canopy biomass, height, and vertical distribution, may provide us the ability to detect and monitor changes in the older stages of succession with improved accuracies (Falkowski et al. 2009).

Maintaining and restoring habitats that keep owl populations well connected across their range is a central goal of the Plan and should remain a priority. Our dispersal-capable landscape analysis was based on known linear dispersal distances (Forsman et al. 2002, Lint et al. 2005), and the analysis window we used to quantify amounts of dispersal habitat across the landscape had a diameter of 31 mi. This distance exceeds both the mean natal dispersal distance for males and females (Forsman et al. 2002) and the root-mean-square dispersal distance, which may be the more appropriate measure of gene flow (Barrowclough et al. 2005). Thus, our results indicate that most of the large reserved network is currently well connected (fig. 3-17) with a few exceptions, such as the Olympic Peninsula, the northern Oregon Coast Range, and the California Klamath, which we suggest might serve as focal areas for future studies on population connectivity and genetics, particularly as recent genetic work suggests northern spotted owls have undergone population bottlenecks resulting in reduced genetic diversity in several parts of their range, including the northern Oregon Coast Ranges, and the Klamath Mountains (Funk et al. 2010). Strong evidence for population bottlenecks in the Washington eastern Cascades were also reported (Funk et al. 2010) consistent with recent population declines in that region (Anthony et al. 2006, Forsman et al. 2011), but there is no definitive evidence that dispersal habitat is limited (this study) or that gene flow is restricted in that region (Barrowclough et al. 2005).

Summary

Rangewide owl habitat losses on federal lands were expected to be about 5 percent per decade, with a loss of 2.5 percent from timber harvest (USDA and USDI 1994) and 2.5 percent from wildfire (FEMAT 1993). We report a rangewide loss of 3.4 percent, between 1994/97 to 2006/07 and conclude that [rangewide] habitat is not declining faster than predicted under the Plan. Timber harvesting accounted for 0.6 percent of this loss, insects and disease 0.1 percent, and wildfire 2.7 percent of the habitat loss. Loss from timber harvesting is occurring at a fraction of what was predicted at Plan implementation, but habitat losses from wildfire are very close to what was predicted (FEMAT 1993). Although rangewide habitat losses have not exceeded what was anticipated under the Plan, the trend of habitat loss has been greater than 5 percent per decade in some physiographic provinces (i.e., Oregon Klamath). If localized habitat losses continue at the current rates within some provinces, it is unclear what effect this may have on the effectiveness of the Plan to maintain well-distributed and connected populations of northern spotted owls throughout their entire range, specifically the assumption that the large reserve network is resilient enough to incur these losses and not result in isolation of population segments (Lint et al. 1999).

Since implementation of the Plan, the majority of habitat loss on federally administered lands has been caused by wildfire, and most of that loss has occurred in reserved allocations. This seems counter to the Plan's goal of habitat maintenance and restoration within the reserved network. However, the reserve network was designed to function despite losses to wildfire, which were anticipated (FEMAT 1993, Murphy and Noon 1992). Although Lint et al. (1999) assumed that habitat conditions within large reserves would improve over time at a rate controlled by successional processes in stands that are not currently nesting/roosting habitat, they did not expect it to happen quickly, but over a period of several decades (Lint et al. 1999). Our latest monitoring shows that maintenance of nesting/roosting habitat within some of the large reserves is being challenged by the occurrence of large wildfires, and also that large-scale restoration of reserved nesting/roosting habitat has not yet occurred.

The monitoring assumption that habitat conditions outside of reserved allocations would continue to decline because of timber harvesting and other habitat-altering disturbances but would still facilitate owl movement across the landscape (Lint et al. 1999) is validated by the latest monitoring. The rate of nesting/roosting habitat loss outside of the reserves from timber harvesting has been lower than expected, and we observed both losses and gains in dispersal habitat. In our monitoring, we did not observe any isolation of owl population segments caused by large-scale disturbance; however, we did note both expansions and contractions of dispersal-capable landscape and that some large reserves in portions of the range have poor dispersal conditions and might be focal areas for further investigation of population isolation studies.

Although not included within the timeframe of this latest monitoring analysis, the southern portion of the owl's range experienced another 615,000 ac (approx.) of wildfire between 2008 and 2009, with most of it occurring within reserved land use allocations. If this trend persists, the actual decadal loss of habitat from wildfire will continue to push against the Plan's assumption of 2.5 percent per decade and, to reemphasize the point made at the beginning of this summary, may have unexpected consequences on the effectiveness of portions of the large reserved network. Outside of the reserved network, the lack of timber harvesting in the nonreserved allocations over the past 15 years has provided some cushion from these losses. And finally, although we still anticipate that recruitment of nesting/roosting habitat from forest succession will eventually begin to offset habitat losses from wildfire, forests grow slowly, and, where they occur in landscapes prone to wildfire, the nesting/roosting habitat conditions may take much longer to develop.

Chapter 4: Large Wildfires Within the Owl's Range

Raymond J. Davis, William C. Aney, Louisa Evers, and Katie M. Dugger

Introduction

When Franklin and Dyrness created their map of physiographic provinces in 1973, they noted that the lines drawn to reduce the complexity of large geographic areas into more manageable proportions are sometimes arbitrary, whereas in nature the transition from one condition to another is often gradual. A modified version of the Franklin and Dyrness (1973) physiographic provinces was used to divide the northern spotted owl's (*Strix occidentalis caurina*) range, which covers 57 million ac that stretch from Canada to northern California, into 10 areas that represented different forest vegetation and environmental characteristics (Thomas et al. 1990). Agee and Edmonds (1992) made the first attempt to delineate fire disturbance regimes within the owl's range during the initial stages of northern spotted owl recovery planning. The spotted owl recovery team (USDI 1992) used this and other information to further subdivide the range into 12 physiographic provinces, which currently provide the framework for monitoring the Northwest Forest Plan (the Plan) (FEMAT 1993, Lint et al. 1999). More recent attempts to map the "dry, fire-prone" portion of the owl's range (Healey et al. 2008, Rapp 2005, Spies et al. 2006) are mainly delineated along these physiographic province boundary lines, which were not drawn specifically to define the underlying nature of wildfire within the owl's range. The result is a line that often shifts, sometimes considerably, between mapping efforts (fig. 4-1).

This desire to map fire-prone areas in the owl's range stems from a concern by many that wildfire will destroy spotted owl habitat. The recent increase in frequency of large wildfire occurrence (and area burned) since the mid-1980s in the Western United States (Schwind 2008, Westerling et al. 2006), and within the owl's range (fig. 4-2)

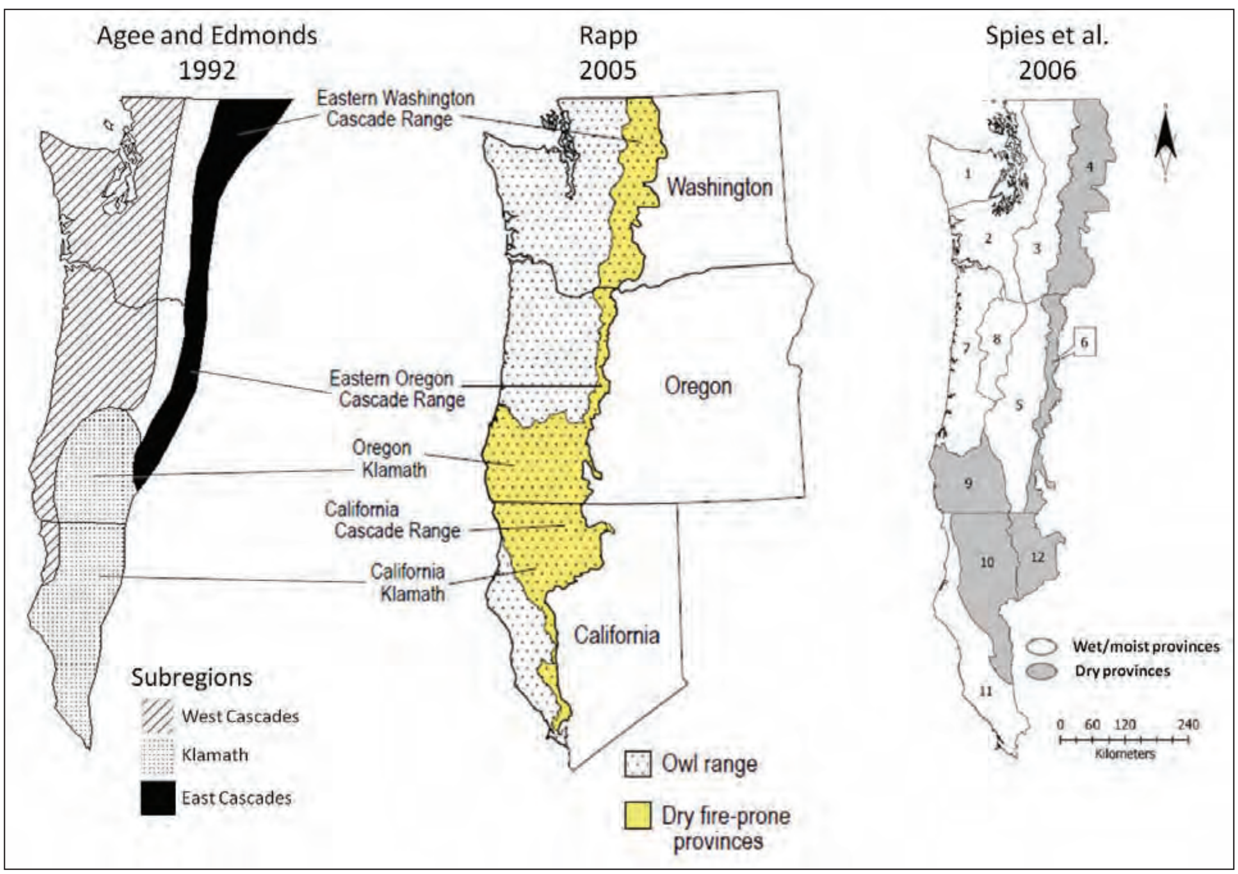

Figure 4-1—Various depictions of the "fire-prone" areas within the range of the northern spotted owl (Agee and Edmonds 1992, Rapp 2005, Spies et al. 2006).

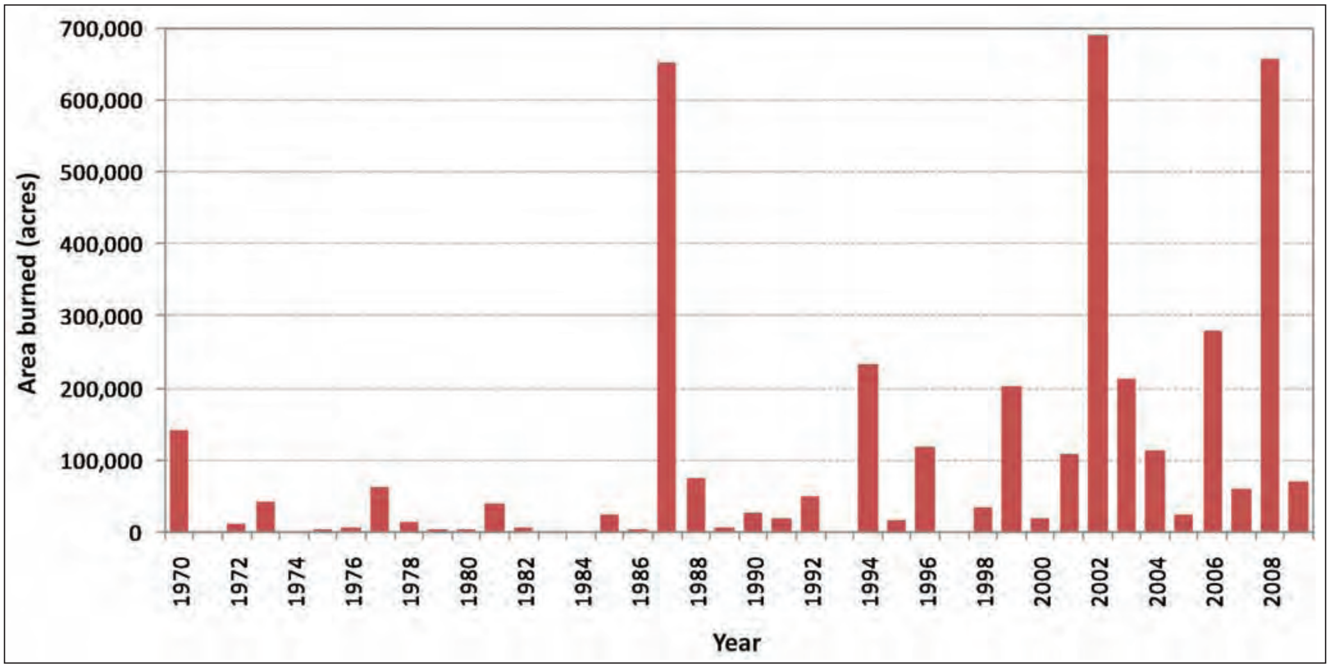

Figure 4-2—Frequency histogram of acres burned by wildfires within the range of the northern spotted owl between 1970 and 2009 (data sources from large wildfire data from this analysis).

has only heightened this concern. There is also evidence that along with this increased frequency there has also been an increase in the amount of high-severity wildfire (Miller et al. 2009, Schwind 2008; but see Hanson et al. 2009). However, evidence from recent studies reveals that the effects of wildfire on owl habitat and demography are mixed (Bond et al. 2009, Clark 2007). In the short term, large wildfires may be detrimental to spotted owls by decreasing survival and occupancy rates because high-severity[1] fire that caused loss and fragmentation of suitable nesting and roosting habitat contributed to existing spotted owl sites becoming unoccupied (Clark 2007). In addition, California spotted owls avoided roosting [breeding season] in forests that had experienced moderate to high-severity[2] fire effects and nested only in stands that were unburned or had experienced low- to moderate-severity fire (Bond et al. 2009). However, spotted owls did forage in areas of high-severity fire, possibly because prey species are more abundant and accessible in these high-severity burn patches (Bond et al. 2009, Clark 2007, Franklin et al. 2000). Thus, although stand-replacing wildfires certainly remove nesting/roosting habitats described in chapter 3, they may not prevent foraging by owls, and only a very large fire that creates a large-scale loss of forest canopy and habitat would have a significant effect on owl demography and dispersal (see the discussion on dispersal habitat in chapter 3). Much more research is needed to fully understand the effects of wildfire frequency and severity on owls and their prey sources (see chapter 5 in this report), but some adaptation to wildfire is expected given that this species has evolved with it in some parts of its range.

Although the relationship between wildfire frequency and severity on owl demography is not fully understood, habitat loss is the primary reason for the owl's decline and subsequent listing as "threatened" under the Endangered Species Act (USDI 1990). The habitat monitoring results presented in chapter 3 (this report) identified wildfire as the leading cause of current spotted owl nesting and roosting habitat loss (3.4 percent) and its future recruitment on federal lands. This was also the finding in the 10-year

[1] Clark (2007) defined high-severity as > 70 percent of the overstory removed by fire.

[2] Bond et al. (2009) defined high-severity as areas where dominant vegetation had high to complete mortality owing to fire.

monitoring report (Davis and Lint 2005), and since completion of that report, several more large wildfires have occurred within the owl's range and more nesting/roosting habitat has been lost. Thus, loss of habitat to wildfire remains a significant concern for the management and conservation of the spotted owl. In response, the current species recovery planning process for the owl (USDI 2008) established working groups to develop recovery actions for fire-prone areas based on the current map of physiographic provinces (USDI 1992).

Here we present a novel modeling method to map areas within the owl's range that are prone to large wildfires. The result is a rangewide map of likelihood (or suitability) gradients for large wildfire occurrence. Instead of using physiographic province boundaries to define fire-prone areas within the owl's range, the gradient map is further classified into a binary map that we believe better represents the fire-prone areas. However, the raw model output (fig. 4-3) maintains the gradual transitions from one condition to another so succinctly alluded to by Franklin and Dyrness (1973).

Methods and Data Sources

There are several modeling approaches and methods available for modeling spatial distributions of environmental phenomenon, each with their own strengths and weaknesses (Guissan and Zimmermann 2000). A recent paper by Elith et al. (2011) summarizes many of these issues, including an ecological explanation of MaxEnt (Phillips and Dudík 2008, Phillips et al. 2006) and discussion on the issue of using presence-only versus presence-absence data (also see page 35 of Davis and Lint 2005). For consistency, we chose to use MaxEnt, the same modeling tool used for mapping spotted owl habitat suitability in chapter 3 (this report), to model and map wildfire suitability (fig. 4-3). This spatial distribution modeling software is commonly used to create predictive maps of habitat suitability (or likelihood of use) based on species location data and a set of environmental predictor variables that contribute to the definition of the species' niche (Phillips et al. 2006). The term "niche" is used to describe the environmental requirements needed for a species to exist (Grinnell 1917). It is the "hypervolume" in the multidimensional environmental space (the number of dimensions are based on the number of environmental variables used to describe the niche) that permits positive growth (Hutchinson 1957). Habitat suitability models are operational applications of the ecological niche, and use multiple environmental variables to predict the likelihood of species occurrence (Hirzel and Le Lay 2008).

Based on our understanding of northern spotted owl ecology, we expect them to nest in landscapes that are heavily forested with older or structurally diverse stands of conifer with relatively closed canopies (see chapter 3 in this report). We call this combination of environmental conditions owl "habitat." Similarly, environmental conditions commonly associated with large wildfires include steep slopes, warm and dry aspects, hot and dry weather, and limited access for ground-based firefighting resources (hand crews, engines, etc.). These have long been identified in the literature as key elements in the development of large wildfires (Albini 1976, Albini et al. 1982, Brown and Davis 1973, Countryman 1964, Deeming et al. 1977, Garfin and Morehouse 2001, Gisborne 1936, Hayes 1941, Rothermel 1983, Schroeder and Buck 1970, Scott and Reinhardt 2001, Sugihara et al. 2006, Van Wagner 1977); in decision-support planning tools for wildfire response such as the National Fire Management Analysis System (NFMAS) and its successor, Fire Program Analysis (FPA); and in practice. It is no surprise that wildfires grow rapidly and become larger in landscapes that have an abundance of these conditions. The combination of these environmental conditions might also be considered a "habitat," not for an animal, but one that is suitable for large wildfires as alluded to by Pyne (2001, 2004). The analogy of wildfire as a "living organism" is not unheard of (Bond and Keeley 2005, Parisien and Moritz 2009), and it seems reasonable that the principles for describing the niche of a plant or animal species should be no different than for defining the "niche" of large wildfires, or for that matter any other natural phenomenon that is associated with unique combinations of environmental conditions.

Our ability to accurately map the environmental conditions that constitute the niche allows us to use modeling software to map the pattern of the relationship between

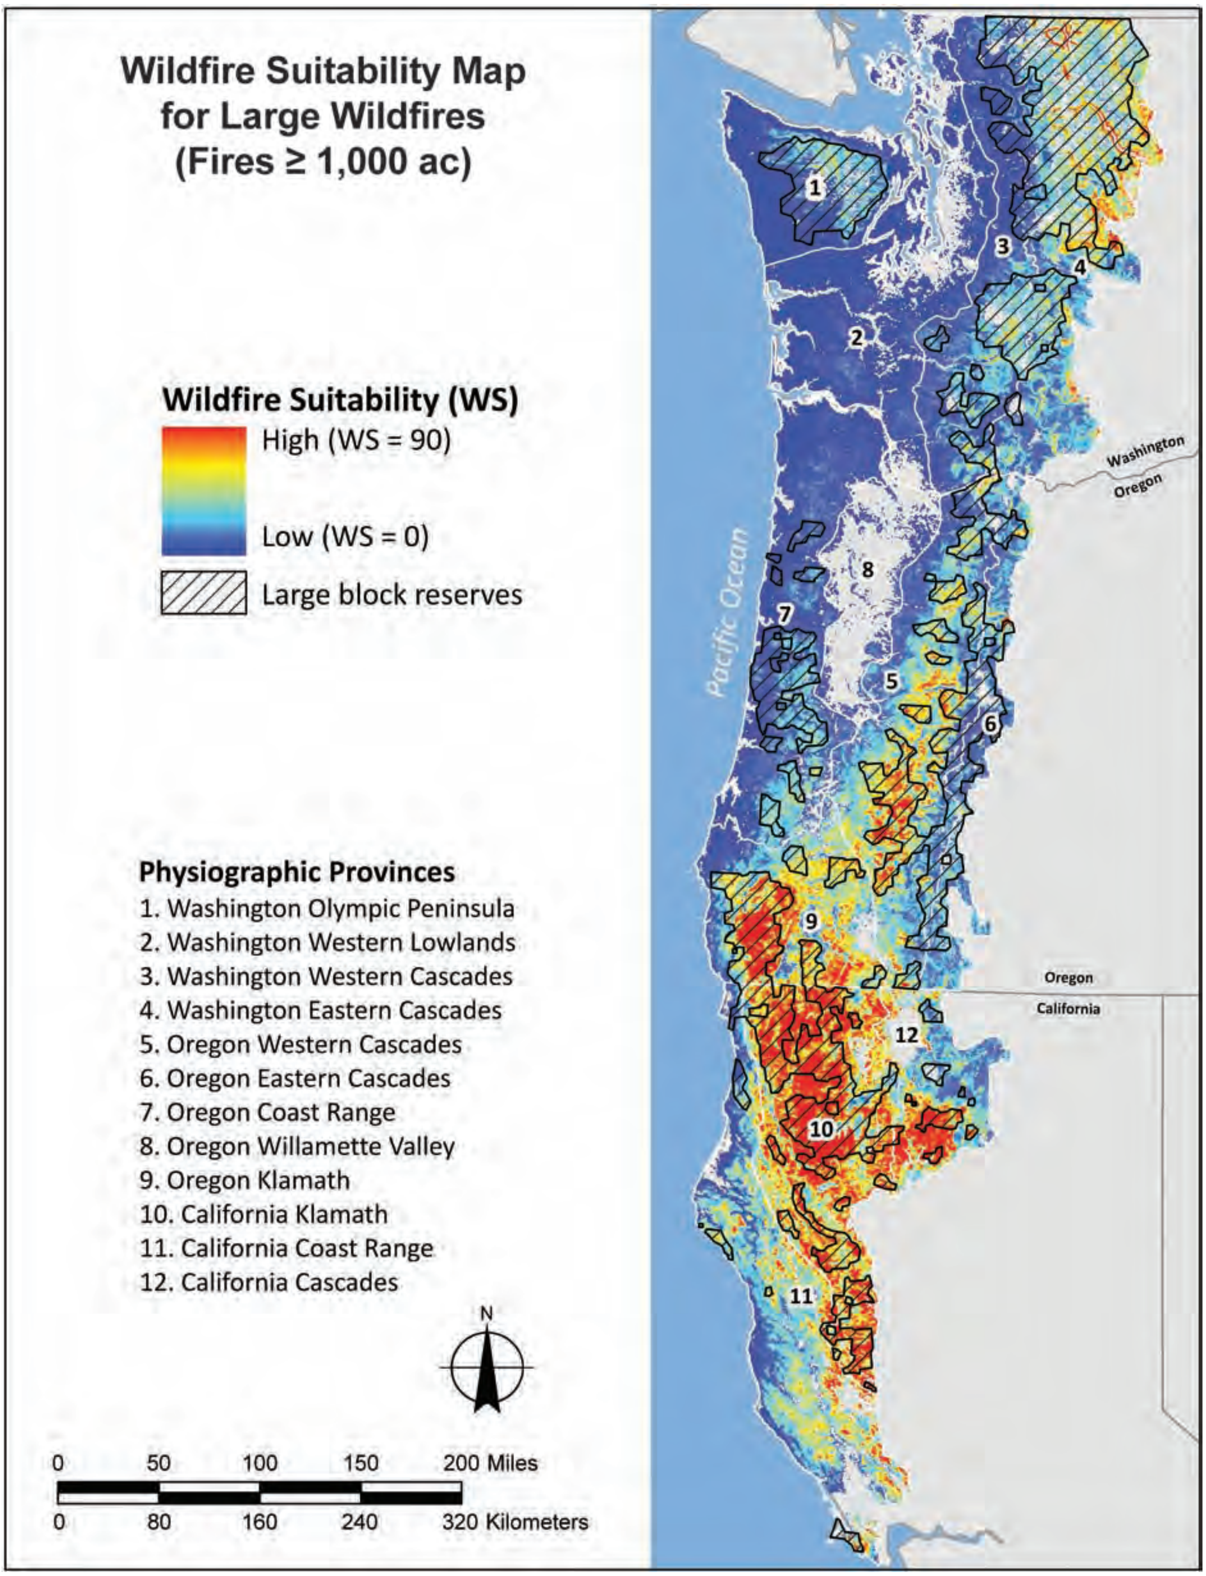

Figure 4-3—Although large (≥ 1,000 ac) wildfires are known throughout the entire range of the owl, this wildfire suitability map represents the likelihood for occurrence of these fires based on three decades of large wildfire occurrence and the underlying combination of "fire environment" variables from where they occurred (see fig. 4-4).

these environmental factors and large wildfire occurrence. This approach has been used recently to model wildfire's broad geographical distribution patterns across the conterminous United States, the state of California, and five wildfire-prone ecoregions within California (Parisien and Moritz 2009). To our knowledge, this marks the first time that "habitat suitability" software was used to map spatial patterns of wildfire likelihood over large landscapes as a function of multiple environmental variables. Coarse-scale maps of global fire patterns that discriminated between "fire-prone" and "fire-free" areas of the world were also produced using similar methods (Krawchuk et al. 2009). Maps produced by this method have been called "wildfire suitability" maps (Parisien and Moritz 2009), and this is the term we use to describe our map (fig. 4-3).

It is not uncommon for wildfires that range from 500 to 1,000 ac and greater to be defined as "large" in the recent fire ecology literature (Potter 1996, Eidenshink et al. 2007, Preisler and Westerling 2007, Westerling et al. 2003). In the 10-year report, a "large wildfire" was defined as a fire that would affect multiple owl territories (Davis and Lint 2005). Here we define "large wildfire" as one that exceeds 1,000 ac, which is larger than the estimated size of a northern spotted owl home range core area[3] throughout most of its range (Bingham and Noon 1997, Courtney et al. 2004, USDI and USDA 2008).

Environmental Data

At an intermediate spatial scale, weather and topography make up two legs of the fire behavior (or environment) triangle (Agee 1993, Countryman 1966), whereas at the larger (regional) spatial scale, climate, ignitions, and broad vegetation patterns define fire regimes (see fig. 1 in Parisien and Mortiz 2009). Our spatial scale of modeling combines both the intermediate and regional scales, and our set of environmental data reflects this, with the exception of fuels and vegetation variable groups. We did not include any fuel variables in our modeling, but the model's geographic background consisted only of forest-capable areas, which represent "vegetation" in the larger spatial scale. Because forest fires are what we were attempting to model, the use of this modeling background allowed us to confine the interactions of environmental variables to locations where forest vegetation and fuels occur. An advantage of not using a fuel variable is that we avoided the difficulties that arise in accurately mapping them (Stratton 2006). Fuels are a dynamic component of the ecosystem, very temporal in nature and always changing in response to forest succession and disturbances (Agee 1993). The inclusion of a fuel variable would produce a map that would only be good as long as the fuel condition remained exactly as modeled. Instead, we wanted to produce a model that was relatively stable, and based on the underlying conditions of topography and climate that support large wildfires.

The set of environmental variables we used for modeling was based on fire climate[4] and environment relationships in the literature and on expert advice (fig. 4-4, app. G). Matching the temporal scale of these environmental data with the fire training data was an important factor. Fire climate variables were derived from "parameter elevated regression on independent slope model" (PRISM) maps (Oregon Climate Service 2008) that provide averaged weather conditions between 1971 and 2000. This timeframe coincides with the 1970 to 2002 timeframe of the fire training data set. As our fire climate variables, we initially chose average maximum temperature in August and summer moisture stress (the ratio of summer temperature and precipitation). However, because of the high correlation between these two variables ($r > 0.7$), we replaced the moisture stress variable with a summer precipitation variable, which is the average amount of precipitation that fell between May and September, corresponding to the average fire season.

Lightning is the primary ignition source for wildfires around the world (Agee 1993) including the forested regions of the Pacific Northwest, especially when it occurs without

[3] An area of concentrated use within a home range that commonly includes nest sites, roost sites, refuges, and regions with the most dependable food sources (Kaufmann 1962, Samuel et al. 1985).

[4] Defined by the National Wildfire Coordinating Group (NWCG) as a "composite pattern of weather elements over time that affect fire behavior in a given region."

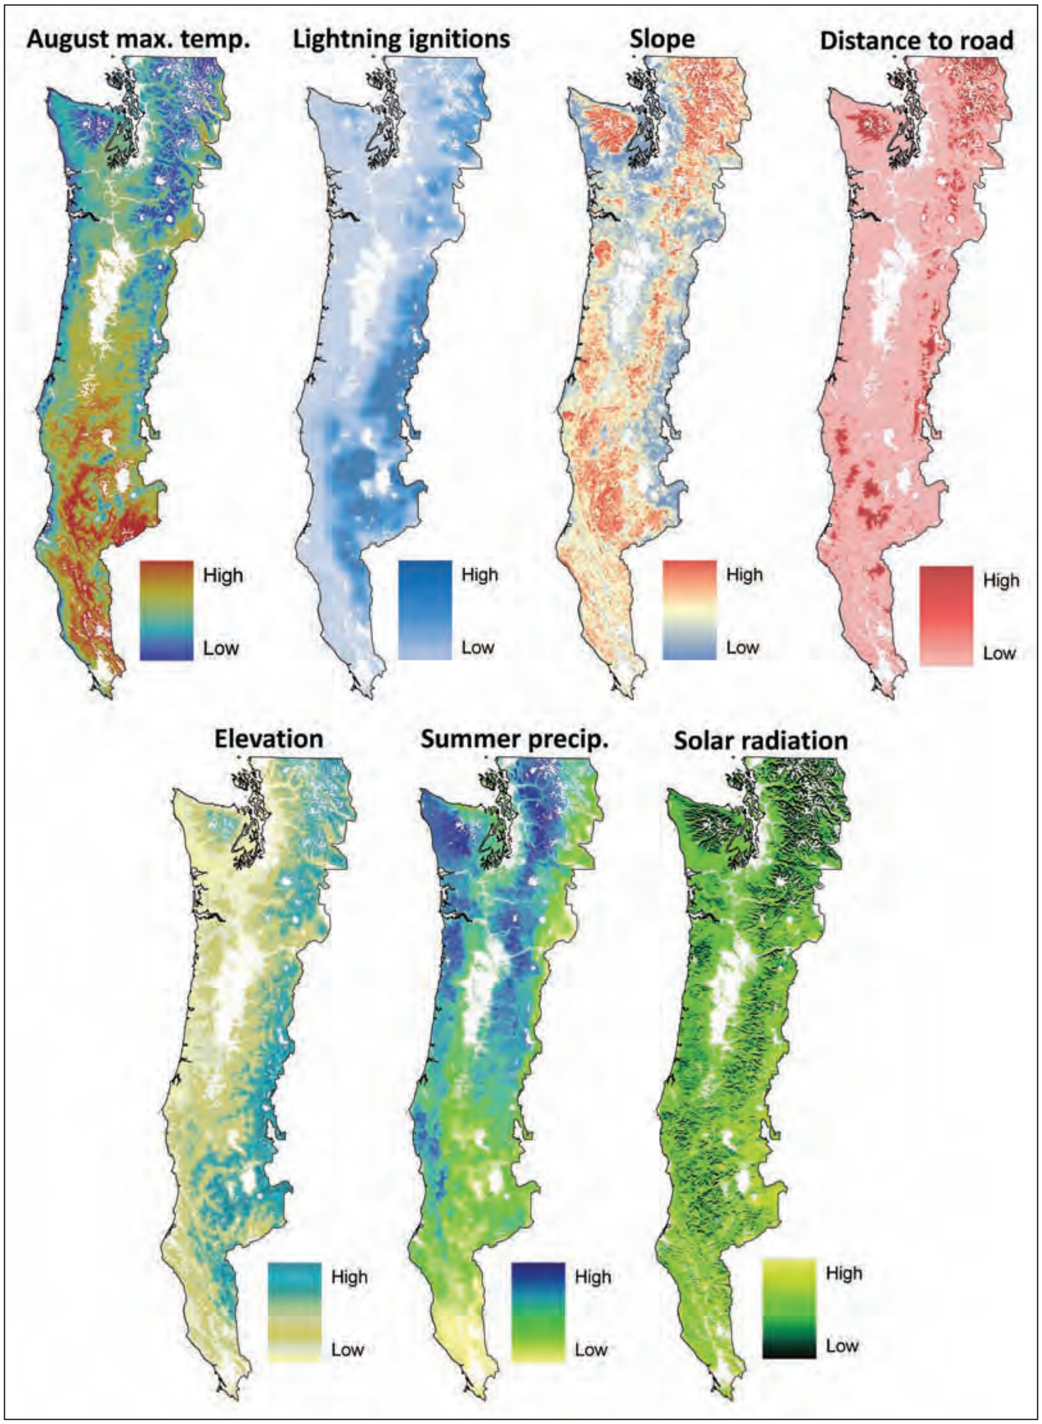

Figure 4-4—Environmental variables used in the model to define the "niche" of large wildfires in the owl's range.

significant rainfall (Rorig and Ferguson 1999). Based on data from the Climate, Ecosystem, and Fire Applications (CEFA) Program (Brown et al. 2002), lightning was the cause for approximately 25,000 wildfires within the range of the owl from 1970 to 2002. Lightning accounted for 68 percent of the wildfires that grew to larger than 1,000 ac and accounted for 75 percent of the total area burned within the owl's range from 1994 through 2002 (Davis and Lint 2005). The geographic patterns of lightning-ignited wildfires in the Pacific Northwest are similar today to what they were throughout the 1900s (Agee 1993, Komarek 1967, Morris 1934, Rorig and Ferguson 1999, Sensenig 2002). Therefore, a lightning-ignited fire density map was created using the CEFA data from 1970 to 2002 and included as one of the environmental variables.

Topographic variables for elevation, slope, and aspect were also used in the model. Elevation provides an environmental gradient that relates to local climate conditions and vegetation zones, which can affect fire behavior and growth (Hayes 1941, Rothermel 1983). Slope is related to fire spread rate, and its orientation, or aspect, relates to the amount of solar radiation, which also affects the local microclimate and vegetation. Southerly aspects in the Northern Hemisphere usually receive more annual solar radiation and are hotter and drier than northerly aspects. We used the potential relative radiation (PRR) index developed by Pierce et al. (2005) as a more realistic measure for solar radiation than simple aspect.

The spatial resolution of our environmental data was 250- by 250-m (15-ac) pixels, which was averaged within a 1,000-ac circular moving window to correspond with our minimum definition of a large wildfire. All "nonforested" (i.e., water, rock, etc.) areas were "masked out" to constrain the modeling background to only those areas where large wildfires are possible. All variables were analyzed for spatial correlations and one variable was dropped or replaced for Pearson correlations > 0.7.

Large Wildfire Data

We chose to train our model using historical occurrence data from only large wildfires (as defined above). Wildfires of this size are relatively rare occurrences, but are responsible for the vast majority of area burned each year. For example, of the roughly 25,000 lightning-ignited wildfires recorded within the owl's range between 1970 to 2002, less than 1 percent were ≥1,000 ac; but these fires accounted for 96 percent of the total 2.5 million ac that burned (based on CEFA data) (Brown et al. 2002). This pattern of large areas of land being burned by a small percentage of large wildfires is a global phenomenon that fits power law distributions (Cui and Perera 2008, Stocks et al. 2003, Westerling and Bryant 2008). It therefore made more sense to focus our modeling on large wildfires because of their disproportionate effect on the environment.

To train the distributional model, the spatial point locations where large wildfires have occurred are linked to the underlying combinations of environmental variable grid cells over which they lay. This relationship between fire occurrence and environmental gradients is then extrapolated to the rest of the modeled region to "score" environmental conditions based on their similarity to where the training data occur. To create a point layer representing large wildfires, we assembled 250 polygons of large wildfire perimeters that, in total, burned about 2.6 million ac of forest lands across the owl's range between 1970 and 2002. Using a geographic information system (GIS), we overlaid these polygons on a grid of randomly generated points that was produced using Hawth's Tools (Beyer 2009). Each grid point was separated by 1.6 mi to reduce spatial autocorrelation issues, as the modeling environmental variables were averaged over a 0.7-mi radius that covered about 1,000 ac, representing a "large wildfire unit" (fig. 4-5). A total of 1,499 random grid points occurred within a large-wildfire perimeter; of these, 104 (about 7 percent) were within overlapping wildfire perimeters, representing sites that had been burned twice during the 32 years represented by our training data. Because these points represent separate large wildfire occurrence from different years, they were included as additional points in the training data set for a total of 1,603 training points. We also generated an independent model-testing data set in the same manner, using 146 large wildfires that had burned 1.4 million ac between 2003 and 2009 (n = 903).

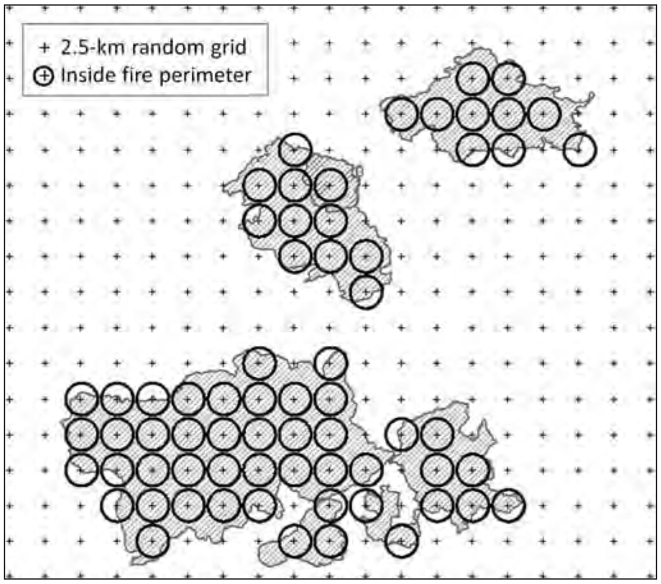

Figure 4-5—Model training and testing data came from grid points that occurred within large-fire perimeters. Points were spaced by 2.5 km to reduce spatial autocorrelation of environmental data, which were averaged within 1,000-ac circles as shown in this figure.

It is likely that without wildfire suppression, there would have been more large wildfires (Sensenig 2002) that burned between 1970 and 2002; thus our training data are likely biased. However, we are uncertain how this bias may have affected our model. It is possible that the training data better represent large wildfires that were more difficult to suppress or contain because of inaccessibility owing to geography or absence of roads. To address this issue, we also included a variable that represents distance from roads. We assumed that wildfires were more apt to get bigger when farther away from a road because it was more difficult to get people and equipment into the area to fight the fire.

Wildfire Suitability Modeling

We chose the same modeling features in MaxEnt that we used for habitat modeling (linear, product, and hinge features) because this combination works well in fitting the environmental data to known or expected relationships between the environmental variables and wildfires based on visual review of response curves generated during the modeling procedure. This combination is also a compromise between using features that may be too restrictive for complex environmental relationships (i.e., only linear) while avoiding features that might allow overfitting the model to the data (i.e., threshold).

Phillips and Dudík (2008) defined the logistic output of their modeling software as an "estimate" of probability of presence, conditioned on the environmental variables used in the modeling. In our case, we used only training data from large wildfires and environmental variables that are commonly associated with wildfire ignition and growth (Albini 1976, Deeming et al. 1977, Gisborne 1936, Hayes 1941, Rothermel 1991). Therefore, the model's logistic output represents a scale of probability (from low to high) of a large wildfire occurring as a function of physical, topographic, climatic, and fire ignition history patterns in the owl's range. Where combinations of these variables are more similar to where large wildfires have occurred in the past, the logistic probability values will be higher. Likewise, underlying patterns of environmental variables that do not commonly occur where large wildfires have burned will have lower probability values.

We ran 10 bootstrapped model replicates using half of the training data set for each replicate, and holding out the other half to test the model's predictions. In other words, MaxEnt produced 10 models using 10 randomly generated subsets of the 1970–2002 large-fire data, each consisting of 802 points. Then each of these models was tested using the subset of large-fire points held out (n = 801). During this process, we increased the regularization multiplier from its default of 1.0, which helps to prevent model overfitting, by increments of 0.5 to minimize the difference between the regularized training gain and test gain, while tryng to maximize the test area under the curve (AUC) statistic and Spearman rank (R_S) correlation coefficient on our held-out test data. These three statistics (gain, AUC, and R_S) are commonly used to measure the discriminative and predictive power of these sorts of models (Boyce et al. 2002, Fielding and Bell 1997, Hirzel et al. 2006).

The gain relates to how different the training or testing data are from the background data. It is similar to "deviance" as used in generalized linear modeling (Phillips et al. 2006), and higher gains indicate larger differences between occurrence location environmental conditions and average background environmental conditions. The exponent of gain produces the mean probability value of occurrence compared to random locations selected from the surrounding modeled landscape. Large differences between the regularized training and testing gains indicates model overfitting.

The AUC statistic is a measure of the model's predictive accuracy, and it was originally developed for evaluations using presence and absence data, producing an index value from 0.5 to 1 with values close to 0.5 indicating poor discrimination and a value of 1 indicating perfect predictions. The AUC values can be interpreted similarly to the traditional academic point system where values between 0.9 and 1.0 indicate an excellent model (A), 0.8 to 0.9 is good (B), 0.7 to 0.8 is fair (C), 0.6 to 0.7 is poor (D), and AUC values between 0.5 and 0.6 represent failure (F), or models that don't predict much better than a random guess. Examples of this interpretation in the field of niche-based species distribution models can be found in Araújo et al. (2005) and Randin et al. (2006). In our situation, MaxEnt uses 10,000 randomly selected background locations (map pixels) instead of true absence data, so it is not possible to achieve an AUC value of 1.0 (Wiley et al. 2003). However, interpretation is similar, with higher AUCs indicating better model predictions (Phillips et al. 2006). Specific to our case, AUC values represent the percentage of times a large wildfire location would have a higher wildfire suitability value than a randomly selected location from the modeling region.

The Spearman rank correlation coefficient is a nonparametric statistic that, in our situation, compares the ranks of large fire occurrence vs. area available to "binned" modeled prediction ranks (Boyce et al. 2002). A good model would predict an increasing ratio of the percentage of fire occurrence to the percentage of the modeled landscape in each model bin as the bin values increase, and an R_S of 1.0 indicates a strong positive correlation (Boyce et al. 2002).

The best model using the training data, and based on these statistics was produced using a regularization multiplier of 1.5. We then reran the same model, using the entire training data set (n = 1,603) and conducted a final test of the model using 7 years of independent test data from large fires that occurred between 2003 and 2009. Following the same rationale and modeling approach used in chapter 3 (this report), our final model product is the "average" model from our bootstrapped replicates. The predictive qualities of the "average" map can be better explained by the diagnostic predicted versus expected (P/E) curve (fig. 4.6) (Hirzel et al. 2006), and this curve allows users to better interpret the modeled values.

We also analyzed the importance of each environmental variable and its relationship with large wildfire occurrence by running jackknifed models (Phillips et al. 2006) for each of the 10 replicates. For each environmental variable, this jackknifing procedure produces a model that excludes the variable, and another model based on only that variable. The gain and AUC model performance statistics from the jackknifed models then inform us on the relationship and importance of each variable in explaining large-wildfire occurrence in the area being modeled.

Results

An average testing gain of 0.80 indicates that our model predicted large-wildfire occurrence 2.2 times that expected by chance. The testing gain was also similar to the regularized training gain of 0.77 indicating that our model was not over-fit to the environmental data. The mean testing data AUC, based on 10 bootstrapped replicates, was 0.83, and using independent test data from large wildfires from 2003 to 2009, the AUC was 0.78. The replicate mean predicted versus expected (P/E) curve (Hirzel et al. 2006) had an R_S = 1.0 ($P < 0.001$) and the test data P/E curve had an R_S = 0.987 ($P < 0.001$). The highest mean logistic probability for our model was 0.90, which we converted into an integer value (90) for GIS mapping purposes by multiplying by a factor of 100. The threshold of 31 along this probability gradient marks where the predicted probability of large-wildfire occurrence is greater than what would be expected by chance (fig. 4-6). One can use that threshold to define the owl's range in binary terms, where mapped values above this threshold represent geographic areas that are more prone to large wildfire occurrence, based on our 32-year training data timeframe, and areas below that threshold are not normally prone to large wildfires during that timeframe.

The strongest environmental variables were August maximum temperature, slope, and lightning ignition

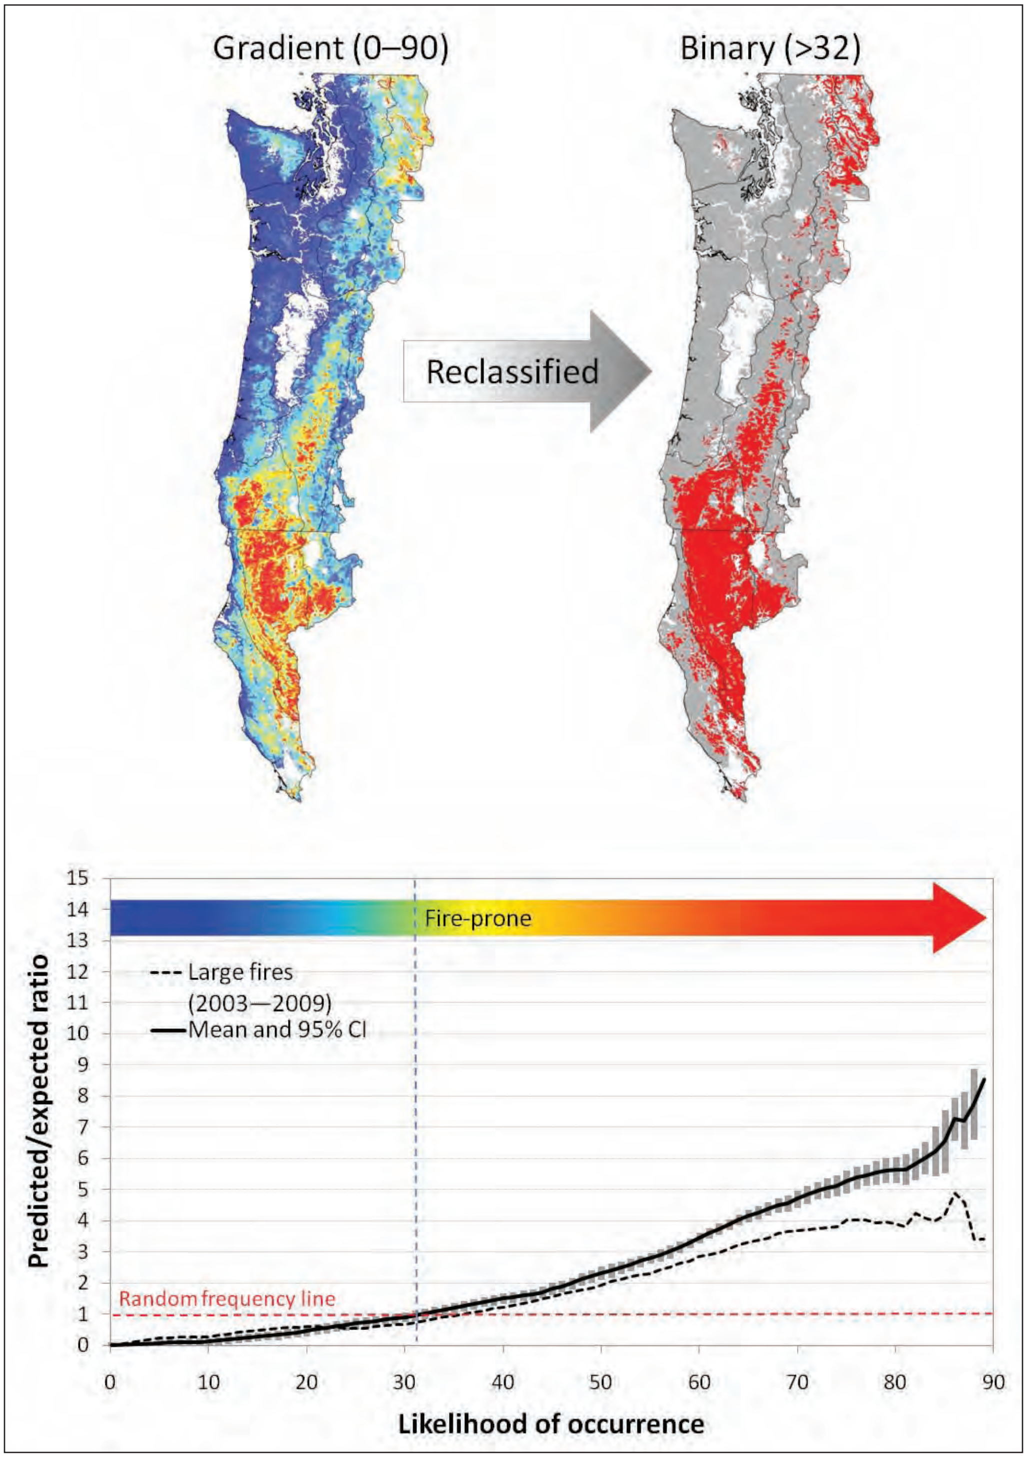

Figure 4-6—Results of model bootstrapped replicates (based on fire data from 1970 to 2002) and independent testing (dashed-line based on fire data from 2003 to 2009) are shown in this predicted vs. expected curve (Hirzel et al. 2006). The curves indicate that the model performed well in both tests. The point at which the mean curve crosses the random frequency line (predicted/expected = 1) is used as the threshold modeled likelihood value (>32) for delineating the "fire-prone" areas of the binary map from the full gradient map. The gray-shaded area along the mean curve represents the 95-percent confidence intervals (95% CI) from the bootstrapped replicates.

density, explaining 76 percent of the geographical patterns of large wildfires. Distance to roads contributed another 15 percent, and, together, these four variables account for 91 percent of the information that relates to wildfire suitability in our model. Response curves (app. G) suggest suitability for large wildfires increases (in almost a logistic fashion) as August maximum temperature and slope increases. The response curves for lightning ignition density and distance to road variable response curves are quadratic in shape, showing sharp increases in suitability as the variable value increases, but then reaching a wide plateau and eventually decreasing (app. G). We suspect this decrease in suitability at the high end is related to elevation effects, which also exhibited a similar quadratic response curve. Extreme distances from roads occurred in many wilderness areas located along the Cascades crest, and these remote areas tend to be at the highest elevations where late snowmelt produces cooler and moister conditions during the fire season. Likewise, lightning ignitions tend to be highest at high elevations. Of the six model variables used, slope had the highest gain when modeled by itself. It also decreased the gain the most when omitted from the model, and therefore is an important variable in our model and appears to have the most information that is not present in the other environmental variables.

Discussion

Four decades of history on large-wildfire occurrence fit well within our map of "wildfire suitability" gradients (fig. 4-7). The binary version of our map (fig. 4-8) has some distinct similarities to previously mapped versions of "fire-prone" areas in the owl's range, especially the map by Agee and Edmonds (1992). But, it also has some distinct differences; most notably, it includes the considerable portions of the western Cascades of Oregon, and it excludes large areas of the eastern Cascades that are commonly shown on previous map versions (fig. 4-1). Based on our map, only the northern half of the Washington Eastern Cascades physiographic province has substantial land area that appears suitable for large-wildfire occurrence. South of this, our map indicates a patchy distribution of high-suitability areas along the eastern Cascades; yet, much of this area historically was covered with ponderosa pine forests, known for its dependency on wildfire. This, and recent occurrences of large wildfires in these areas (i.e., B&B Complex, Link Fire, Davis Lake Fire, and the Eyerly Fire) may point to potential model limitations, which we discuss below.

To begin with, our map represents suitability for what we defined as "large" wildfires, and perhaps ones that are harder to suppress and contain, given the potential bias of our training data. The map does not represent a suitability gradient for all wildfire occurrences, nor behaviors, such as fire severity. Secondly, our map was trained with about three decades of large wildfire data and therefore, represents the likelihood of large wildfire occurrence within that specific timeframe. If we go further back in time, the fire history record within the owl's range clearly shows the occurrence of large wildfires in the lower suitability areas ("bluer areas") of our map (fig. 4-3), such as the Yacolt and Columbia Fires of 1902, the Tillamook Fire of 1933, and the more recent Oxbow Fire of 1966 (see fig. 3-16 in chapter 3). As noted above, our model is based on climate and topographic variables that have been relatively stable over the last century. The large wildfires that have occurred within the lower suitability areas of our map have been consistently associated with extreme weather (i.e., high winds) or heavy, contiguous, dry fuel (McClure 2005, Morris 1935), which could not be included in the model. We suspect a map characterizing long-term means of these extreme, episodic climatic events would be even more difficult to produce than a rangewide fuel map. However, fire ecologists have recently divided the range of the owl into five "fire regime groups,"[5] which represent a coarse spatial integration of fire frequency and severity (Keane et al. 2002, Morgan et al. 2001, Schmidt et al. 2002). Whereas fire regimes relate to the frequency, severity, and spatial distribution of historical wildfire in the ecosystem (Rollins et al. 2002), our map sheds light only on the latter of these three characteristics. However, it still shows spatial similarities to the fire regime group map, and, in particular, the lower suitability areas complement Fire Regime Group V, which represents infrequent fires (>200-year intervals) and mostly occurs in the

[5] LANDFIRE data products and their descriptions are available online at http://www.landfire.gov/products_overview.php.

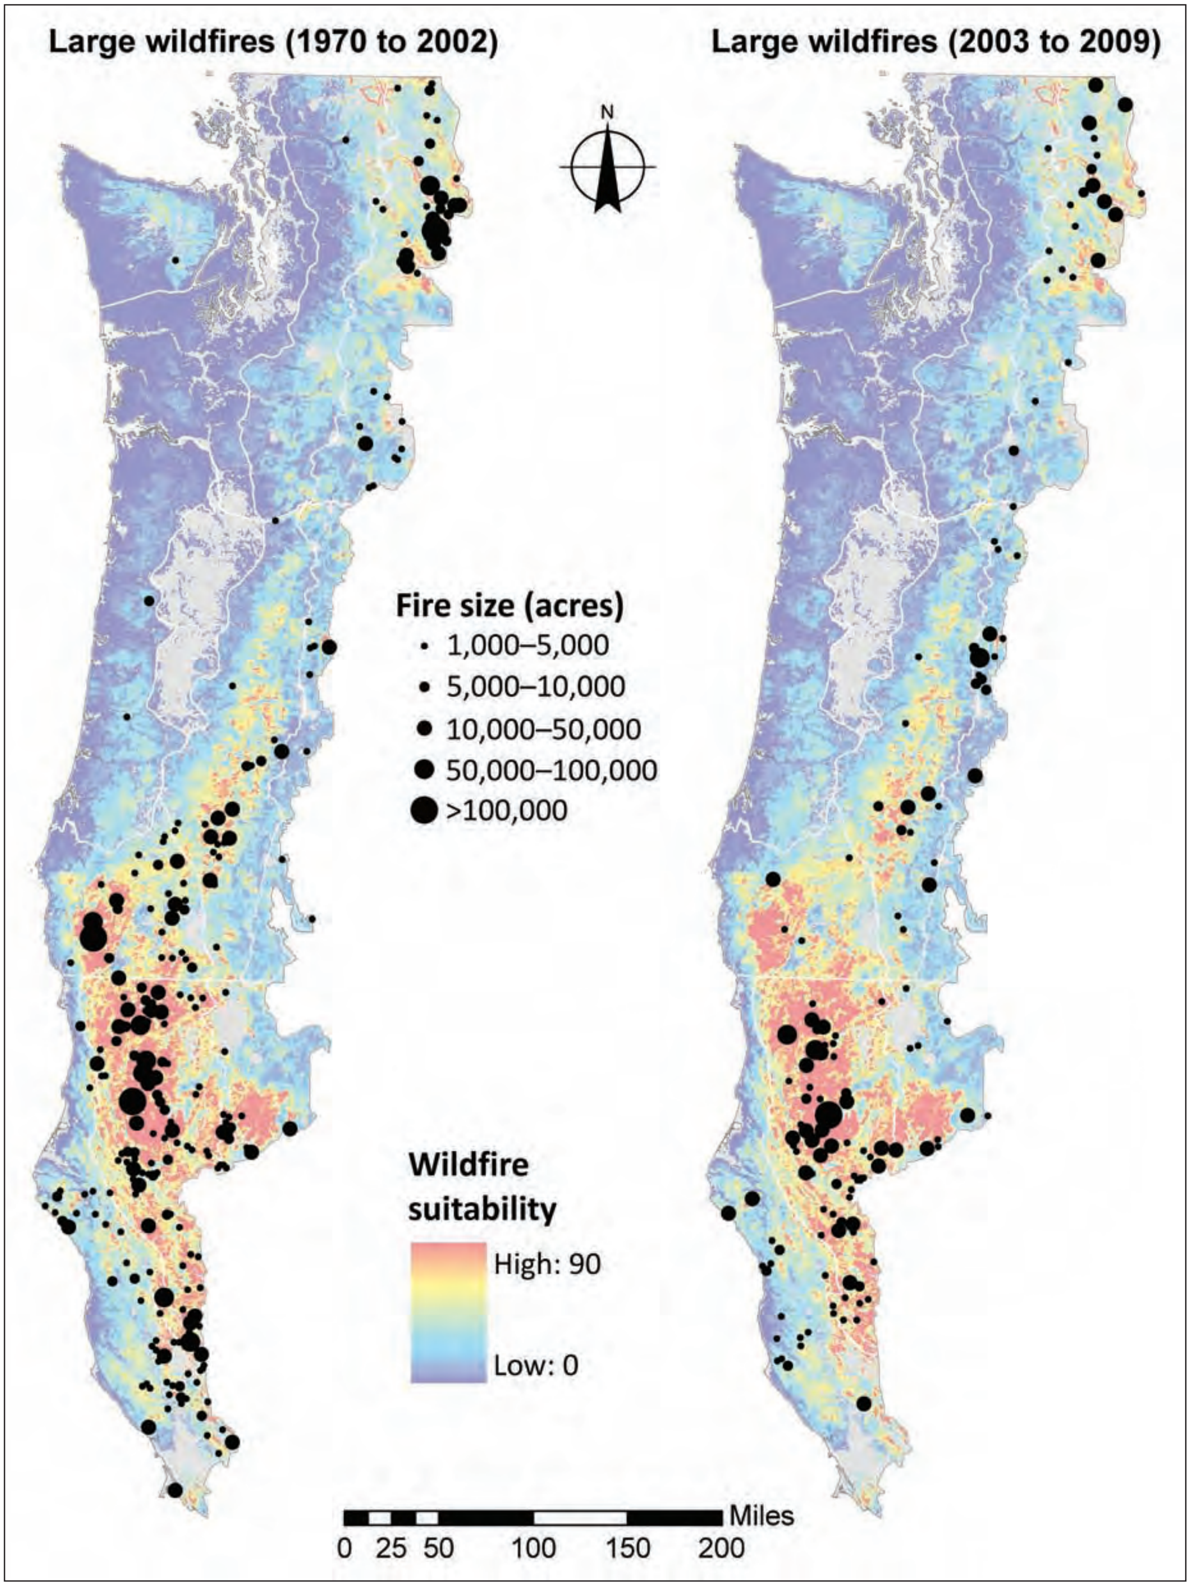

Figure 4-7—The full gradient version of the wildfire suitability model showing locations of large wildfires used to train the model (left) and locations of large wildfires that occurred after 2002 (right) that served as our independent testing data.

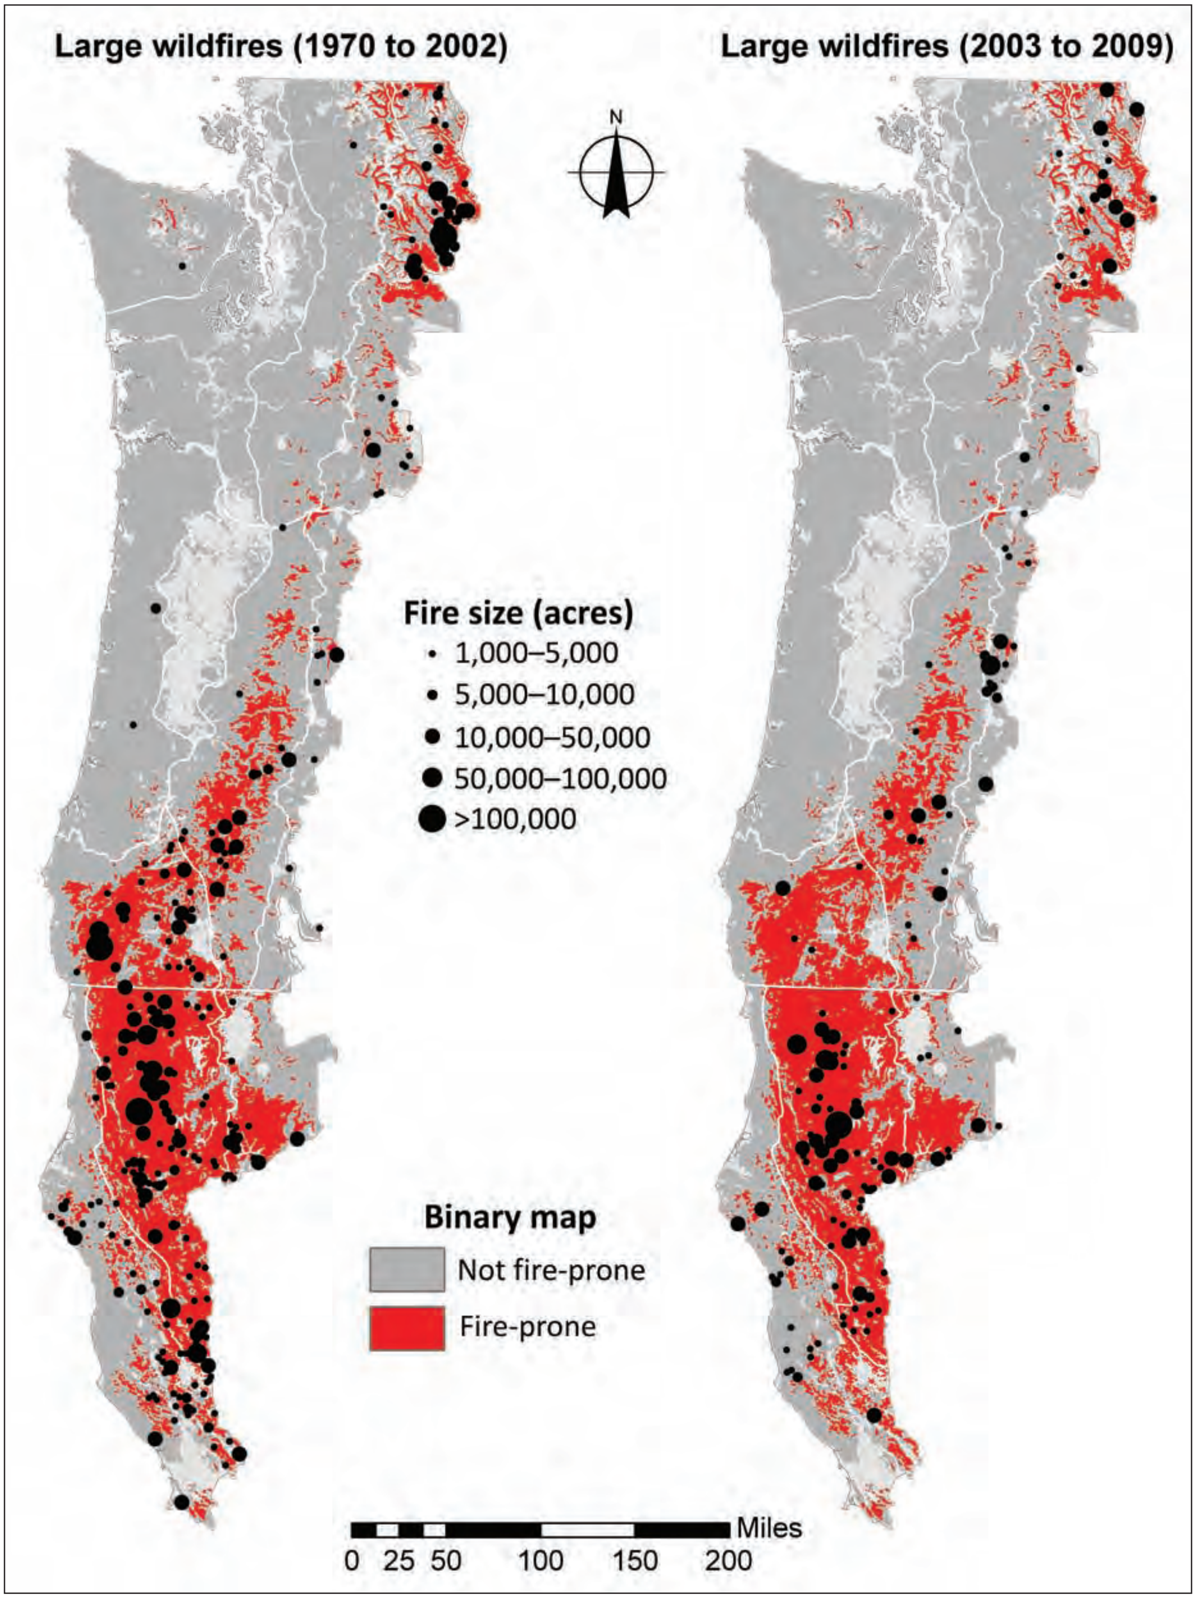

Figure 4-8—The binary version of the wildfire suitability model showing locations of large wildfires used to train the model (left) and locations of large wildfires that occurred after 2002 (right) that served as our independent testing data.

coastal zones and highest elevations of the mountain ranges. These areas have been defined as incurring infrequent wildfires that, when they do happen, tend to be extremely large and severe (Agee 1993, 1998; Morgan et al. 2001; Noss et al. 2006).

On the other end of the fire regime group spectrum, wildfires were more frequent (<35-year intervals) and less severe, maintaining open forests, or a mosaic of different-aged forest seral stages (Hann and Strohm 2003). On our map, portions of the Cascades east of the high-elevation crest, where ponderosa pine forests historically dominated, fit this description. These pine forests were once dependent on frequent surface fires that burned heterogeneously through the landscape, creating open, parklike distributions of trees that were often clumped into small groups (Agee 1994, Graham and Jain 2005). Historically, wildfires in ponderosa pine forests were relatively easy to contain (Munger 1917). Fire suppression and exclusion in ponderosa pine forests produced changes that have been well documented by scientists since the 1990s (Agee 1990, Deeming 1990, Kauffman 1990, Mitchell 1990, Mutch et al. 1993, Wickman 1992). The lack of natural wildfires allows understory development of shade-tolerant vegetation that produces resource-stressed stands, making them more susceptible to insects and disease. This, in turn, leads to weakened or dead trees, generating fuel loadings that are unnaturally heavy and also contiguous over large areas (Hessburg et al. 2005). The understory development also creates ladder fuels that can lead to crown fires, and this fuel combination produces conditions ripe for large wildfires (Hessburg et al. 2005). Today, these areas have developed fuel characteristics that support larger, and more severe, wildfires (Hessburg et al. 2005), and the recent wildfires in central eastern Oregon Cascades have been larger than those of historical records (Eckert et al. 2008).

To what extent fire suppression may have biased our map is uncertain. We suspect fire suppression has likely affected the frequency of large wildfires, but it is much less clear that it has affected the distribution of large wildfires on the landscape. Studies of large wildfires in the large wilderness areas of the southwest and northern Rockies (Rollins et al. 2002, 2004) suggest there has not been an effect on the distribution, although that evidence is indirect as distribution on the landscape was not the focus of any of these studies. Because we have almost no data on how the distribution of large fires might have differed in the absence of suppression actions within the study area, we cannot characterize any model bias in that regard.

Using forest health protection aerial survey data from 1983 to 2008 (USDA 2008), spatial patterns of recent western spruce budworm (*Choristoneura occidentalis*) and mountain pine beetle (*Dendroctonus ponderosae*) outbreaks become apparent (fig. 4-9). In 1983, the spruce budworm began expanding its distribution in the eastern Cascades of Oregon, spreading northward into Washington. It mostly ran its course in the eastern Oregon Cascades by 1993, and then became more active in the southern portions of the Washington Eastern Cascades province. The increased fuel loads created by severe insect outbreaks certainly increase suitability for large wildfires, especially if the fuels are concentrated in a contiguous fashion. In general, the spatial pattern of concentrated spruce budworm outbreaks correspond highly with the B&B Complex and Link Fires from 2003 (fig. 4-9), and also the Lake George, Puzzle, and Black Crater Fires from 2006, and the loss of owl habitat in these areas has largely been attributed to this spruce budworm epidemic and its contribution to the wildfire’s size and severity (Courtney et al. 2004). In addition, the Davis Fire of 2003 occurred in a concentrated area of recent mountain pine beetle outbreaks, and we consider it is likely these episodic insect infections added to the suitability of those specific areas to support these large wildfires.

Agee (1993) pointed out that fire regimes are dependent on the interaction of all parts of the fire behavior triangle—weather, topography, and fuel. Parisien and Moritz (2009) described the fire regime triangle as the interaction of climate, ignitions, and vegetation. Our map spans both the spatial and temporal scales that these triangles represent (see fig. 1 in Parisian and Moritz 2009) and appears to reasonably reflect the last four decades of wildfire history within the range of the owl. However, we suspect that additional spatial information on long-term means of episodic climatic events or insect outbreaks would likely increase its accuracy.

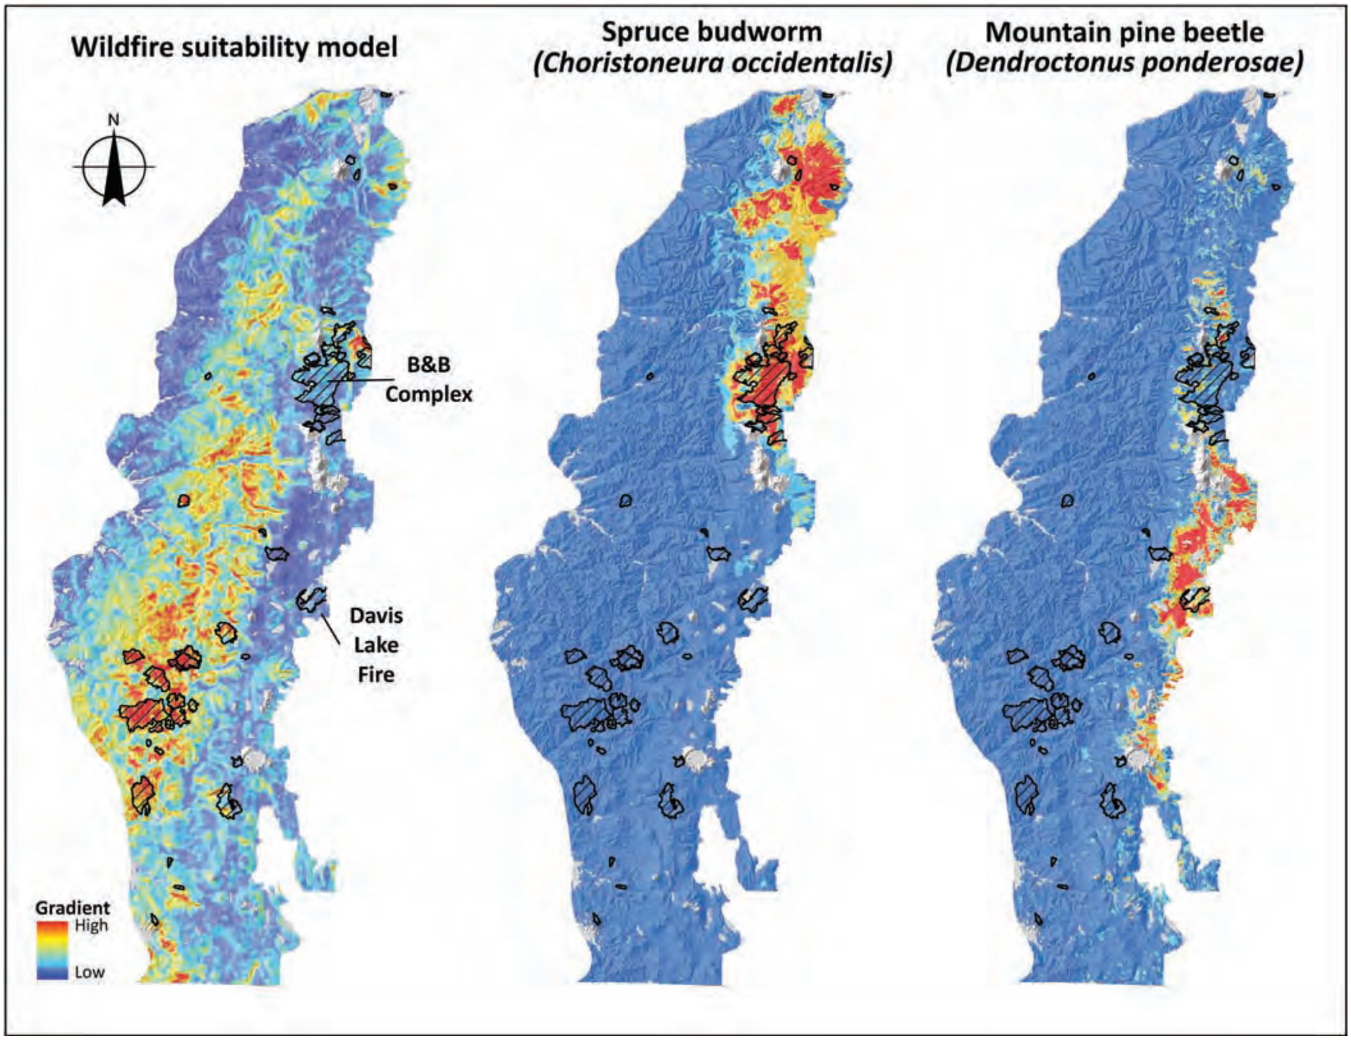

Figure 4-9—Episodic outbreaks of insects in the Oregon Cascades provinces beginning in the 1980s, shown above, may help explain why portions of the eastern Cascades of Oregon have experienced recent large wildfires in areas where the wildfire suitability map indicates lower wildfire suitability (blue indicates lower amounts in the maps above, such as wildfire suitability or years of insect detection, whereas red indicates higher amounts). Large wildfires from 1970 to 2009 are shown as black cross-hatched polygons.

Perhaps one of the most compelling validations of our wildfire suitability map is the relationship of the distributions of three fire-dependent pine species (Little 1971, USDI 1999) with our binary characterization of wildfire suitability (fig. 4-10). As a group in general, pines are associated with forests where wildfire is an integral part of the environment (Fonda 2001). In the range of the owl, sugar pine (*Pinus lambertiana* Dougl.), Jeffrey pine (*P. jeffreyi* Grev. & Balf.), and ponderosa pine (*P. ponderosa* P. & C. Lawson) are common associates with fire-prone ecosystems having shorter fire-return intervals (Skinner and Chang 1996, Taylor and Skinner 1998). These species are members of the "fire-resistant" group of pines (McCune 1988) that evolved in fire-prone environments and developed characteristics like thick bark to insulate the cambium and long needles to insulate buds from the heat of wildfires. Using a map comparison technique[6] (Visser and de Nijs 2006), we

[6] This analysis was performed by using the Map Comparison Kit software (version 3.2) (Netherlands Environmental Assessment Agency) developed by the Research Institute for Knowledge Systems, and available online at http://www.riks.nl/mck/.

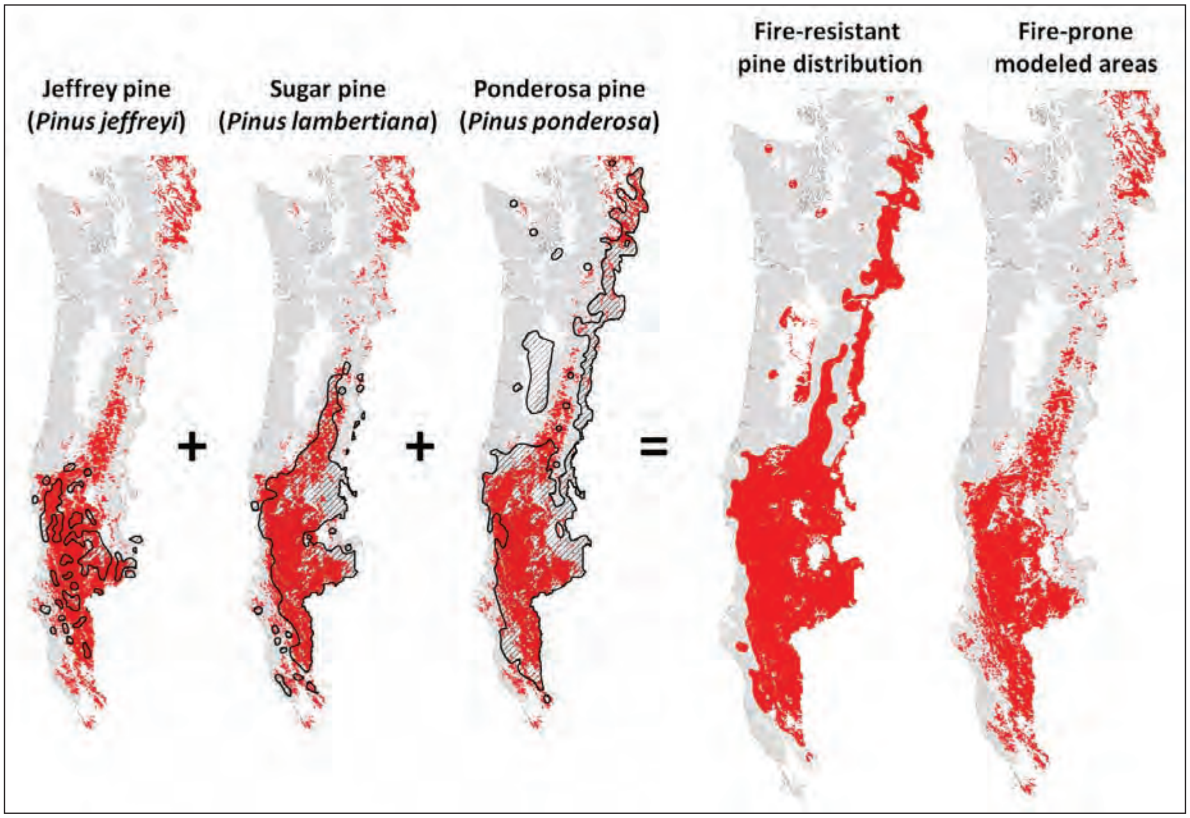

Figure 4-10—Fire-resistant pine distribution maps that were delineated in 1971 (Little 1971, USDI 1999) overlaid on the wildfire suitability binary map.

found that their combined geographic distributions (Little 1971) coincide (cell to cell) moderately well (kappa = 0.46, K_{LOC} = 0.76, K_{HISTO} = 0.60) with the fire-prone areas of the binary version of our model. We believe the historical distributions of these fire-resistant conifers provide further evidence that our binary map effectively identifies portions of the owl's range that wildfire regularly "inhabits."

Countryman (1966) described "fire environment" as the complex of fuel, topographic, and weather (air mass) factors that influences the inception, growth, and behavior of fire. He realized that it was a "pattern phenomena," and advised that its pattern "must be considered in order to understand and predict a fire's behavior." Our map of wildfire suitability is essentially a modeling application of the concept Countryman first described over 40 years ago and is well-validated by almost 40 years of large wildfire data.

Summary

Our goal was to identify landscape-scale areas within the owl's range where large wildfires are more probable over time using factors that are mostly spatially and temporally stable. The use of topographic and climate variables that summarized weather patterns over multiple years (1970–2000) resulted in a map that we believe met this goal, as evidenced by the map's moderate to good correlations (AUC of 0.78 to 0.83 and $R_s \geq 0.987$) with large wildfire locations that post-date the wildfire data used to train the model as well as historical distribution maps of fire-dependent pine species (fig. 4-10). A binary classification of our map (based on the threshold where the map predicts large wildfires more often than would be expected by chance) provides a less arbitrary way to identify "fire-prone" areas of the northern spotted owl's range that normally experience large wildfires.

With this knowledge, we can overlay our wildfire suitability map on the current habitat suitability map produced in chapter 3, to confirm that the physiographic province with the most owl habitat in fire-prone landscapes is the California Klamath province (fig. 4-11). The next highest province is the Oregon Western Cascades province. However, the recent occurrence and trends of insect outbreaks in the eastern Cascades needs to be considered as well. The effects of past management practices combined with these outbreaks have probably increased the suitability for large wildfires of areas that otherwise have underlying physical and climatic factors that are not suitable. If this is the case, our results suggest that once the current fuel build-ups in the eastern Cascade provinces are reduced to more natural levels, the occurrence of large wildfires in that area should decline.

The effects of wildfire on owl biology are difficult to assess and will likely remain a source of uncertainty (Courtney et al. 2004) for some time. Yet, the latest estimates of wildfire's effect on current and future owl habitat, as displayed in chapter 3, indicate wildfires are the major source of habitat loss and future recruitment on federal lands in certain parts of the owl's range. Fortunately, our capabilities to map owl habitat suitability, wildfire effects on vegetation, and wildfire suitability are improving; informing us better on what the habitat effects might be and where this interaction is most likely to happen.

A limitation of our map is that, by itself, it does not provide information on where within the range, large wildfires may occur as a result of atypical or unusual, infrequent conditions or events such as extreme fire weather (Bessie and Johnson 1995; Westerling et al. 2003, 2006), fuel conditions, or a combination of the two. There are other tools available to monitor and track those conditions. However, our map can be used in conjunction with this ancillary data, such as insect outbreak maps, to better inform us on where the next large wildfires might happen.

Finally, the inclusion of climate variables that summarize fire weather in our model may give us the ability to explore climate change scenarios (Carroll 2010) and what effect they may have on patterns of wildfire suitability in the future.

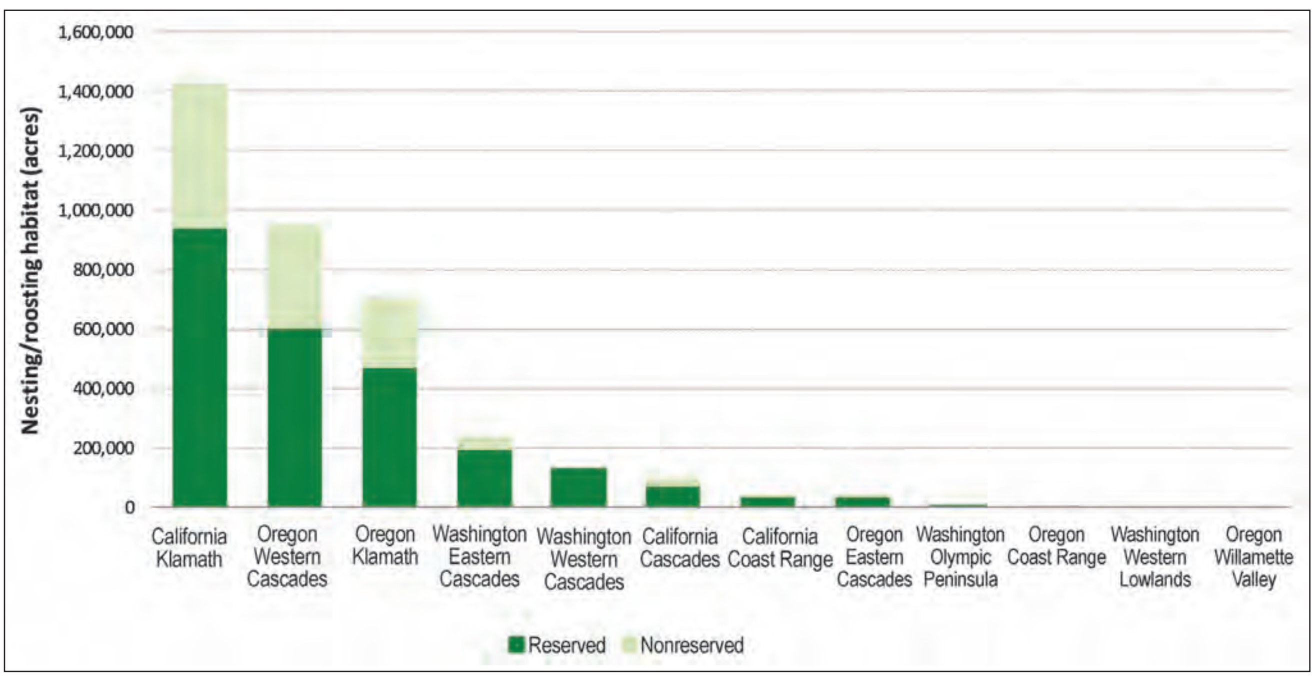

Figure 4-11—Fire-prone spotted owl nesting/roosting habitat, both reserved and nonreserved, by physiographic province, 2006/07. The majority of the fire-prone habitat occurs within the Klamath provinces, and the southern portions of the Oregon Western Cascades. Over half is in reserved land use allocations.

Chapter 5: Emerging Issues, Related Research, and Research Needs

Katie M. Dugger and Raymond J. Davis

Emerging Issues

The 10-year report on the status and trends of northern spotted owl (*Strix occidentalis caurina*) populations and habitat recognized that the conservation and recovery of the owl is not solely related to the amount and quality of habitat across its range (Lint 2005). Other factors including interactions with prey and prey biology, competition with barred owls (*S. varia*), and the emergence of West Nile virus in the Pacific Northwest were noted as emerging issues (Lint 2005). The potential threat of West Nile virus infections to spotted owl populations has not been realized, despite early evidence that owls in the wild were susceptible to natural infection (Fitzgerald et al. 2003). For unknown reasons, outbreaks of the West Nile virus in spotted owls that were anticipated 5 years ago have not occurred, although the virus is present throughout the owls range (Franklin 2010). Although West Nile virus has not developed into as much of a threat to owl populations as predicted previously (Lint 2005), documentation of the negative association between the invasive barred owl and spotted owl vital rates has con-tinued over the last 5 years (Anthony et al. 2006, Dugger et al. 2008, Forsman et al. 2011, Glenn et al. 2010, Kroll et al. 2010). The barred owl is now found at significant densities throughout the entire range of the northern spotted owl (Livezey 2009), and the range expansion of this species constitutes a significant threat to northern spotted owl persistence, which was not evident when the spotted owl was first listed (Courtney et al. 2004). The proportion of spotted owl territories where barred owls have been detected has increased steadily since the early 1990s in the eight effectiveness monitoring areas administered under the Northwest Forest Plan (the Plan) (fig. 5.1) along with increased evidence of negative interactions, presumably owing to competition or interference between the two species (Dugger et al. 2008, 2009; Kroll et al. 2010; Olson et al. 2005).

The invasion of barred owls into the range of the northern spotted owl has been associated with a decreased ability to detect and monitor spotted owls when barred owls are present (Dugger et al. 2009, Glenn et al. 2010, Kroll et al. 2010, Olson et al. 2005). In addition, the detection of barred owls on spotted owl territories is associated with decreased site occupancy by spotted owls and changes in extinction and colonization rates (Dugger et al. 2008, 2009; Kroll et al. 2010; Olson et al. 2005). The strongest association is between detections of barred owls and increased extinction rates across the entire range of the spotted owl, and decreased colonization rates have been reported for some study areas as well (Dugger et al. 2008, 2009; Kroll et al. 2010; Olson et al. 2005). The most recent meta-analysis of spotted owl population dynamics reports a clear negative association between barred owl presence and spotted owl survival (Forsman et al. 2011; chapter 2, this report). Effects on fecundity are less apparent, but declines in spotted owl recruitment on four demographic study areas (Olympic, H.J. Andrews, Coast Ranges, Tyee) in association with barred owl presence has been reported (Glenn et al. 2010). Thus, researchers continue to compile negative associations between barred owl presence and spotted owl vital rates strengthening the evidence that barred owls are negatively affecting spotted owl demography.

Climate change is another emerging issue that may affect spotted owl habitat, populations, and the functionality of the network of reserved land use allocations across the owl's range (Carroll 2010, Carroll et al. 2009, Glenn et al. 2010, Spies et al. 2010). Forest Service research objectives include developing projections for changes in fire regimes and shifts in habitat distributions because altered forest structures with increased threats from wildfire and insect and disease outbreaks are anticipated in association with predicted climate change (USDA 2009). Rate of change in spotted owl population was negatively associated with hot, dry growing seasons and wet, stormy winters (Glenn et al. 2010). Climate models for the first half of the 21st century predict warmer, wetter winters and hotter, drier summers, which could potentially have negative consequences for spotted owls (Glenn et al. 2010). Considering the potential effects of different climate change scenarios in models predicting wildfire suitability (see chapter 4 in this report) may help estimate potential changes in the fire regime within the owl's range and thus potential threats to habitat. In addition,

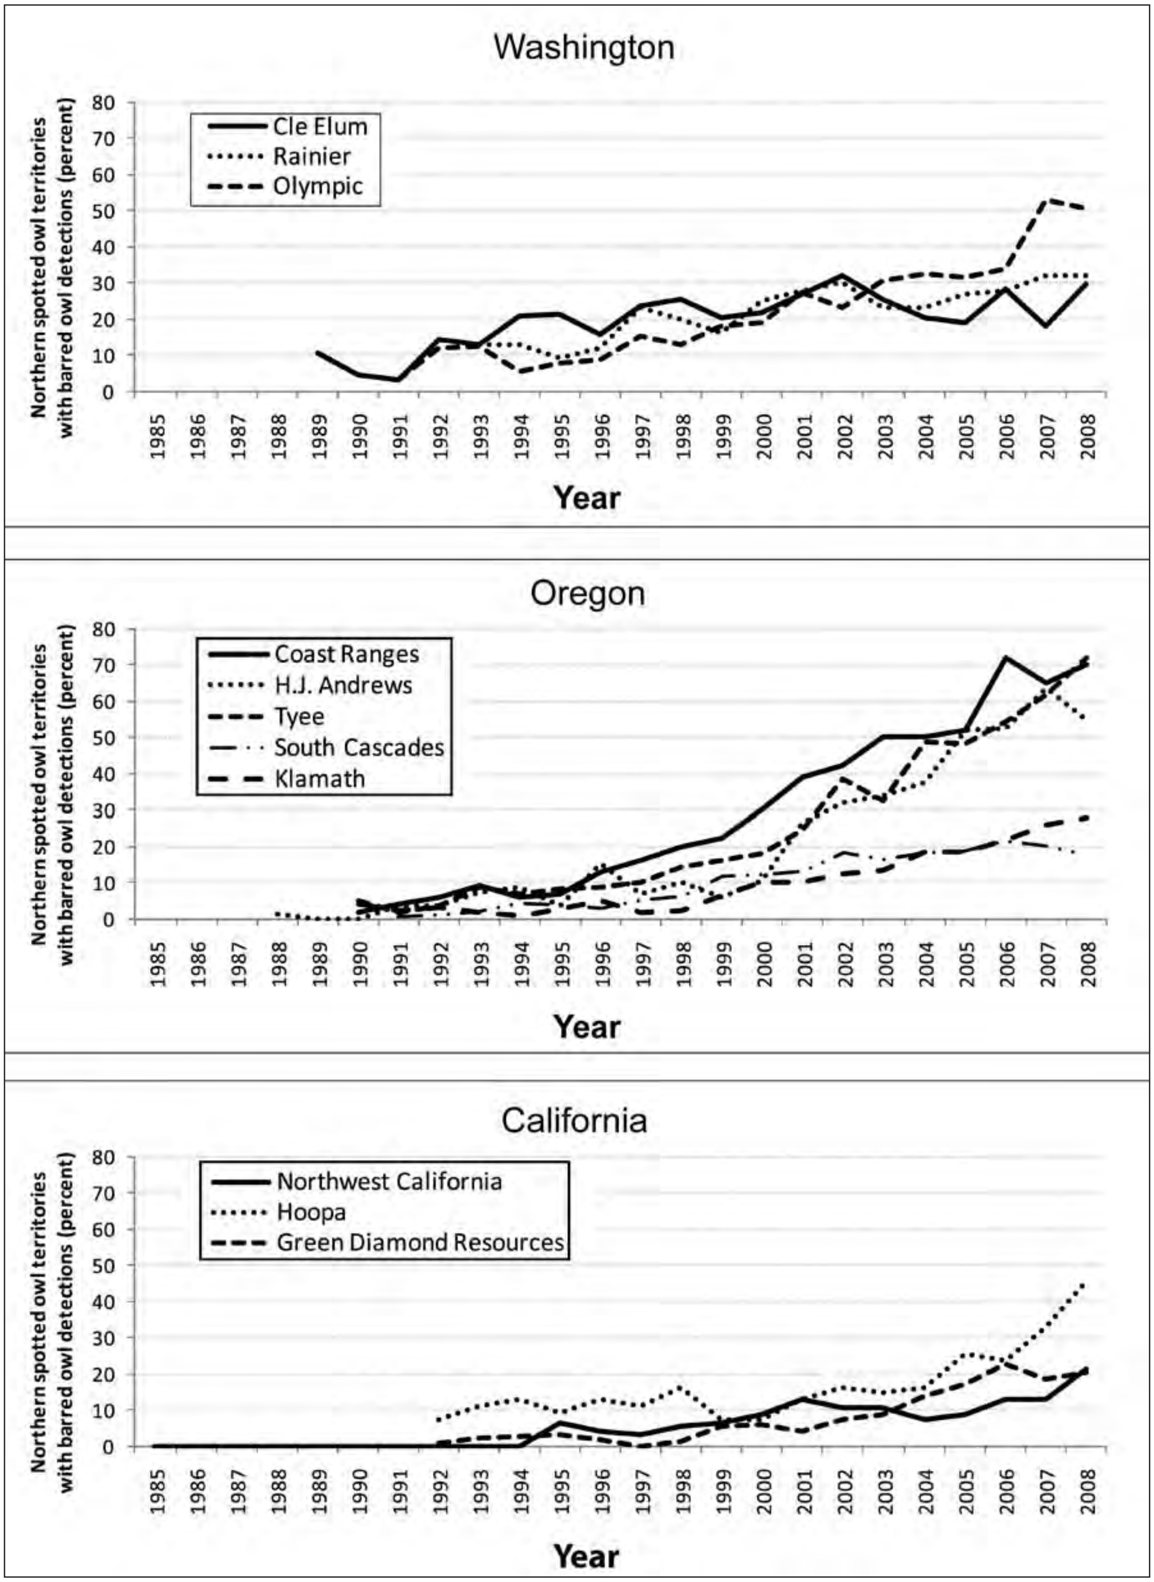

Figure 5-1—Annual proportion of northern spotted owl territories with barred owl detections on study areas in Washington, Oregon, and California. Source: adapted from Forsman et al. (2011).

the inclusion of forest type variables in the owl habitat models can also be modified based on climate change scenarios and used to explore the effects of climate change on suitable owl habitat. As noted by Glenn et al. (2010), however, in the face of climate change and barred owl persistence, the best management strategy for conserving spotted owl populations is to maintain sufficient, high-quality, suitable habitat throughout the species' range.

Related Research and Research Needs

Current research efforts to further understand the competitive interactions between barred and spotted owls are ongoing by D. Wiens, an Oregon State University Ph.D. student. In addition, the U.S. Fish and Wildlife Service (FWS) is proceeding with a proposal to clarify interactions between the two species using an experimental approach as part of Recovery Action 29 in the *Final Recovery Plan for the Northern Spotted Owl* (USDI 2008). This recovery action calls for the FWS to "Design and implement large-scale control experiments in key spotted owl areas to assess the effects of barred owl removal on spotted owl site occupancy, reproduction, and survival." By removing barred owls from spotted owl territories, researchers will be able to document a clear cause-effect relationship between barred owl presence and spotted owl demography (Gutiérrez et al. 2007). The information gained from this experiment may aid in the management and conservation of spotted owls in the face of the continued threat posed by the invasion and establishment of the barred owl in the Pacific Northwest. This proposed research may elucidate new management actions or clarify management and conservation limitations regarding the negative interactions of these two species.

The extent to which habitat management can affect interactions between barred and spotted owls is not clear, but barred owls are habitat generalists that can occupy a wide variety of forest conditions including late-successional forests (Herter and Hicks 2000, Pearson and Livezey 2003, Singleton et al. 2010). In addition, their territories are only 1/4 to 1/9 the size of spotted owl territories (Singleton et al. 2010), so the ratio of the number of barred to spotted owls can be as high as 9 to 1 in some areas. This argues for the increased importance of high-quality, contiguous blocks of nesting/roosting habitat for spotted owls, and the effects of habitat loss cannot be decoupled from the additional stressor imposed by the barred owl range expansion (Dugger et al. 2008).

In particular, the relationship between spotted owl fitness and habitat characteristics may have become disconnected through interspecific competition with barred owls in the landscape (Dugger et al. 2008). Our comparison of habitat suitability at spotted owl pair locations between 1994/96 and 2006/07 (see chapter 3 in this report) showed an average decrease in habitat suitability value of 9.4 percent across the owl's range, suggesting that the quality of habitat at spotted owl pair locations has decreased over time. As loss of suitable nesting/roosting habitat since 1994/96 has been low (3.4 percent), it is unlikely this decline in habitat quality of owl pair locations is the result of general habitat loss, so it is possible this change reflects competition for space with barred owls. Barred owls will use a wide variety of forested landscapes (Hamer et al. 2007, Singleton et al. 2010) and may be excluding spotted owls from the best spotted owl habitat in places where their densities are high (Dugger et al. 2008), but this hypothesis needs to be tested directly with barred owl removal experiments. It is possible that competition with barred owls also might be the reason we have had difficulty developing predictive models (see following discussion) that provide a clear understanding of the relationship between habitat characteristics and spotted owl demographics across the species' range (Anthony et al. 1998, 2002a, 2002b; but see Dugger et al. 2005, Olson et al. 2004).

The effectiveness monitoring plan for spotted owls recommended the development of predictive models linking survival, fecundity, and occupancy to observed vegetation characteristics of owl habitat (Lint et al. 1999). The expectation was that these predictive models could be validated and proved to generate owl vital rate predictions with acceptable error. If so, then there would be a shift from intensive collection of mark-recapture data via annual field surveys to the use of remotely sensed habitat data to monitor owl populations on at least some of the eight study areas (Lint et al. 1999). The spotted owl monitoring program funded a 5-year study to explore the development and feasibility of predicting occupancy and demographic performance of spotted owls using remotely sensed habitat data (Anthony et al. 1998), and most of that work has been completed (Anthony et al. 2002a, 2002b; Dugger et al. 2005, 2006, 2008; Olson et al. 2004, 2005).

Unfortunately, this component of the effectiveness monitoring program has produced mixed results, with only a few strong relationships between habitat characteristics and survival and fecundity noted for some of the demographic study areas (Dugger et al. 2005, Franklin et al. 2000, Olson et al. 2004). As noted by Lint (2005) in the 10-year report, results at that point did not warrant moving on to phase II monitoring, where models would be substituted for mark-recapture studies. However, although simple, universal models linking habitat characteristics to survival and fecundity of owls are likely not possible, these efforts have provided more insight into the effects of climate and habitat characteristics on owl demography. Some general findings include the strong positive effect of late-successional forest at the core of an owl's territory (around the nest site or activity center) on survival and fecundity (Dugger et al. 2005, Franklin et al. 2000, Olson et al. 2004). In addition, at least on some study areas in the southern portion of the owls' range, some component of edge habitat may be important, probably as a source of prey (Franklin et al. 2000, Olson et al. 2004).

Since the 10-year report, models for two study areas have been developed linking occupancy dynamics of spotted owls to habitat characteristics (Dugger et al. 2008; Sovern, 2010). The effect of barred owls and habitat characteristics on extinction and colonization rates can be modeled using multiseason, single-species occupancy models (MacKenzie et al. 2006) or even multiple-species models within seasons (Bailey et al. 2009, MacKenzie et al. 2006). Estimates of annual site occupancy can also be derived from these models, which rely on a mark-recapture framework with a "site" or owl territory as the sample unit and presence/absence data across multiple visits within and between years to allow the separation of occupancy dynamics and detection probabilities (MacKenzie et al. 2006). Accounting for variations in detection rates of spotted owls is important for developing accurate estimates of site occupancy (MacKenzie et al. 2006, Olson et al. 2005). In addition, understanding the mechanisms or processes that drive site occupancy, like the factors that affect the probability that an occupied site becomes unoccupied (i.e., local extinction rate) or the probability that an unoccupied site becomes occupied (i.e., local colonization rate) are proving vital to understanding the impact of barred owls and habitat characteristics on spotted owl persistence (Olson et al. 2005; Kroll et al. 2010; Dugger et al., in press). Based on these models, strong relationships between the amount of old-forest habitat at the core scale (410-ac circle around nest tree or activity center) and extinction rates were observed for the South Cascades study area; spotted owl territories with small amounts of old forest near the site center experienced higher extinction rates of owl pairs (Dugger et al. 2008). In addition, increased fragmentation of old forest at the home range scale (3,700-ac circle around nest site or activity center) decreased colonization rates by owl pairs, and both occupancy parameters were affected by barred owl presence as well (Dugger et al. 2008).

It is unclear why we observed stronger associations between habitat characteristics and occupancy parameters as compared to habitat characteristics and survival or fecundity (Anthony et al. 2002a, 2002b; Dugger et al. 2005, 2006, 2008; Olson et al. 2004, 2005), but it is possible that occupancy reflects the first level of selection by a species, and this is where the strongest selections for habitat are being made. In other words, an area of habitat selected for defense and maintenance of a territory by an owl also meets some minimum standard of suitability for survival and reproduction; thus, habitat quality most strongly affects territory selection, but other factors (climate, age/experience of individuals, individual variation) are more important for explaining the variation in survival and fecundity.

Recent advances in the development of remotely sensed vegetation (Ohmann and Gregory 2002) and change-detection data (Kennedy et al. 2007) may provide an opportunity to investigate habitat relationships across the range of the species in conjunction with barred owl influences. Previous efforts included a range of map products based on a single point in time, or limited temporally and of varying quality (Glenn and Ripple 2004), precluding a meta-analysis using data from all the study areas. The development of this new vegetation layer will now allow us to search for and quantify consistent relationships between habitat characteristics and owl demography, particularly occupancy across the entire range of the species within a meta-analysis framework. In addition, the change-detection data provide an annual time sequence of vegetation changes that can now be linked to annual demographic data. This kind of analysis based on data from eight effectiveness monitoring areas and conducted in a workshop format as a meta-analysis following previous efforts for survival and fecundity (Anthony et al. 2006, Burnham et al. 1996, Forsman et al. 2011, Franklin et al. 1999) should be a priority for future research.

A better understanding of the population dynamics of many of the important spotted owl prey species across the range of the owl will likely be essential to understanding patterns and variation in spotted owl fecundity (Courtney et al. 2004, Forsman et al. 2011). New monitoring and research programs should be initiated to investigate prey cycles and their relationship to spotted owl demographics while incorporating the potential competitive effects of barred owls. This remains a large gap in our understanding of spotted owl ecology, and our lack of baseline information increases the difficulty we face trying to manage spotted owl populations in conjunction with the barred owl, most likely a direct competitor for food resources.

Another area of much needed research includes the effect of fire on owls and their prey, and how fuel reduction treatments proposed to reduce wildfire risk affect owl demography. Fire suppression over the last century has reduced wildfire's presence in its "natural habitats" (Agee 1993, Atzet and Martin 1992, Sensenig 2002), and although wildfire risk has not increased dramatically in the moister/cooler forests, this suppression is believed to have increased the risk for severe wildfires in the fire-prone, or drier/warmer forests. The increased frequency of large wildfires since the mid-1980s in the Western United States (Westerling et al. 2006, Schwind 2008) and within the owl's range (see chapter 4 in this report) have created concern about how wildfires might affect efforts to conserve the owl. Hotter, drier climates associated with climate change are believed to be at least partially responsible for this increase in large-wildfire frequency (Westerling et al. 2006), and there is also evidence that the amount of high-severity wildfire has increased (Miller et al. 2009, Schwind 2008; but see Hanson et al. 2009), in some cases, as the result of accumulated fuels and higher stand densities (Sensenig 2002).

The relationship between wildfire and owl demography is not well understood, but likely includes a complex interaction of fire frequency and severity (Bond et al. 2009, Clark 2007). Owls use forest stands that have burned understories or partially removed overstories, but they tend to avoid areas of complete stand replacement for nesting and roosting (Clark 2007), although use of high-severity burn areas for foraging has been documented for the California spotted owl (*Strix occidentalis occidentalis*) (Bond et al. 2009). This species has likely evolved the ability to adapt and utilize forests that have been subjected to light to moderate fire severity, particularly in the fire-prone portions of its range (chapter 4, this report), but again short-term vs. long-term effects on demography and dispersal are unknown.

Although wildfire has long been a natural agent of disturbance, owls evolved with it in historically forested landscapes that could accommodate the habitat changes caused by it. Today, much of the spotted owl habitat that remains has been "squeezed" into federally managed lands, covers a much smaller portion of the owl's historical range, is highly fragmented (Davis and Lint 2005), and may no longer be able to accommodate large wildfires without incurring adverse consequences to the owl. To lessen the chances of adverse impacts from occurring, the *Final Recovery Plan for the Northern Spotted Owl* (USDI 2008) advocated landscape-level treatments to reduce the risk of large-scale habitat loss to high-severity wildfire for Eastern Cascades and Klamath provinces of the owl's range (USDI 2008). However, it is currently unclear what short- or long-term effects these forest thinning and fuel reduction treatments will have on northern spotted owl populations.

A case study on a single owl territory in second-growth forests in the northern Oregon Coast Range suggests commercial thinning may cause northern spotted owls to alter their habitat use and increase the size of their home ranges, particularly during the nonbreeding season (Meiman et al. 2003). This one case study suggested that thinning operations within core-use areas may be detrimental for northern spotted owls, at least in the short term. But it is not known whether thinning produces long-lasting adverse impacts or long-term benefits associated with owl vital rates. No other published literature is available on thinning and the effects of fuel reductions on habitat use and demography of threatened spotted owls. Understanding the relationship between wildfire and owl demography and the effect of both commercial and noncommercial thinning activities (to reduce fire fuel loads) on owl vital rates should be high research priorities.

Summary

As we have summarized above, there are several large gaps in our understanding of spotted owl ecology, particularly in relation to cycles of prey distribution and abundance, disturbance by fire, and forest management activities associated with developing future habitat or reducing fire risk. Emerging issues, primarily the competitive interactions with the barred owl, are also of very high concern, particularly as the negative effect of this invasive species may be in addition to, or somewhat independent of, maintenance of high-quality spotted owl habitat. The information we have on these issues is dependent on continued research and, in particular, the continued long-term monitoring of owl vital rates throughout this species' range. The effectiveness monitoring program for spotted owls was designed to monitor the long-term results of the Plan and its effect on owl populations (Lint et al. 1999). This monitoring program has done much more, however, as the unique, large-scale demography data set resulting from this program has not only allowed resource managers to document the effects of management activities, but has also contributed valuable information regarding basic owl ecology and the factors that affect vital rates. In large part, the effectiveness monitoring program has been responsible for documentation of the barred owl expansion southward into the spotted owl's range and the negative effects of this invasion on spotted owls (Dugger et al. 2008, 2009; Olson et al. 2005). Recovery goals and actions associated with the *Final Recovery Plan for the Northern Spotted Owl* (USDI 2008) and proposed revisions have been informed directly by or are reliant on the demography data collected on the eight effectiveness monitoring study areas, as well as the remotely sensed data developed for habitat monitoring. Data from this long-term monitoring program have also aided researchers in the development of new analytical approaches for answering complex demography questions (Bailey et al. 2009, MacKenzie et al. 2006). These examples illustrate how the value of the spotted owl effectiveness monitoring program reaches far beyond the original objectives and is truly vital to management and conservation of this species.

Acknowledgments

This report is the result of a large group effort focused on monitoring the effectiveness of the Northwest Forest Plan (the Plan). It would not have been possible without the continued hard work of many dedicated biologists who annually collect the field data and help to generate the natural resource information that we periodically analyze to produce these monitoring reports on the status and trends of northern spotted owls and how they are faring under the Plan. This unique set of field data is the cornerstone of our population monitoring and would not exist without the vision and leadership of the principal investigators of the demography study areas—Robert Anthony, USGS (retired); Eric Forsman, USDA Forest Service; Alan Franklin, Colorado State University: Rocky Gutierrez, University of Minnesota; and their many research associates. We thank them for their tremendous contribution to this effort. The federal demographic survey area crew leaders (from north to south) are Brian Biswell, Scott Gremel, Stan Sovern, Tom Snetsinger, Steve Ackers, Janice Reid, Robert Horn, Steve Andrews, and Peter Carslon, who, in addition to making the field work happen, took the time to review and comment on the habitat models that we generated from their data. We thank them. We also thank Diana Stralberg, Renée Cormier, and Dave Press for sharing their northern spotted owl data from the southernmost tip of its range.

For the habitat monitoring, we thank Janet Ohmann, Matthew Gregory, and Heather Roberts, also known as the Landscape, Ecology, Modeling, Mapping, and Analysis team for providing us with our first consistent rangewide vegetation data sets. This could not have been done without the collaborative efforts of Robert Kennedy, Warren Cohen, and Zhiqiang Yang from the Laboratory for Applications of Remote Sensing in Ecology research laboratory, which also produced the change-detection data for our analysis. This group was incredibly helpful to our modeling efforts and always available to answer questions and offer advice. We are grateful for the collaborative support we received from the Marbled Murrelet Monitoring Team, our close partners in habitat monitoring, particularly Martin Raphael, Gary Falxa, Beth Galleher, and Rich Young. Thanks to Carol Apple for her advice and assistance in the inventory plot analysis. We are also grateful for the data and advice provided by Alexandre Hirzel and Stephen Phillips (developers of the BioMapper and MaxEnt habitat modeling software, respectively), who patiently answered our many questions as we experimented with different habitat modeling methods during the early phases of this report.

The chapter on wildfire suitability was the result of a long-term collaboration with several people from several agencies, including Joe Lint (retired), Jim Thrailkill, Lynn Gemlo, Cindy Donegan, Scott Center, Elaine Rybak, and Josh Chapman. We thank them for the many discussions, ideas, and assistance that eventually led to us being able to portray large wildfires in this unique ecological and geographical perspective.

This report benefited from the helpful comments of several reviewers who read various drafts or chapters of it, including Tom Spies, Robert Anthony, Elizabeth Glenn, Warren Cohen, Carl Skinner, and Ayn Shlisky. We thank Ashley Steel for the statistical review and Jim Baldwin for his early comments and assistance in developing a spreadsheet for calculating the Continuous Boyce Index. A special thanks to Shawne Mohoric (retired) and all those involved in the Interagency Regional Monitoring Program—especially Melinda Moeur (retired) for her efforts to continually advance and improve the vegetation data that several modules use for monitoring. We greatly appreciate the budget and personnel support from the federal partnership that made this all happen, as well as the Interagency Senior Managers Group and the Regional Interagency Executive Committee for their continuing commitment and support for the Northwest Forest Plan effectiveness monitoring program. And last, but certainly not least, we thank Joe Lint for laying down a solid spotted owl monitoring foundation upon which we hope to continue to build.

Appendix A: Environmental Variables Used for Habitat Suitability Modeling

Table A-1—Environmental variables that were used for habitat modeling

Variable	Description	Units
Diameter diversity index	A measure of the structural diversity of a forest stand based on tree densities in different diameter at breast height (d.b.h.) classes. Calculation procedures are described in appendix 1 of McComb et al. (2002)[a]	Index
Canopy cover of all conifers	Percentage of conifer cover in the canopy as calculated using methods in the Forest Vegetation Simulator	Percentage
Stand height	Average height of dominant and codominant trees	Meters
Mean conifer diameter	Basal area weighted mean diameter of all live conifers	Centimeters
Density of large conifers	Estimated tree density for all live conifers ≥ 30 in d.b.h.	Trees/ha
Stand age (no remnants)	Average stand age based on field-recorded ages of dominant and codominant tree species, and excluding remnant trees	Years
Subalpine forest	Stand component of Pacific silver fir (*Abies amabilis* Dougl. ex Forbes), subalpine fir (*Abies lasiocarpa* (Hook.) Nutt.), noble fir (*Abies procera* Rehd.), Shasta red fir (*Abies shastensis* (Lemmon) Lemmon), Alaska cedar (*Chamaecyparis nootkatensis* (D. Don) Spach), Engelmann spruce (*Picea engelmannii* Parry ex Engelm.), whitebark pine (*Pinus albicaulis* Engelm.), and mountain hemlock (*Tsuga mertensiana* (Bong.) Carr.)	Percentage of total basal area
Pine forest	Stand component of lodgepole pine (*Pinus contorta* Dougl. ex Loud.), Jeffrey pine (*Pinus jeffreyi* Grev. & Balf.), Bishop pine (*Pinus muricata* D. Don), and ponderosa pine (*Pinus ponderosa* Dougl. ex Laws.)	Percentage of total basal area
Oak woodlands	Stand component of blue oak (*Quercus douglasii* Hook. & Arn.), Oregon white oak (*Quercus garryana* Dougl. ex Hook.), and California black oak (*Quercus kelloggii* Newb.)	Percentage of total basal area
Evergreen hardwoods	Stand component of Pacific madrone (*Arbutus menziesii* Pursh), tanoak (*Lithocarpus densiflorus* Rehd.), California live oak (*Quercus agrifolia* Née), canyon live oak (*Quercus chrysolepis* Liebm.), and California laurel (*Umbellularia californica* (Hook. & Arn.) Nutt.)	Percentage of total basal area
Redwood forest	Stand component of redwood (*Sequoia sempervirens* D. Don) Endl.)	Percentage of total basal area

Appendix B: Nearest Neighbor Distance Analysis of Demographic Study Area Data

An analysis of nearest neighbor distances (Clark and Evans 1954) was conducted on several demographic study area owl pair location (fig. B–1) data sets from 1994 through 1997 to correspond with the baseline satellite imagery. The purpose of this analysis was to determine biologically relevant distances for use as minimum distance parameters in the random sampling of owl pair locations from the 10-year report owl presence data set (Davis and Lint 2005). The purpose of this sampling was to provide additional habitat model training data points, outside of demographic study areas, for the habitat modeling described in chapter 3.

Only one location was used to represent each owl territory center. To minimize erroneous results, we only used owl locations from the 50-percent harmonic mean core (Dixon and Chapman 1980) of each study area's data set. This removed outlier locations that would introduce errors in the analysis, especially for study areas that have disjunct areas or survey areas that are separated by several miles. The analysis was conducted in ArcView Spatial Analyst using the Animal Movement extension (v2.0) by Hooge and Eichenlaub (2000).

Results show a decreasing trend in distance between owl pair territories from north to south (fig. B-2). The greatest mean nearest neighbor distance occurs in the Washington Eastern Cascades (4.5 km), and the shortest mean distance occurs within the California Coast (1.4 km). The longer distances in the northern portions of the range may relate to more limited prey resources. Likewise the shorter distances in the southern portion of the range may be due to increased prey base diversity and abundance associated with the presence of mast-producing evergreen hardwoods that occur in the coniferous forests of that region.

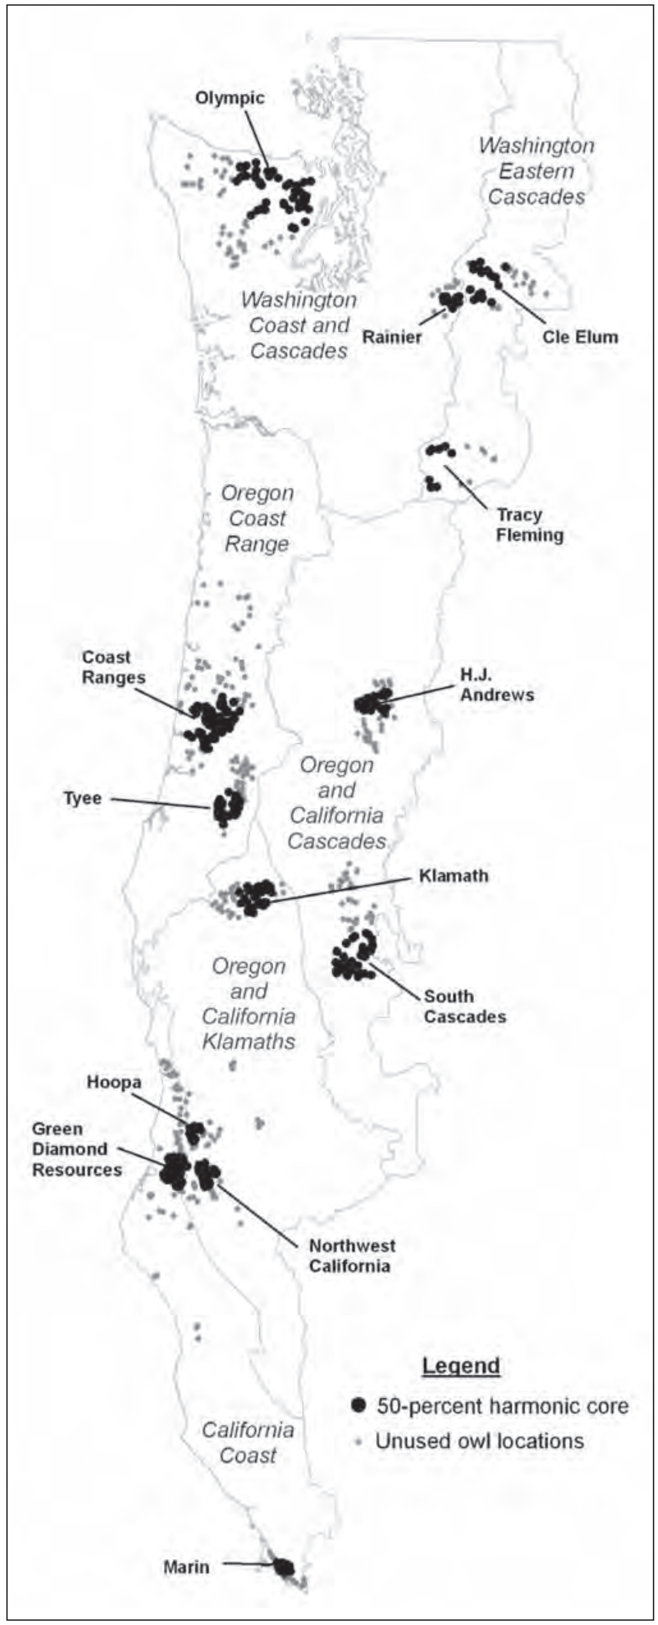

Figure B-1—Owl territories, 1994 through 1997.

Table B-1–Summary statistics from the nearest neighbor analysis for each habitat modeling region

Modeling region	Data sets used	n[a]	Mean distance	Median distance	StDev
			– – – – – Kilometers – – – – –		
Washington Eastern Cascades	Cle Elum and T. Fleming study areas	26	4.5	3.9	2.4
Washington Coast and Cascades	Olympic and Rainier study areas	53	3.6	3.1	1.7
Oregon and California Cascades	H.J. Andrews and Southern Cascades study areas	57	3.1	2.9	1.5
Oregon Coast Range	Oregon Coast Ranges and Tyee study areas	79	2.7	2.5	1.2
Oregon and California Klamaths	Klamath, Northwest California, and Hoopa study areas	70	2.4	2.1	1.1
California Coast	Green Diamond Resources and Marin study areas	77	1.4	1.3	0.6

[a] Only locations from the 50-percent harmonic core of the study area data set were used. StDev = standard deviation.

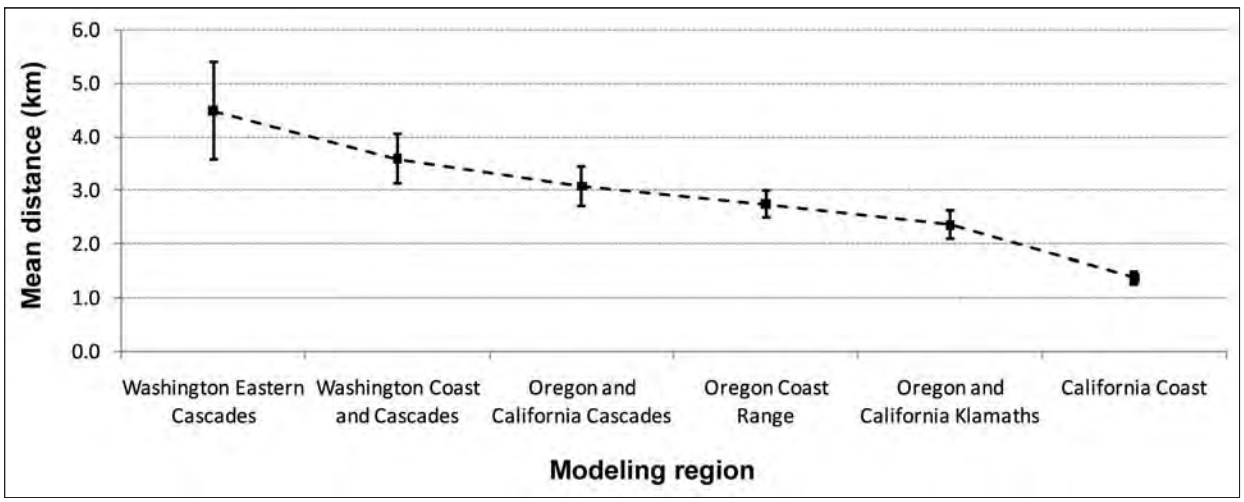

Figure B-2—Results of the nearest neighbor distance analysis showing mean distances between northern spotted owl territory centers with 95-percent confidence intervals for each habitat modeling region.

Table C-1–Results of the MaxEnt bootstrapped replicate habitat suitability models (10 replicates for each modeling region) showing mean percentage for environmental variable model contributions and changes in model test gain associated with inclusion or exclusion of specific environmental variables

	Stand structure and age variables						Species composition variables						
Modeling region	**Conifer cover**	**Mean conifer d.b.h.**	**Large conifer density**	**Diameter diversity index**	**Stand height**	**Stand age**	**Subalpine forest**	**Pine forest**	**Oak woodland**	**Evergreen hardwood**	**Redwood forest**	**Highest gain by itself**	**Lowered gain the most when removed**
	Percentage of contribution												
Washington Coast and Cascades	21.0	1.7	35.2	7.8	3.2	20.2	10.8	n/a	n/a	n/a	n/a	Diameter diversity	Subalpine forest
Washington Eastern Cascades	34.6	0.5	11.0	6.0	7.4	2.7	31.8	4.9	1.3	n/a	n/a	Diameter diversity index	Subalpine forest
Oregon Coast Range	13.3	4.6	58.1	5.4	4.6	11.2	n/a	n/a	0.9	1.9	n/a	Stand age	Conifer cover
Oregon and California Cascades	15.6	5.2	33.4	21.7	3.8	4.7	6.3	5.5	1.1	2.6	n/a	Diameter diversity index	Subalpine forest
Oregon and California Klamaths	19.1	1.8	15.0	14.1	8.9	5.1	2.4	18.3	4.4	10.9	n/a	diversity index	Pine forest
California Coast	43.7	7.1	3.0	2.6	6.3	2.3	n/a	5.7	13.0	10.2	6.2	Conifer cover	Evergreen hardwood

Note: MaxEnt replicate variable response curve information for each modeling region is available upon request.
d.b.h. = diameter at breast height.

The following sections in this appendix summarize the MaxEnt modeling regions and the modeling results of the bootstrapped replicates. Model region descriptions are largely based on information from the Landscape Ecology Modeling, Mapping and Analysis Web site (http://www.fsl.orst.edu/lemma/main.php?project=nwfp&id=home).

Washington Coast and Cascades Modeling Region (MR 221)

This modeling region conforms to the Washington Douglas-fir ecological region used in the demographic meta-analyses, and contains the Olympic Peninsula and the Rainier demographic study areas. It encompasses the Washington Olympic Peninsula, Washington Western Lowlands, and the Washington Western Cascades physiographic provinces. The Olympic Peninsula is dominated by moist, productive coniferous rain forest on the western slope, and drier Douglas-fir forest in the rain shadow on the eastern slope. Wildfire frequency is very low. Federally managed lands occupy the interior half of the province, the core being Olympic National Park girded by the Olympic National Forest. Most of the Western Lowlands are in private and state ownership, with extensive urban and agricultural areas. It is dominated by wide, glaciated valleys, except for the Willapa Hills in the coastal section. Lowland coniferous forest, deciduous forest, and native prairie were its natural dominant vegetation types. The Western Cascades lower elevation forests are dominated by Douglas-fir (*Pseudotsuga menziesii* (Mirb.) Franco) and western hemlock (*Tsuga heterophylla* (Raf.) Sarg.) grading into Pacific silver fir (*Abies procera* Rehd.) at midelevations, and mountain hemlock (*Tsuga mertensiana* (Bong.) Carr.) and subalpine vegetation at higher elevations. Wildfire frequencies are low to moderate. About two-thirds of the province is administered by federal agencies.

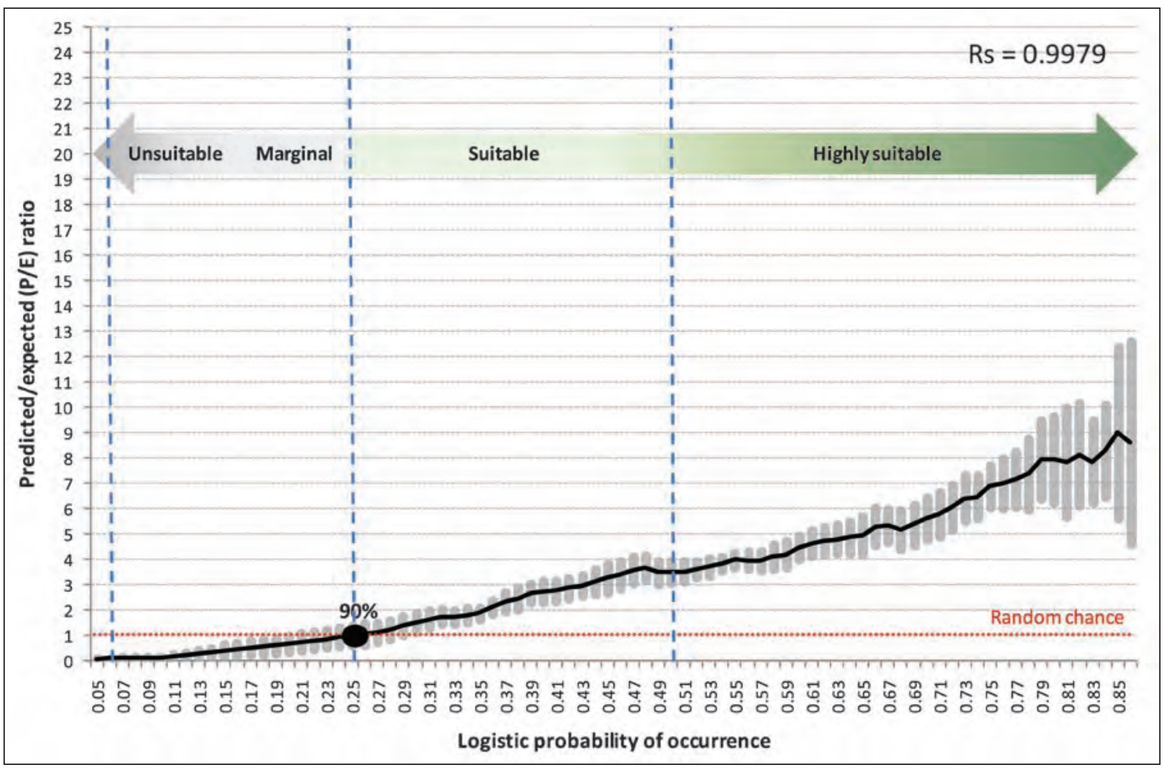

Figure C-1–The mean predicted vs. expected curve (solid black line) from the model replicates, showing 95-percent confidence intervals (gray-shaded vertical bars) for the Washington Coast and Cascades modeling region. The logistic thresholds used to define the four-class habitat map are represented by vertical blue-dashed lines. The P/E = 1 threshold is where the curve crosses the random chance line (red-dashed line). The solid black dot represents the 10-percentile threshold (see fig. C-2 below) indicating where 90 percent of the training data (owl pair site centers) occured above that threshold. The mean Spearman rank correlation (Rs) is shown in the upper right-hand corner. See Hirzel et al. (2006) for more information.

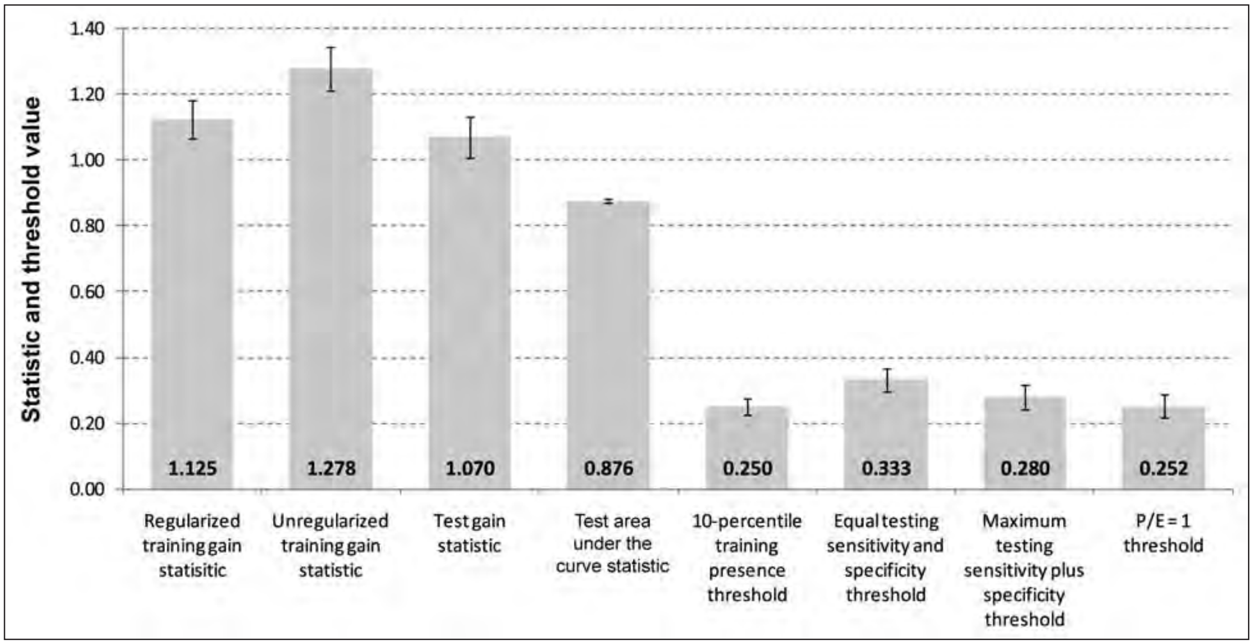

Figure C-2–Habitat modeling statistics produced during the MaxEnt model bootstrapped replicates for the Washington Coast and Cascades modeling region. Bars represent the mean statistic value, and error bars show the 95-percent confidence intervals. The first four bars represent model fit and discrimination statistics; the last four bars are common "thresholds" used to classify continuous habitat suitability models into binary maps of "not-suitable" and "suitable" habitat. P/E = predicted vs. expected.

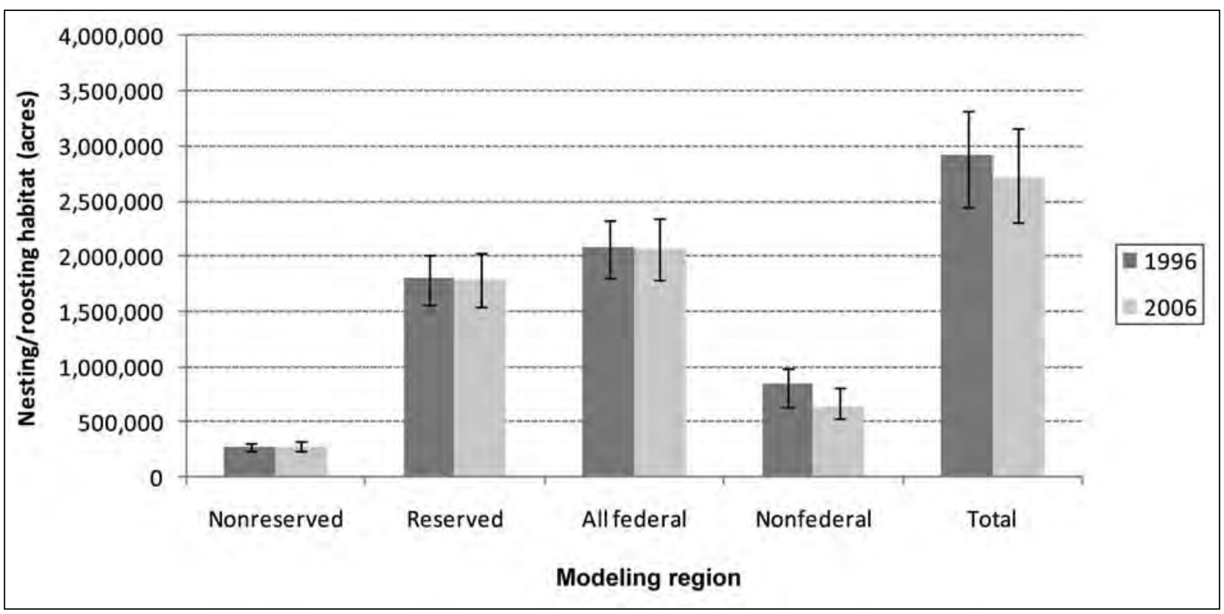

Figure C-3–Bookend habitat model area of suitable nesting/roosting habitat for northern spotted owls for the Washington Coast and Cascades modeling region. The bars represent the mean estimate of suitable habitat, and error bars show the 95-percent confidence intervals. This histogram shows net change (losses and gains) between 1996 and 2006.

Washington Eastern Cascades Modeling Region (MR 222)

This modeling region conforms to the Washington Mixed-Conifer ecological region used in the demographic meta-analyses, and contains the Cle Elum demographic study area. It also conforms to the Washington Eastern Cascades physiographic province. The slopes of the Washington Eastern Cascades province are dominated by mixed-conifer forest and ponderosa pine (*Pinus ponderosa* Dougl. ex Laws.) forest at lower to midelevations, and by true fir (*Abies* spp.) and mountain hemlock at higher elevations. Forest productivity is low in places owing to poor soils and high elevations. Historically, fire frequencies were high (≤35-year fire-return intervals). Intensive fire suppression practices since the latter half of the 20th century have resulted in areas with significant accumulations of fuel and shifts in species composition and stand structure. About two-thirds of the area is federally managed.

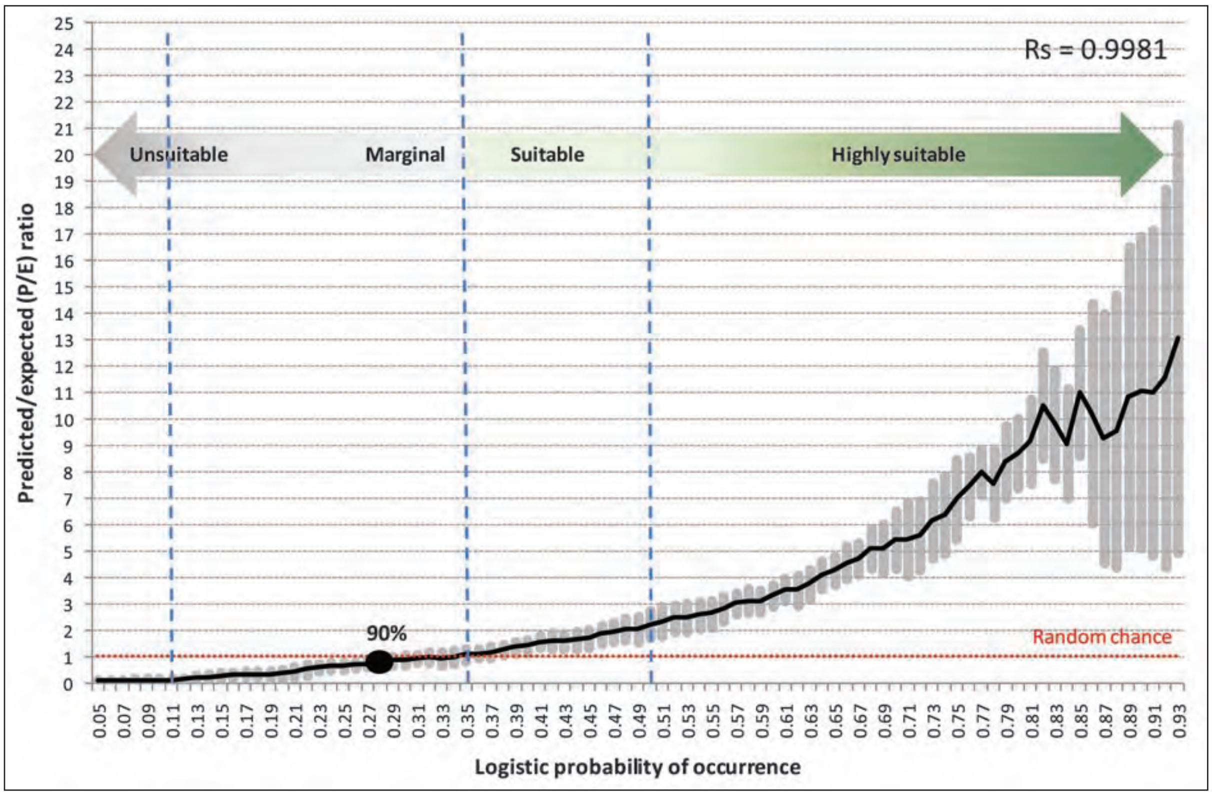

Figure C-4–The mean predicted vs. expected curve (solid black line) from the model replicates, showing 95-percent confidence intervals (gray-shaded vertical bars) for the Washington Eastern Cascades modeling region. The logistic thresholds used to define the four-class habitat map are represented by vertical blue-dashed lines. The P/E = 1 threshold is where the curve crosses the random chance line (red-dashed line). The solid black dot represents the 10-percentile threshold (see fig. C-5 below) indicating where 90 percent of the training data (owl pair site centers) occured above that threshold. The mean Spearman rank correlation (Rs) is shown in the upper right-hand corner. See Hirzel et al. (2006) for more information.

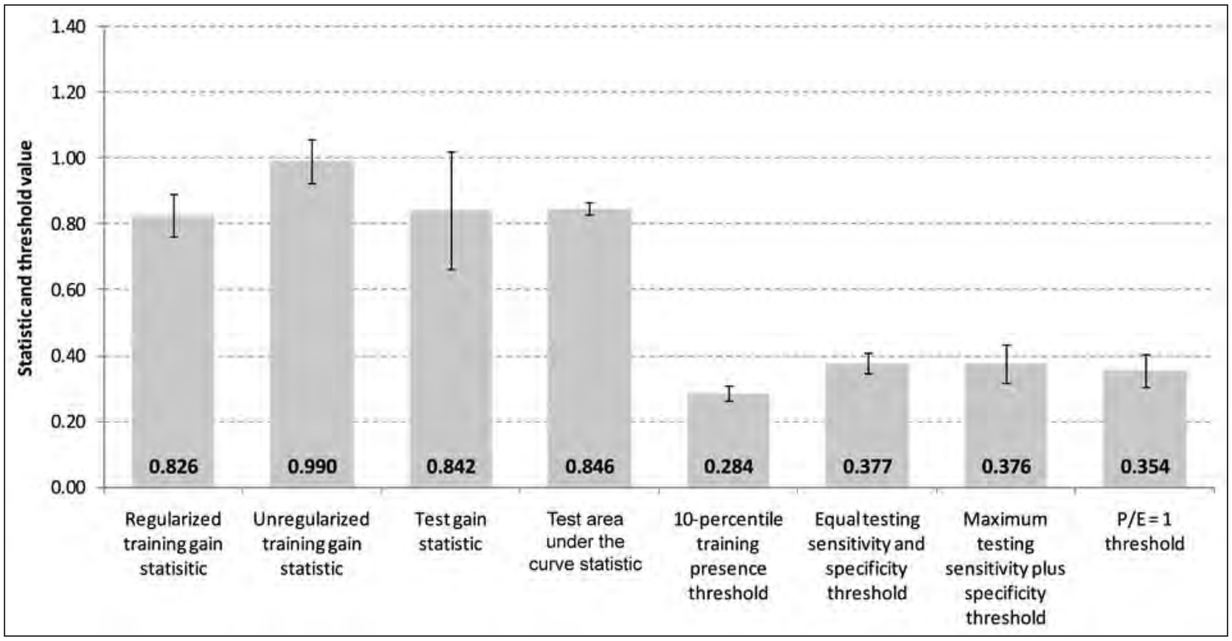

Figure C-5–Habitat modeling statistics produced during the MaxEnt model bootstrapped replicates for the Washington Eastern Cascades modeling region. Bars represent the mean statistic value, and error bars show the 95-percent confidence intervals. The first four bars represent model fit and discrimination statistics; the last four bars are common "thresholds" used to classify continuous habitat suitability models into binary maps of "not-suitable" and "suitable" habitat. P/E = predicted/expected ratio.

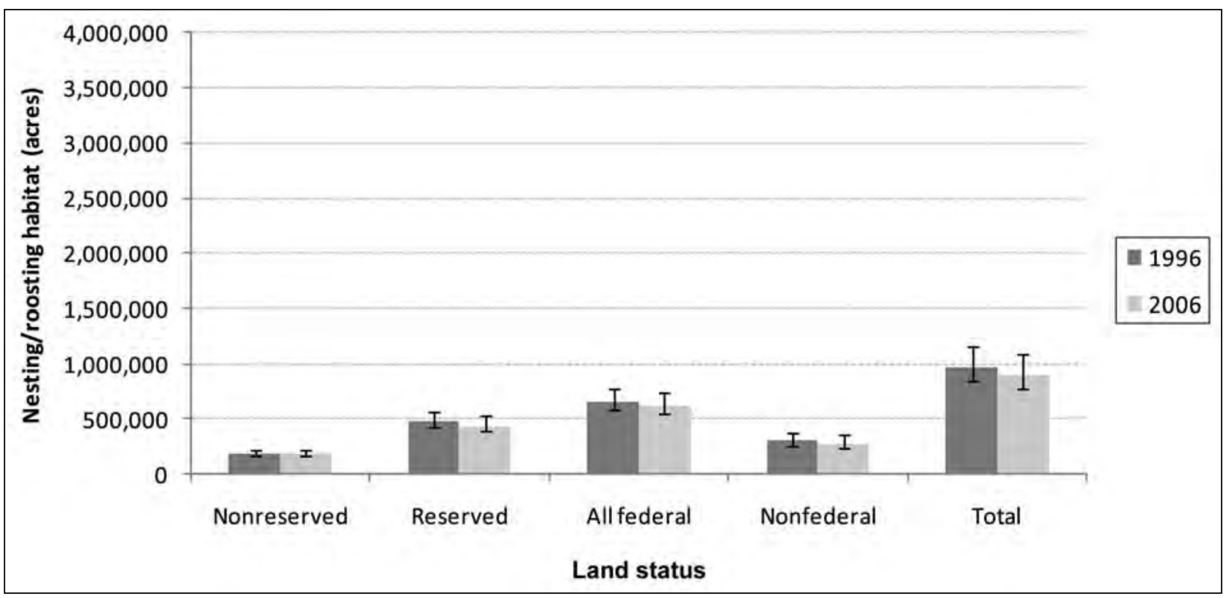

Figure C-6–Bookend habitat model area of suitable nesting/roosting habitat for northern spotted owls for the Washington Eastern Cascades modeling region. The bars represent the mean estimate of suitable habitat, and error bars show the 95-percent confidence intervals. This histogram shows net change (losses and gains) between 1996 and 2006.

Oregon Coast Range Modeling Region (MR 223)

This modeling region conforms to the Oregon Coastal Douglas-fir ecological region used in the demographic meta-analyses, and contains the Oregon Coast Ranges and Tyee demographic study areas. It contains the Oregon Coast physiographic province, and also the Willamette Valley physiographic province west of the Willamette River, as well as the coastal margins of the Oregon Klamath physiographic province. The moist, productive forests in this modeling region are dominated by Douglas-fir, western hemlock, and western redcedar (*Thuja plicata* Donn ex D. Don). The Forest Service and Bureau of Land Management together manage about one-quarter of the land in the region. Older forests are highly fragmented, largely as a result of infrequent but very large wildfires in the 1800s and 1900s, and heavy cutting, as well as checkerboard ownership patterns. Most of the Willamette Valley is in private ownership and includes extensive urban and agricultural areas. Lowland coniferous forest, deciduous forest, and native prairie were the natural dominant vegetation types.

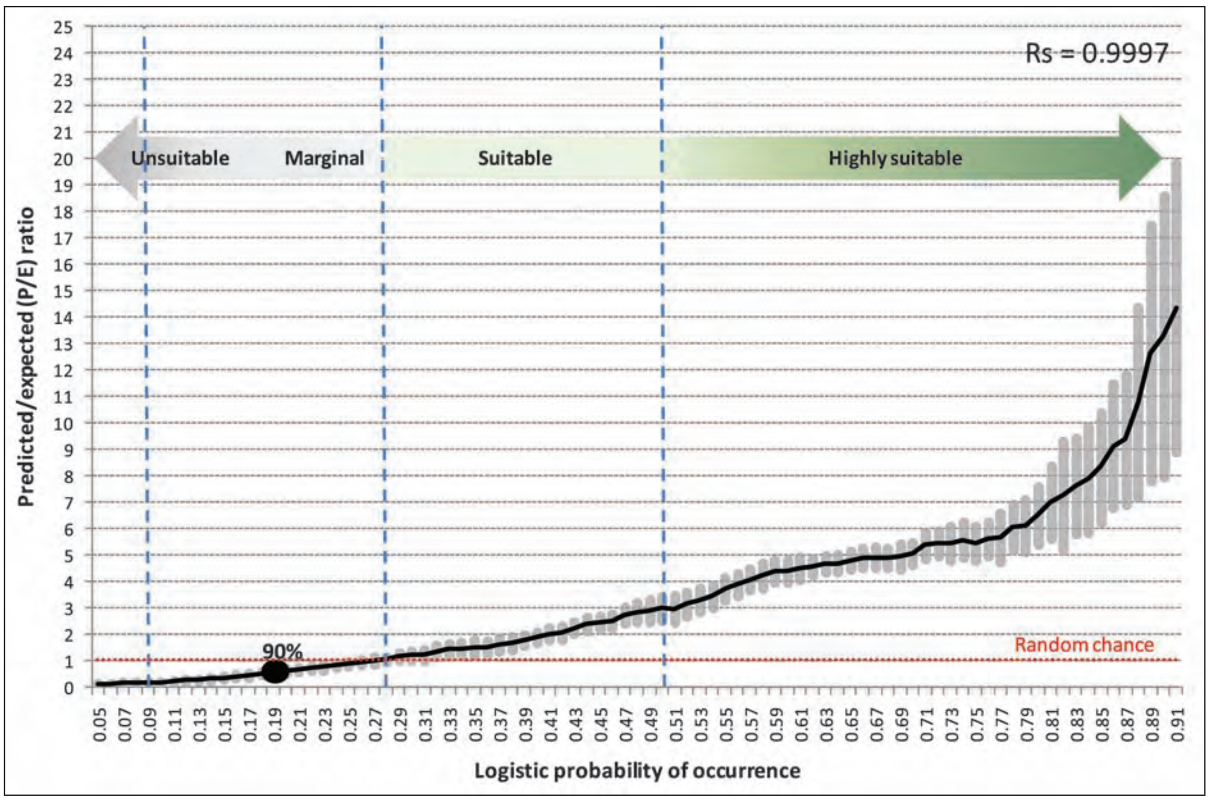

Figure C-7–The mean predicted vs. expected curve (solid black line) from the model replicates, showing 95-percent confidence intervals (gray-shaded vertical bars) for the Oregon Coast Range modeling region. The logistic thresholds used to define the four-class habitat map are represented by vertical blue-dashed lines. The P/E = 1 threshold is where the curve crosses the random chance line (red-dashed line). The solid black dot represents the 10-percentile threshold (see fig. C-8 below) indicating where 90 percent of the training data (owl pair site centers) occured above that threshold. The mean Spearman rank correlation (Rs) is shown in the upper right-hand corner. See Hirzel et al. (2006) for more information.

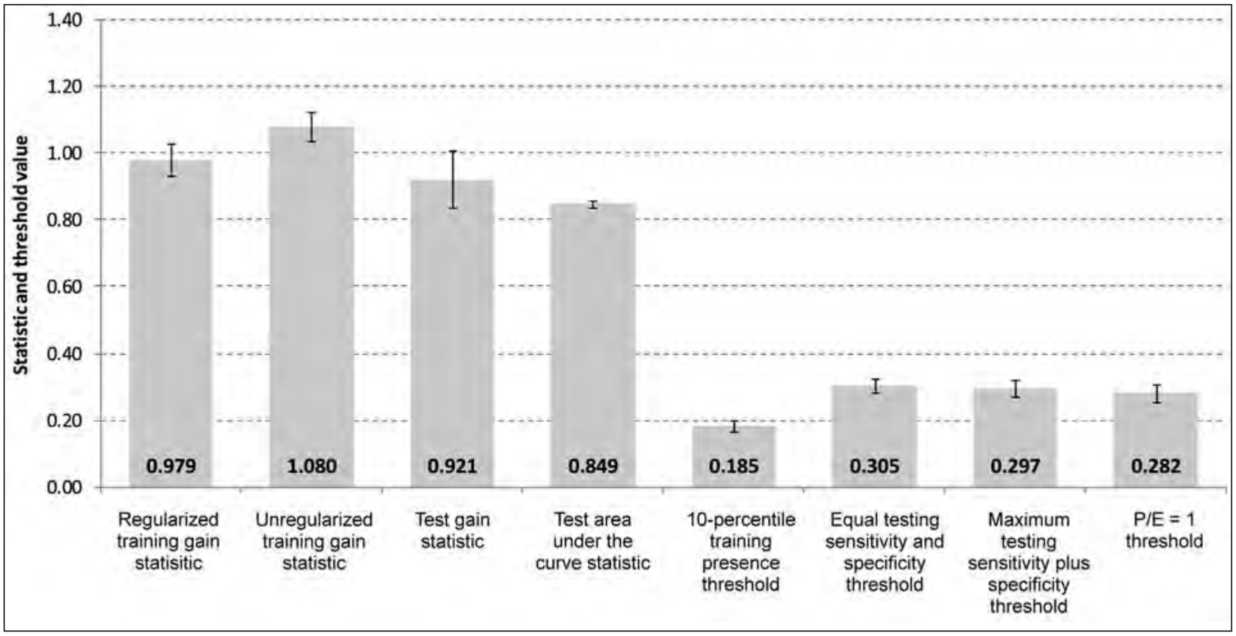

Figure C-8–Habitat modeling statistics produced during the MaxEnt model bootstrapped replicates for the Oregon Coast Range modeling region. Bars represent the mean statistic value, and error bars show the 95-percent confidence intervals. The first four bars represent model fit and discrimination statistics; the last four bars are common "thresholds" used to classify continuous habitat suitability models into binary maps of "not-suitable" and "suitable" habitat.

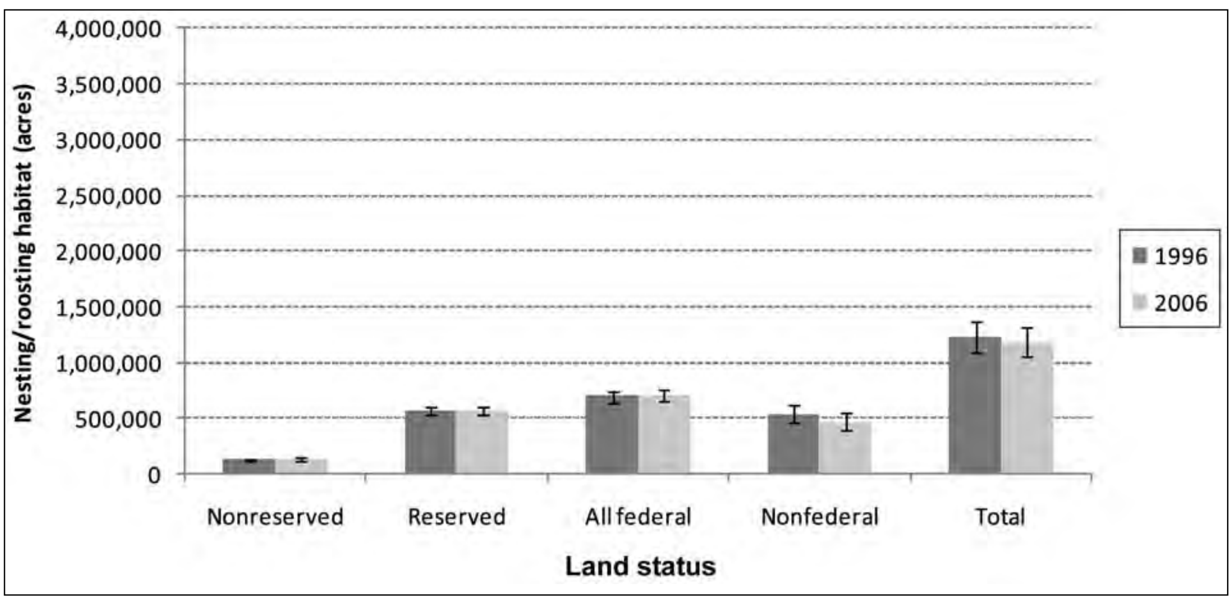

Figure C-9–Bookend habitat model area of suitable nesting/roosting habitat for northern spotted owls for the Oregon Coast Range modeling region. The bars represent the mean estimate of suitable habitat, and error bars show the 95-percent confidence intervals. This histogram shows net change (losses and gains) between 1996 and 2006.

Oregon and California Cascades Modeling Region (MR 224)

This modeling region conforms to the Oregon Cascades Douglas-fir ecological region used in the meta-analyses, and contains the H.J. Andrews and South Cascades demographic study areas. It encompasses the east and west Cascades provinces in Oregon and portions of the California Cascades province as delineated along level III ecoregion lines. Although there are differences between the east and west Cascades, our decision to lump them into one modeling region was based on how the east Cascades province was originally drawn to define the eastern margin of the owl's range, which extends into the larger eastern Cascades ecoregion (as delineated by the Environmental Protection Agency). This thin delineation represents the ecotone between the East and West Cascades, and not the entire East Cascades province. On the west slope, Douglas-fir and western hemlock give way to Pacific silver fir at midelevations, and mountain hemlock and subalpine fir (*Abies lasiocarpa* (Hook.) Nutt.) at high elevations. The east slope is covered by mixed-conifer and ponderosa pine forest at lower elevations, and true firs and mountain hemlock at higher elevations. The southern portion is mixed-conifer and pine forests in fire-adapted landscapes. Fire frequencies range from low to high along a north-to-south moisture gradient. Fire suppression has resulted in shifts in species composition and stand structure. About two-thirds of the land is administered by federal agencies.

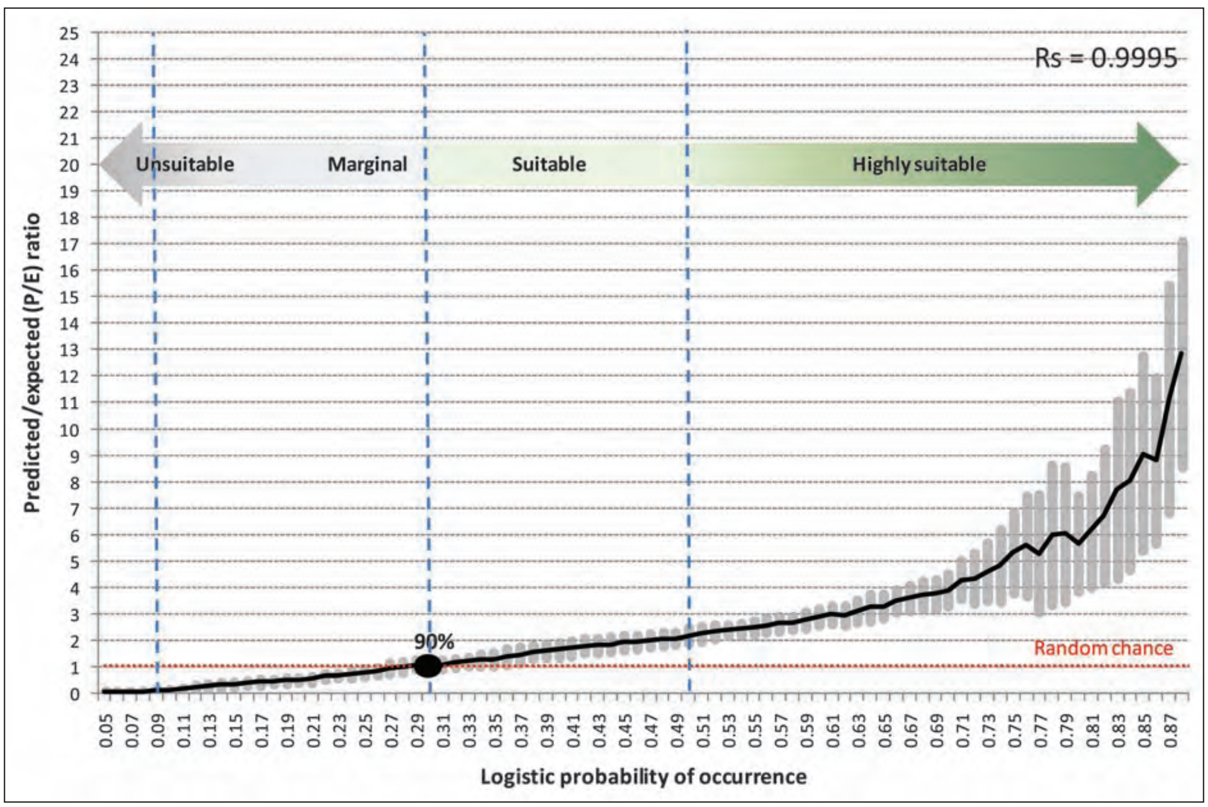

Figure C-10–The mean predicted vs. expected curve (solid black line) from the model replicates, showing 95-percent confidence intervals (gray-shaded vertical bars) for the Oregon and California Cascades modeling region. The logistic thresholds used to define the four-class habitat map are represented by vertical blue-dashed lines. The P/E = 1 threshold is where the curve crosses the random chance line (red-dashed line). The solid black dot represents the 10-percentile threshold (see fig. C-11 below) indicating where 90 percent of the training data (owl pair site centers) occured above that threshold. The mean Spearman rank correlation (Rs) is shown in the upper right-hand corner. See Hirzel et al. (2006) for more information.

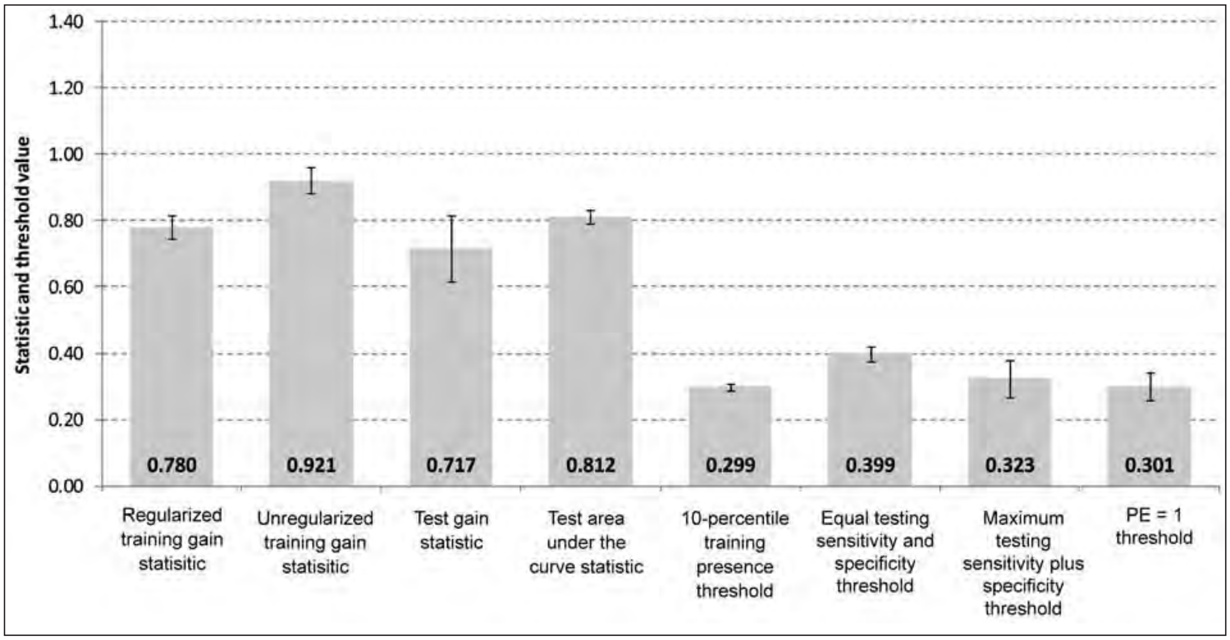

Figure C-11–Habitat modeling statistics produced during the MaxEnt model bootstrapped replicates for the Oregon and California Cascades modeling region. Bars represent the mean statistic value, and error bars show the 95-percent confidence intervals. The first four bars represent model fit and discrimination statistics; the last four bars are common "thresholds" used to classify continuous habitat suitability models into binary maps of "not-suitable" and "suitable" habitat.

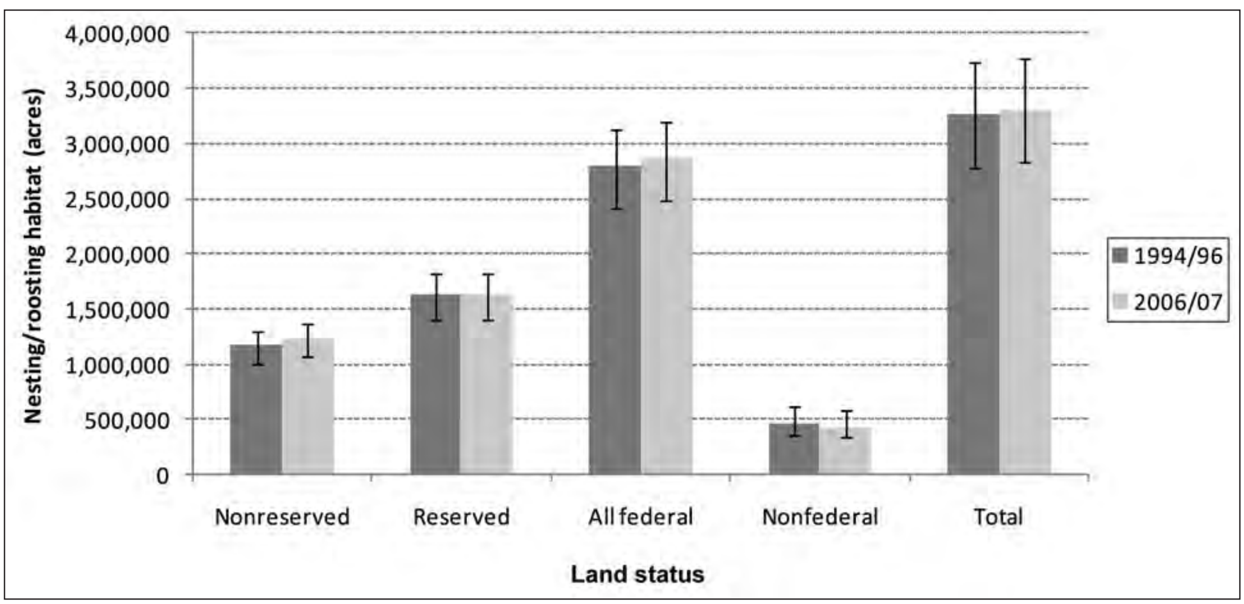

Figure C-12–Bookend habitat model area of suitable nesting/roosting habitat for northern spotted owls for the Oregon and California Cascades modeling region. The bars represent the mean estimate of suitable habitat, and error bars show the 95-percent confidence intervals. This histogram shows net change (losses and gains) between 1994/96 and 2006/07.

Oregon and California Klamaths Modeling Region (MR 225)

This modeling region conforms to the Oregon/California Mixed-Conifer ecological region used in the demographic meta-analyses, and contains the Klamath and Northwest California demographic study areas. It encompasses the Klamath physiographic provinces of Oregon and California. It is influenced by unique geologic conditions. In many areas, serpentine soils formed by the accretion of rocks onto the continent control the native vegetation, which is dominated by mixed-conifer and mixed-conifer and hardwood forest such as Douglas-fir mixed with tanoak (*Lithocarpus densiflorus* (Hook. & Arn.) Rehd.), and Pacific madrone (*Arbutus menziesii* Pursh). The region is characterized by historically high fire frequencies (≤35-year fire-return intervals), and fire suppression has resulted in areas with significant accumulations of fuel, shifts in species composition, and changes in stand structure. Forests are highly fragmented as a result of dry climate, poor soils, and past harvest practices, as well as ownership patterns, especially in areas of "checkerboard" ownership. Slightly over half of the province in Oregon is federally managed. In California, national forests cover about three-quarters of the region.

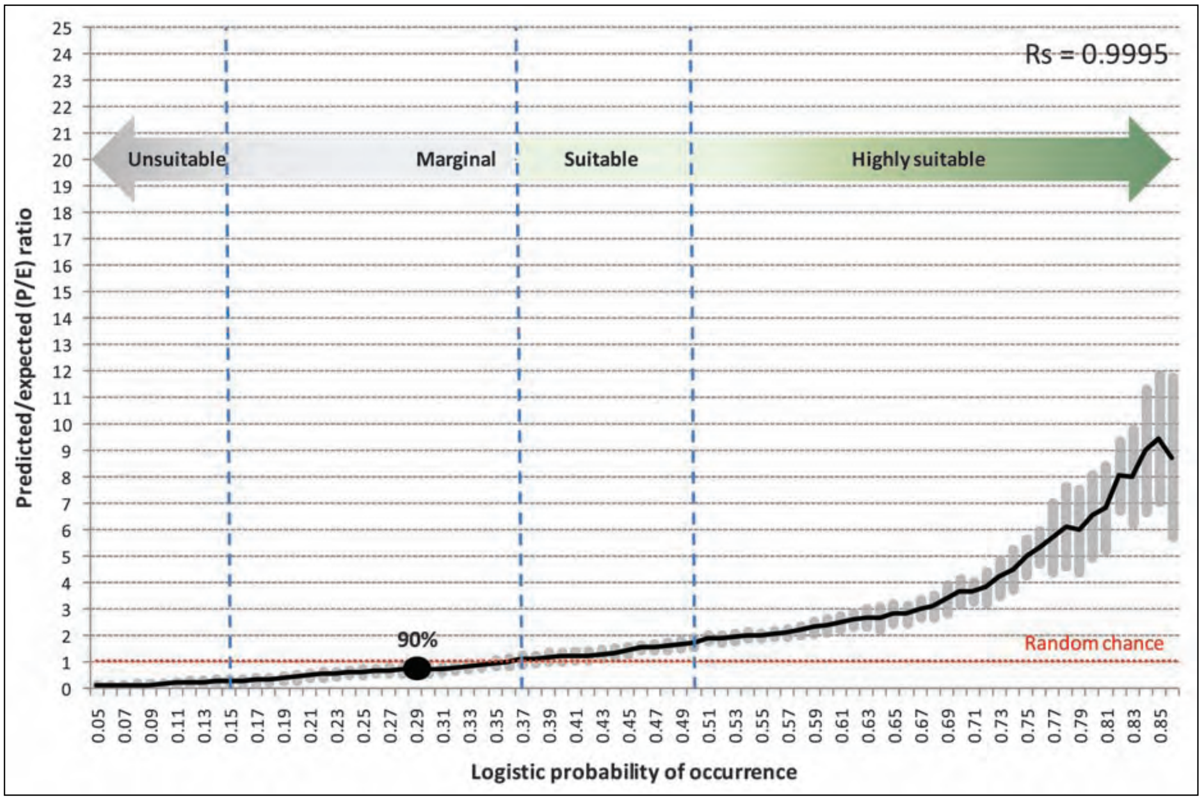

Figure C-13–The mean predicted vs. expected curve (solid black line) from the model replicates, showing 95-percent confidence intervals (gray-shaded vertical bars) for the Oregon and California Klamaths modeling region. The logistic thresholds used to define the four-class habitat map are represented by vertical blue-dashed lines. The P/E = 1 threshold is where the curve crosses the random chance line (red-dashed line). The solid black dot represents the 10-percentile threshold (see fig. C-14 below) indicating where 90 percent of the training data (owl pair site centers) occured above that threshold. The mean Spearman rank correlation (Rs) is shown in the upper right-hand corner. See Hirzel et al. (2006) for more information.

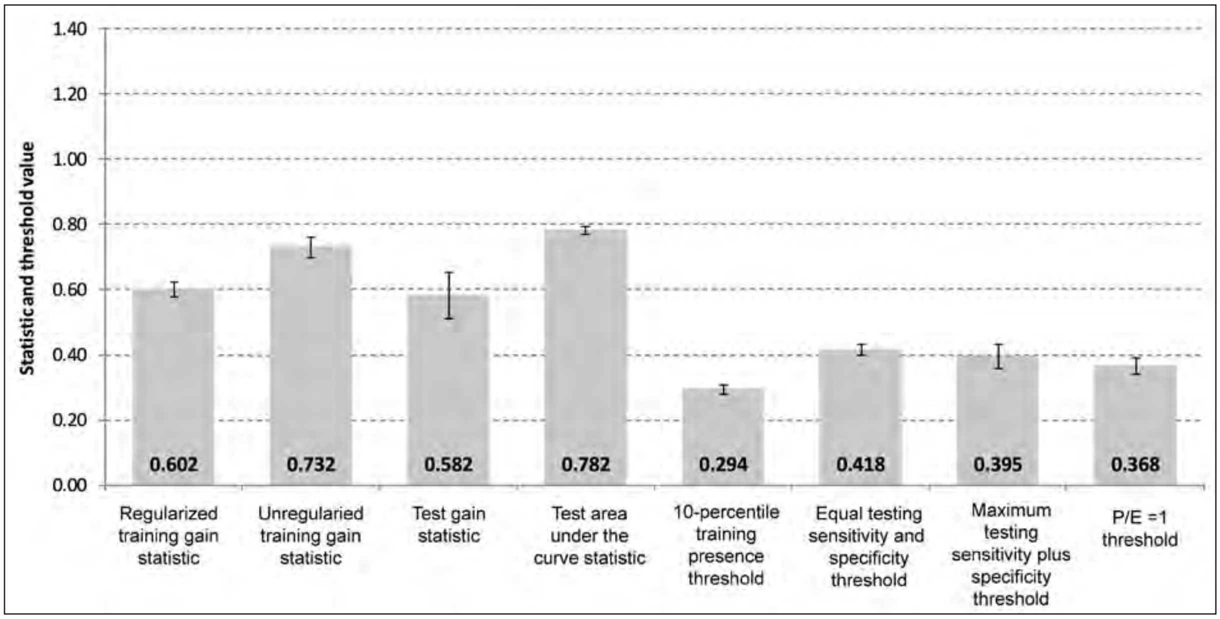

Figure C-14–Habitat modeling statistics produced during the MaxEnt model bootstrapped replicates for the Oregon and California Klamaths modeling region. Bars represent the mean statistic value, and error bars show the 95-percent confidence intervals. The first four bars represent model fit and discrimination statistics; the last four bars are common "thresholds" used to classify continuous habitat suitability models into binary maps of "not-suitable" and "suitable" habitat.

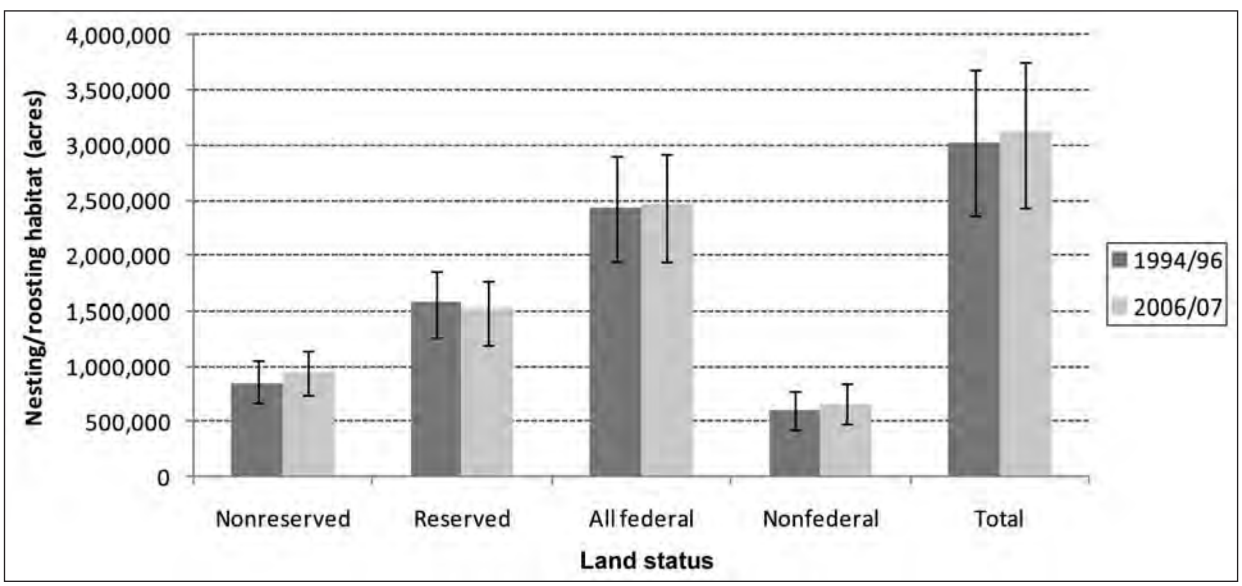

Figure C-15–Bookend habitat model area of suitable nesting/roosting habitat for northern spotted owls for Oregon and California Klamaths modeling region. The bars represent the mean estimate of suitable habitat, and error bars show the 95-percent confidence intervals. This histogram shows net change (losses and gains) between 1994/96 and 2006/07.

California Coast Modeling Region (MR 226)

This modeling region conforms to the California Coast ecological region used in demographic meta-analyses, and contains the independently operated Green Diamond Resources and Hoopa Reservation demographic study areas. It conforms to the California Coast Range physiographic province, extending slightly into coastal Oregon Klamath physiographic province to encompass the coastal redwood forests in that area. Moist, productive forests in the California Coast region are dominated by Douglas-fir and western hemlock, and contain most of the coastal redwood forests. The southeastern portion of this modeling region falls within the Central California Chaparral and Oak Woodlands ecoregion. Only a small proportion of the California Coast region is administered by federal agencies.

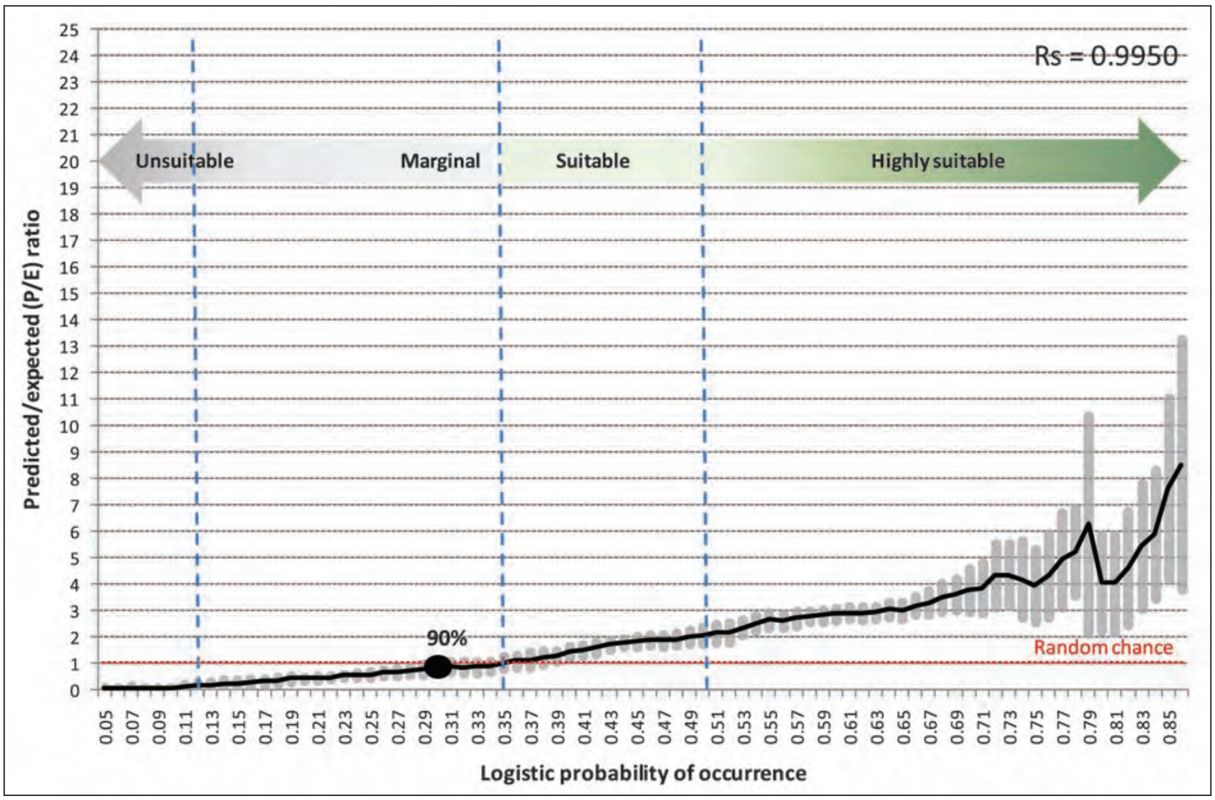

Figure C-16–The mean predicted vs. expected curve (solid black line) from the model replicates, showing 95-percent confidence intervals (gray-shaded vertical bars) for the California Coast modeling region. The logistic thresholds used to define the four-class habitat map are represented by vertical blue-dashed lines. The P/E = 1 threshold is where the curve crosses the random chance line (red-dashed line). The solid black dot represents the 10-percentile threshold (see fig. C-17 below) indicating where 90 percent of the training data (owl pair site centers) occured above that threshold. The mean Spearman rank correlation (Rs) is shown in the upper right-hand corner. See Hirzel et al. (2006) for more information.

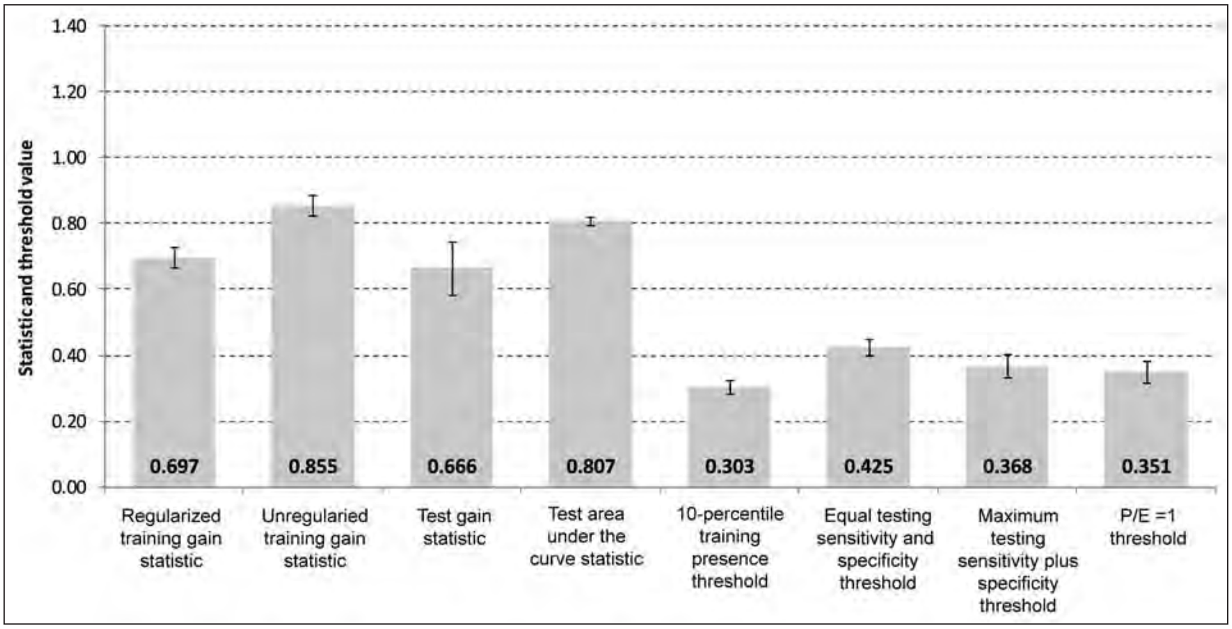

Figure C-17–Habitat modeling statistics produced during the MaxEnt model bootstrapped replicates for the California Coast modeling region. Bars represent the mean statistic value, and error bars show the 95-percent confidence intervals. The first four bars represent model fit and discrimination statistics; the last four bars are common "thresholds" used to classify continuous habitat suitability models into binary maps of "not-suitable" and "suitable" habitat.

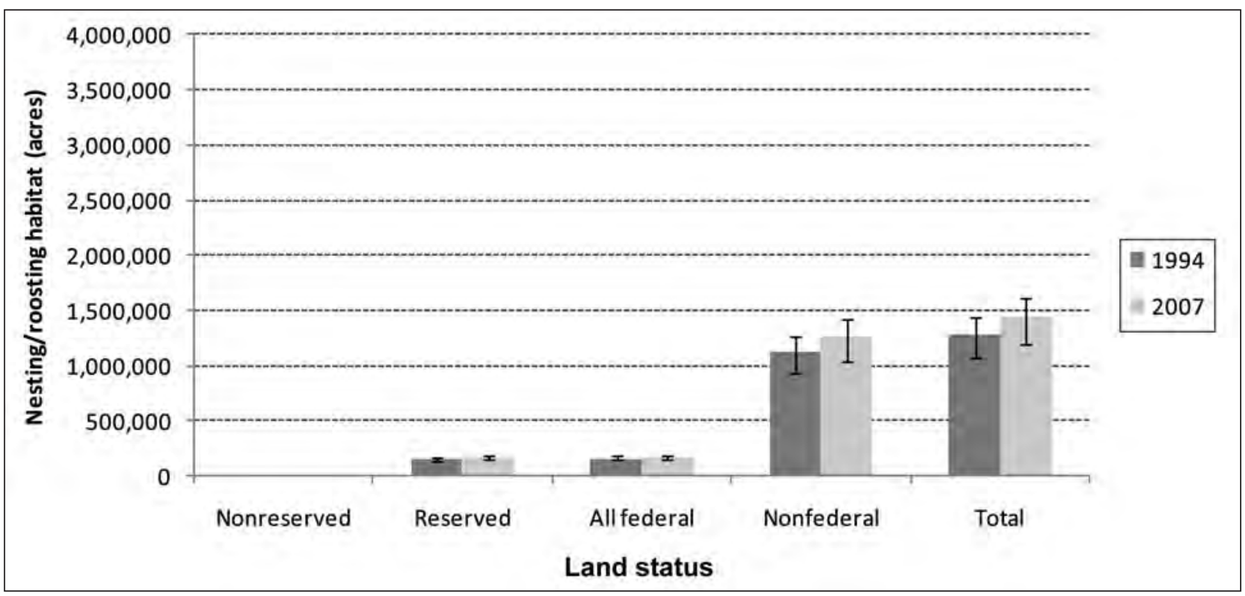

Figure C-18–Bookend habitat model area of suitable nesting/roosting habitat for northern spotted owls for the California Coast modeling region. The bars represent the mean estimate of suitable habitat, and error bars show the 95-percent confidence intervals. This histogram shows net change (losses and gains) between 1994 and 2007.

Appendix F: Crosswalk for Modifying Bookend 2 (2006/07) Map for Making Habitat Suitability Histograms

As discussed in chapter 3, we chose to not report on the highly suspect suitable habitat gains in nesting/roosting habitat for this monitoring cycle given the short timespan of our analysis and because of uncertainties with model transferability, bookend 2 (2006/07) map reviews with 1-m color aerial imagery Natonal Agricultural Imagery Program, geographic information system (GIS) analysis of model variable changes, and an inventory plot analysis (app. H). However, we anticipate that our ability to measure these gains will improve with the passing of more time to separate the bookend maps, and with improved remote sensing technologies. This appendix presents the following table to describe the crosswalk we used for creating a modified bookend 2 map for the purpose of making "habitat suitability histograms" to help visualize shifts in habitat classes between bookend 1 (1994/96) and bookend 2. This approach is similar to what was done in the 10-year report, where we had only a baseline map and change-detection data to estimate habitat changes. The habitat suitability histograms on the following pages are formatted to be similar to the histograms in appendix G of the 10-year report. The modified bookend 2 map (as described below) is our best estimate of habitat classes as of 2006/07. It is conservative in nature, as it maintains suitable habitat classes (3 and 4) from bookend 1, and only shows loss in these suitable classes **if** verified by LandTrendr (LT) data. We allow for minor shifts within habitat classes that may represent subtle changes but do not result in a change between the broader categories of "unsuitable/marginal" (i.e., classes 1 and 2) and the "suitable" classes (i.e., classes 3 and 4).

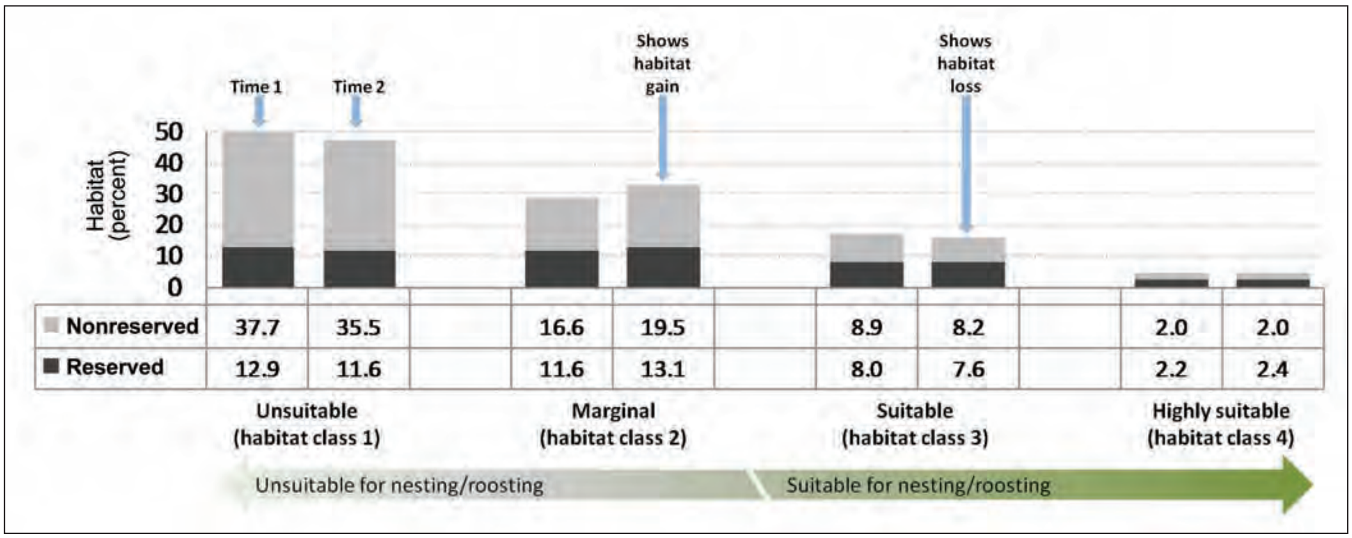
Table F-1–Crosswalk table for modified bookend 2 map

Bookend model habitat classes 1994/6	Bookend model habitat classes 2006/7	Assumptions (based on aerial image review and GIS analysis of environmental variables)	Modified 2006/07 habitat class (modified bookend 2)
1	1	Not suitable either period; no change	1
1	2	Not suitable either period; accept shift from unsuitable to marginal	2
1	3	Trend toward suitable, but highly uncertain gain; limit shift to marginal class	2
1	4	Trend toward suitable, but highly uncertain gain; limit shift to marginal class	2
2	1	Not suitable either period; accept shift from marginal to unsuitable	1
2	2	Not suitable either period; no change	2
2	3	Trend toward suitable, but highly uncertain gain; keep in marginal class	2
2	4	Trend toward suitable, but highly uncertain gain; keep in marginal class	2
3	1	If LT[a] verified habitat loss, moved to unsuitable; otherwise no change	1 if LT verified, otherwise 3
3	2	If LT verified habitat loss, moved to marginal; otherwise no change	2 if LT verified, otherwise 3
3	3	Suitable habitat both periods; no change	3
3	4	Suitable habitat both periods; accept shift to highly suitable	4
4	1	If LT verified habitat loss, moved to unsuitable; otherwise no change	1 if LT verified, otherwise 4
4	2	If LT verified habitat loss, moved to marginal; otherwise no change	2 if LT verified, otherwise 4
4	3	Suitable habitat both periods; accept shift to suitable (degraded)	3
4	4	Suitable habitat both periods; no change	4

[a] LT = LandTrendr.

GIS = geographic information system.

The histograms on the following pages establish the format we propose for visually representing status and trends in habitat classes for future monitoring efforts. They are based on habitat conditions at roughly the time of the Northwest Forest Plan (the Plan) implementation (1994/96) to the end of our analysis data set in 2006/07. There are four pairs of histogram bars, one pair per habitat suitability class as described in chapter 3. The first bar in the pair shows conditions at time 1 (1994/96); the second bar shows conditions at time 2 (2006/07), based on our modified bookend 2 map. They also provide a visual on how owl habitat is distributed across reserved and nonreserved federal lands. The example histogram below is provided to help interpret the histograms provided for each physiographic province in the following pages.



In the example above, we observe a slight decrease (3.5 percent) in unsuitable habitat class 1 between time 1 and time 2. We also observe a slightly larger (4.4 percent) increase in marginal habitat class (but still unsuitable for nesting/roosting). There has been a slight decrease in the suitable habitat class 3 (1.1 percent) with a very slight (0.2 percent) increase in the highly suitable habitat class. We can conclude that forest succession in habitat class 1 accounted for most of the increase in habitat class 2, but some of the loss in habitat class 3 may have also accounted for some of the changes in habitat class 2, or perhaps offset some of the decrease in habitat class 1. The slight increase in habitat class 4 may be a result of changes in habitat class 3, as seen in the plot analysis (app. H) where there may have been some subtle changes. However, this does not result in a change in the broader "suitable" class. The simplest interpretation indicates that the increase in the marginal habitat class (class 2) will continue to progress to the suitable classes with time. This province has very little suitable nesting/roosting habitat.

The table under the graphs shows the estimates of percentage of forest-capable land changes between habitat maps for both periods. The percentages are split into nonreserved and reserved land use allocations. The following graphs illustrate our best estimate of how habitat is changing (trending) at this early stage of the Plan. These graphs are primarily for interpretive purposes. The observed change between the bookends is small, with the largest changes being increases in the marginal classes. We observed similar changes in dispersal habitat (see chapter 3) and consider this an indication of noticeable future recruitment from marginal to suitable habitat within the next two to three decades.

Appendix H: Regional Inventory Plot Analysis

Carol A. Apple[a] and Raymond J. Davis[b]

PLOT ANALYSIS

An analysis of regional vegetation inventory plots was performed to determine if there have been significant gains in northern spotted owl (*Strix occidentalis caurina*) nesting/roosting habitat since monitoring was implemented. We used plot data from the Current Vegetation Survey (CVS) inventory program on USDA Forest Service (FS) and USDI Bureau of Land Management (BLM) lands in Oregon and Washington. Forest Inventory and Analysis (FIA) program data were used for FS lands in California. Data were not available for USDI National Park Service lands or BLM lands in Washington or California.

The CVS inventory provides comprehensive information on vegetative resources on FS lands in Oregon and Washington and BLM lands in the Northwest Forest Plan area in Oregon. The CVS plots consist of four grids of field plots that are separated by 3.4 mi on a north-south, east-west direction. These four inventory grids are offset from one another to produce one single 1.7-mi grid of plots across BLM lands and FS lands, except in wilderness areas where the grid density is 3.4 mi. The FIA plots for FS lands in California are also distributed geographically on a 3.4-mi grid. For specific information on the attributes that are collected on FS lands, refer to the Web sites: http://www.fs.fed.us/r6/survey/ and http://www.fs.fed.us/r5/rsl/projects/inventory/InvInfo.shtml. Refer to pages 31–36 in Moeur et al. (2005) for additional discussion of the CVS and FIA.

A spotted owl nesting/roosting habitat query was developed (table H-1) that is similar to what was used in the 10-year report (Davis and Lint 2005). There were differences that included:

- Use of a slightly different set of plots
- Summarized data at the plot level vs. subplot level
- Top story quadratic mean diameter for only conifer and not all species
- Use of a different strata attribute

These differences were made to adjust to the new gradient nearest neighbor variables used for the spatial habitat modeling (see chapter 3, this report). The intent of this analysis was to explore for differences in "query group" acres between the initial measurement and remeasurement period, and not for differences between the 10-year report map results and this report's map results. In addition, the results of this analysis should not be compared to the results of the 10-year report plot analysis.

On Pacific Northwest Region FS lands, nearly all CVS plots have had two samples, but on Oregon BLM lands, only one-quarter of the original CVS plots had been remeasured at the time of this analysis. Based on the numbers of plots for each year of measurement, the weighted average year for initial plot measurements in Oregon and Washington was 1995 for initial plot measurements and 2002 for remeasurements. For California, the plot measurement period spans 1997 to 2005. The first inventory in California was conducted under the older FIA "periodic" sample design. This protocol was replaced by FIA's "annual" sample design, which was used for the plot remeasurments. This change in inventory protocol confounds inferences on habitat changes in California, as "real" change cannot be separated from effects related to changing sampling protocols (see Moeur et al. 2011) for more discussion.

As in the 10-year report, the "query groups" in table H-1 represent a progression of stand conditions, based on conifer diameter, total canopy cover, and stand structure complexity (strata) that represent habitat similarity to conditions used by spotted owls for nesting and roosting. A query was applied to both the initial measurement and remeasurement plot data in each physiographic province that occurred within the "habitat capable" areas described in Davis and Lint (2005) to assign a group code to each plot. In addition to the six groups in table H-1, two combined groups of EF and DEF were also assigned.

Table H-1—Forest stand condition query for Current Vegetation Survey plot data

	Low <------- Spotted owl nesting/roosting habitat similarity -------> High					
	Query group					
Query attributes	**A**	**B**	**C**	**D**	**E**	**F**
Query part 1:						
Quadratic mean diameter (inches)	<10.5	≥10.5	10.5–20.5	10.5–20.5	≥20.5	≥20.5
Canopy cover (percent)	All	≤40	>40	>40	41–70	>70
Strata	All	All	1	≥2	≥2	≥2
Query part 2:						
Quadratic mean diameter (inches)	NA	NA	NA	≥20.5	NA	NA
Canopy cover (percent)				>40		
Strata				1		

An analysis was then done using the jackknife method to estimate the variance of mean acres for each query group by measurement period and province. The variance was used in performing a t-test to look at the differences in the means between the two periods. This test assumes independence between the two samples, but in reality many of the plots were remeasured. Taking that into consideration, this test provided conservative results for significance: if it is significant, it is very significant.

The results of this analysis did not show any evidence of significant habitat recruitment into classes EF or the broader class DEF. There were some significant decreases in class E, but these were concurrent with significant increases in class F; therefore, these changes “cancelled” each other out, resulting in no significant change in the EF group. Significant, decreases in EF and DEF were observed in the California Cascades and Klamath Mountain provinces (table H-4); however, as stated above, the change in protocol used to collect plot information in California confounds this inference. The histograms on the following page display the results of the plot analysis for each physiographic province with significant amounts of federal lands. The results of the t-test are shown in tables H-2 thru H-4.

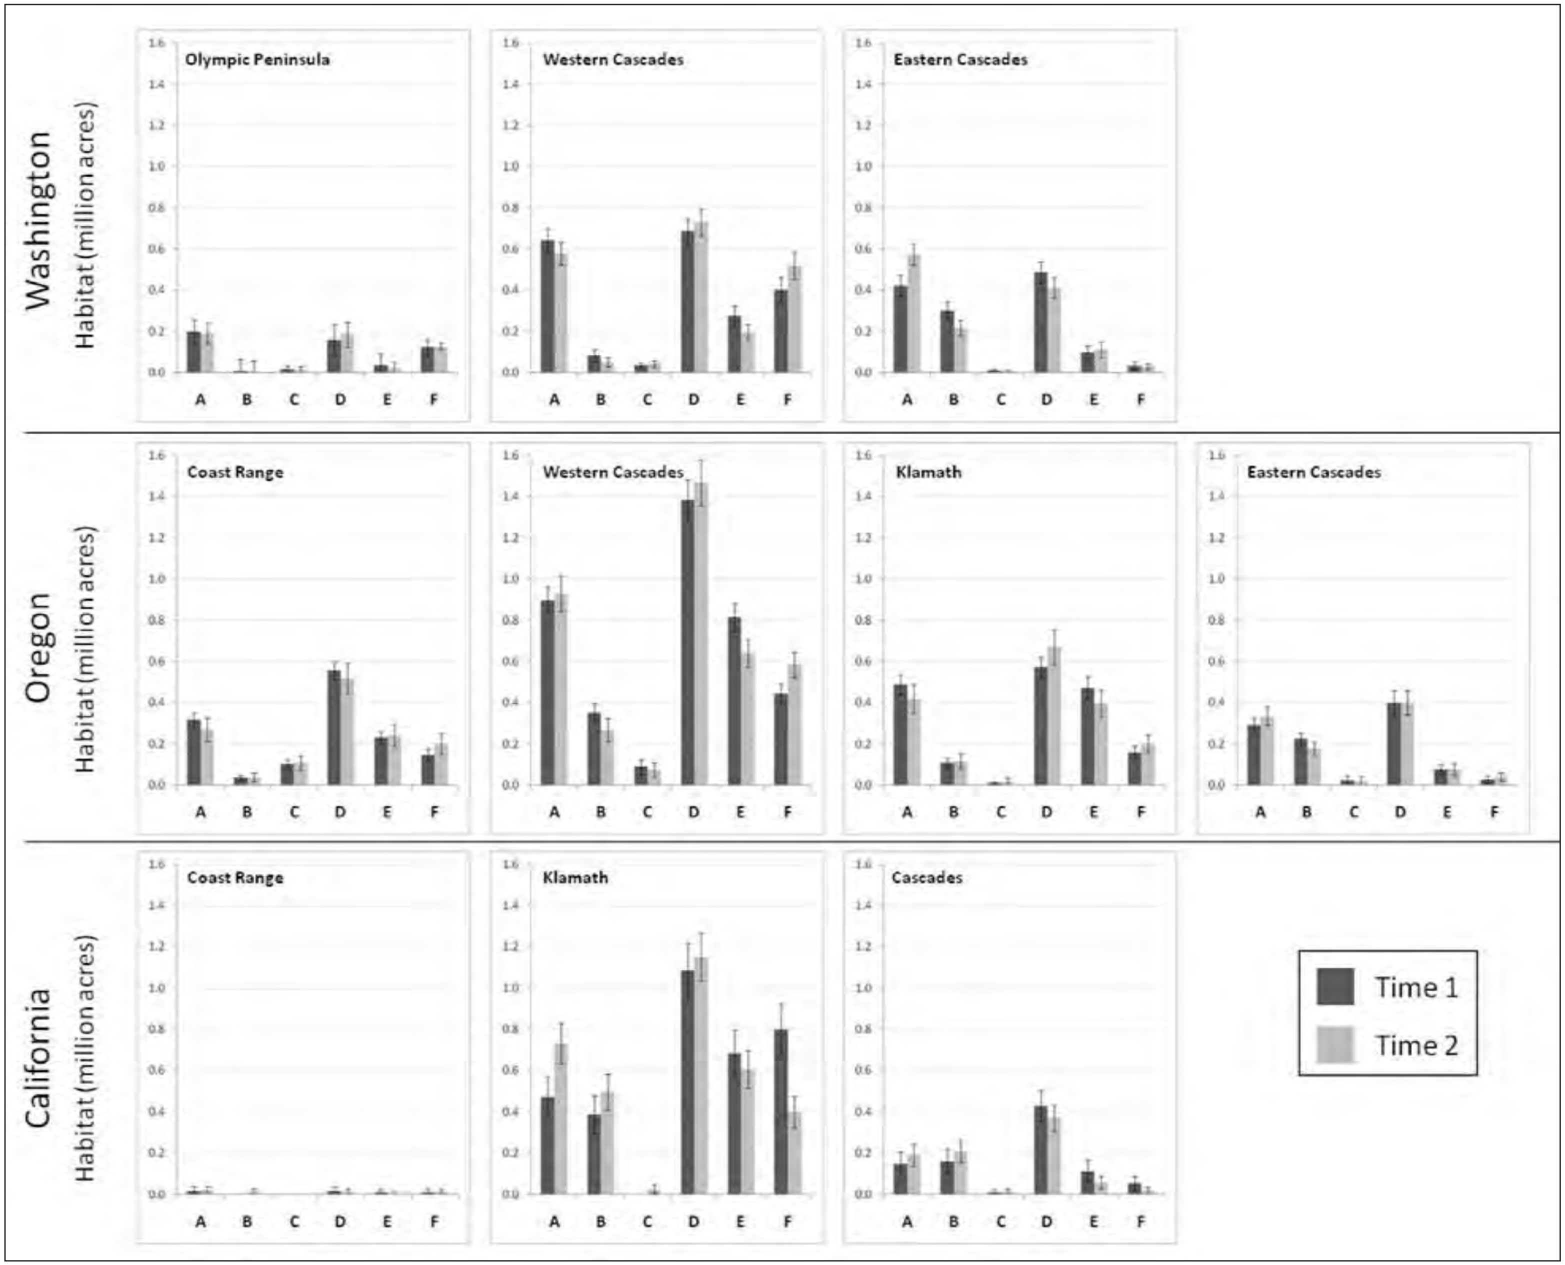

Figure H-1—Habitat changes between plot measurement periods (Time 1 = 1995 to 1997 and Time 2 = 2002 to 2005). Histrograms represent estimate of mean acres with 90-percent confidence intervals for each period.

Subject: Technical Assistance for Sierra Pacific Industries 2013 Proposed Survey Modification Request

Dear Mr. Bacca:

This is in response to your request for U.S. Fish and Wildlife Service (Service) technical assistance, dated and received in this office on February 20, 2013. Jan Johnson, of my staff, discussed preliminary information pertaining to this request with you, other CAL FIRE staff, and Sierra Pacific Industries' (SPI) staff on February 6, 2013. Subsequent to that meeting, drafts of this request were reviewed by the Service; your February 20, 2013, request incorporates our comments. At issue is the potential for incidental take of the federally listed northern spotted owl *(Strix occidentalis caurina)* (NSO) as a result of modifying NSO survey requirements in 2013 in specified areas of SPI ownership. Our review is based upon information provided with this request, along with outcomes of your recent reyiews of SPI survey data. After reviewing this information, the Service offers the following technical assistance.

Background

SPI's proposal pertains to minor modifications to NSO survey methodology and a request for clarification of pre-operation "Spot Check Surveys", as defined by the 2011 NSO Survey Protocol, revised January, 2012 (2012 Protocol, USDI 2012). This technical assistance applies to the lands managed by the SPI Weaverville District, excepting twelve legal sections, as identified in your request (Attachment 1).

Habitat Conditions

Existing landscape conditions is an important consideration when evaluating requests for survey modifications. Numerous prior technical assistance requests, field reviews by Service staff, and SPI's NSO habitat classification system, using the parameters as described by the Service (USDI

'J.&1

2009), have determined that SPI's landscape is dominated by habitats considered to provide foraging and 10\quality foraging habitat. Suitable nesting/roosting (Nhabitat on SPI managed lands is much more limited. As described in your request, SPI will continue to evaluate NSO habitat suitability in a 1.3 mile area around each Timber Harvest Plan (THP) proposing to affect suitable NSO habitat and will continue to survey all suitable habitat within 1.3 miles of SPI ownership.

Survey History

The survey history of a landscape is also an important consideration when evaluating alternative approaches to survey strategies. Project-level NSO surveys have been conducted on SPI lands since the early 1990's. Landscape-level surveys on SPI's Weaverville district were conducted from 2003-2007. Starting in 2010, through the present SPI has been surveying suitable habitat 1.3 miles from their ownership boundaries. Additionally, SPI has recently obtained a Recovery Permit (USDI Permit #TE80705A-O) for an ownership wide NSO banding program. During these same time periods adjacent federal and non-federal landowners have also conducted surveys and these available data will be reviewed by SPI as part of development of new THPs. The combination of surveys between SPI and other adjacent landowners and their review and analysis will maximize the knowledge ofNSO locations relative to proposed THPs.

Proposed Survey Modification for the 2013 Survey Season

When operations are within 1.3 miles of current or historical (known) NSO activity centers or barred owl responses, the Service concurs that operations proposed within unsuitable or LOW QUALITY foraging (LQF) habitat (USFWS 2009) may occur between February 1 and March 15 or concurrent with, landscape level surveys in 2013 provided:

a) No operations will occur within 0.5 mile of known NSO Activity Centers, during the breeding season, until location and reproductive success is determined or complete reproductive survey efforts following Section 17.0 of the 2012 protocol have yielded negative results.

b) If operations are within LQF or unsuitable habitat between 0.5 and 1.3 miles of known NSO Activity Centers *have not* commenced prior to February 1, and occur within 0.25 mile of high quality foraging or nesting/roosting habitat, operations *shall be* delayed. SPI Weaverville District must complete one of the three visits of all survey stations within 0.25 mile of the subject unit(s) prior to operations. The survey stations are those that have been previously reviewed and accepted by CAL FIRE. All NSO responses must be followed with survey methodology described in Section 10.3 of the 2012 protocol.

Spot Check Clarification

The Service and CAL FIRE have determined that the current landscape level surveys meet the intent of the 3rd and 4th year "spot check" surveys provided SPI:

- Maintains complete annual survey coverage of all suitable habitat out to 1.3 miles of SPI boundaries,

- Maintains annual Activity Center Searches (ACS) (2012 protocol) on known NSO out to 1.3 miles from SPI boundaries or ACS·will be coordinated with adjacent landowners.

Based on the above information on habitat conditions, survey history, known NSO locations and barred owls within and adjacent to the survey areas, the Service concurs that the above methodology is consistent with the intent of the 2012 Protocol, and that the likelihood of take of NSO is not likely to occur.

All data used to provide this technical assistance are on file at this office. If you have questions please contact Jan Johnson, Fish and Wildlife Biologist, at (530)841-3102 or janjohnson@fws.gov.

Sincerely,

EJ Willi
Field Supervisor

Regulatory and Scientific Basis for U.S. Fish and Wildlife Service Guidance for Evaluation of Take for Northern Spotted Owls on Private Timberlands in California's Northern Interior Region

Introduction

In 1999, the California Department of Forestry and Fire Protection (CALFIRE) requested that the U.S. Fish and Wildlife Service (FWS) review timber harvest plans (THP) and Non-industrial Timber Management Plans to ensure that such plans would not result in incidental take of northern spotted owls (NSO). For nearly a decade, the FWS provided this technical assistance. At first, the criteria and thresholds employed by the FWS to make our take evaluations were based on habitat retention regulations in the California Forest Practice Rules (Title 14, California Code of Regulations) (FPRs), which were originally developed collaboratively by the FWS, California Department of Fish and Game (CDFG), CALFIRE, and the California Board of Forestry. However, as knowledge of the habitat relationships of this species increased after 1992, the FWS increasingly made use of new scientific information to guide our evaluations of the potential for incidental take. The accumulation of published research results, combined with direct field experience with management of NSO and their habitat, resulted in substantial changes in the quantity and quality of habitat the FWS considered necessary to maintain continued occupancy and reproduction at NSO territories.

In 2008, the FWS returned responsibility for THP review to CALFIRE, the authorized agency under the California Environmental Quality Act. As a part of this transfer, the FWS provided CALFIRE with documentation of the criteria and thresholds currently used by the FWS in making take evaluations. This documentation, hereafter called the FWS guidelines, represents the best scientific information available to the FWS upon which to base evaluations of the likelihood of incidental take resulting from timber harvest operations in the Northern Interior Region. The FWS guidelines are not regulations and are not intended to substitute for regulations; they do, however, provide the scientific and biological foundation for reviewing proposed projects and determining the likelihood of incidental take of NSO. In this report, we provide the scientific basis for the FWS guidelines.

The habitat descriptions within the FWS guidelines were developed to enable CALFIRE personnel (who may not have extensive experience with NSO biology and habitat associations) to evaluate the likelihood of take posed by a proposed THP. This process contrasts with the technical assistance process formerly conducted by the FWS, wherein NSO experts conducted detailed evaluations of stand structure, habitat quantities, and NSO survey results to support a determination of the likelihood of take. While the FWS believes that expert review should play a central role in these evaluations, it is also true that robust habitat retention guidelines may be used to avoid take. Application of habitat retention guidelines in the absence of expert review, however, may limit managers' flexibility to classify habitat based on specific local conditions and to design harvest proposals based on these conditions.

Evaluation of the scientific bases of the FWS guidelines for NSO in the Interior Region of California (Klamath Province) is dependant on understanding the concept and regulatory definition of take, the practical and operational considerations of determining the likelihood of take, and the information supporting our conclusion that existing habitat guidelines in the FPRs are not sufficient for avoiding take. It is also important to recognize the difference between the use of habitat guidelines in the determination of take versus descriptions of desired habitat conditions for conservation of NSO.

Section I: Regulatory and operational aspects of take evaluation guidelines

A. Regulation and definition of take under Endangered Species Act

Regulatory Authority

Section 9(a)(B) of the Endangered Species Act of 1973 (ESA) prohibits the take of listed species within the United States, except as provided in section 10 of the ESA, which allows for permitted incidental take on private lands. Section 9 is intended to protect individual members of listed species.

Regulatory definition of take

The ESA defines "take" as "…to harass, harm, pursue, hunt, shoot, wound, kill, trap, capture, or collect, or attempt to engage in any such conduct." The term "harm" is further defined in 50 CFR 17.3:

> "Harm" in the definition of "take" in the Act means an act which actually kills or injures wildlife. Such act may include significant habitat modification or degradation where it actually kills or injures wildlife by significantly impairing essential behavioral patterns, including breeding, feeding, or sheltering.

Process for estimating the likelihood of incidental take and establishing habitat retention guidelines

Although the regulatory definition of take clearly expresses the intent of the ESA's Section 9, it does not provide any metrics or criteria upon which a determination of take should be made. Because our reviews of proposed projects under section 9 are typically conducted prior to project implementation, our determination is an estimate of the likelihood of take, based on the predicted effects of the project. Habitat retention guidelines such as those in the FPRs are intended to provide guidance as to the amount and quality of habitat that must be retained in order to avoid incidental take of NSO at sites where the species is known to occur. When the FPR guidelines were adopted in 1992, data relating habitat variables to occupancy, reproduction, and survival of NSO were limited. The FPR guidelines for avoiding incidental take of NSO were therefore based on comparison of proposed post-harvest habitat conditions with the amount and quality of habitat observed at occupied NSO sites described in various studies. Under this standard, habitat modification potentially could result in substantial reduction of reproduction, survival, and occupancy at NSO activity centers without the appearance of take, because habitat conditions still resemble other lower-quality NSO territories. NSO are known to occupy low-quality sites where their reproduction and survival are substantially reduced (Franklin *et al*. 2000, Dugger *et al.* 2005); the existence of these low-quality sites suggests that reliance on habitat conditions corresponding to the presence or absence of owls at historic territories represents a low bar for determining habitat thresholds and take.

Recent results from demographic studies of NSO in the Klamath Province provide new insights into the relationships between habitat and NSO population rates (e.g., occupancy, reproduction, and survival). By developing predictive models of these relationships, Franklin *et al*. (2000) and Dugger *et al*. (2005) introduce the concept of habitat fitness potential (HFP); "the fitness conferred on an individual occupying a territory of certain habitat characteristics" (Franklin *et al.* 2000:558). Habitat fitness potential is a function of both the survival and reproduction of individuals within a given territory. Evaluation of habitat parameters influencing these rates provides a more rigorous measure of "significant impairment of essential behavioral patterns such as breeding, feeding, or sheltering" that is readily incorporated into review of timber harvest plans. By incorporating the concept of HFP, the FWS can evaluate the predicted effects of habitat modification on fitness of NSO potentially affected by a project. Evaluation of incidental take based on habitat modification that measurably and significantly reduces the fitness of NSO within the project area (as estimated by HFP models) provides a quantitative element to our estimation of "significant impairment of breeding, feeding and sheltering" in Section 9 of the ESA. Furthermore, HFP models also provide information allowing determination of significant thresholds that may occur, such as average habitat conditions corresponding to HFP < 1.0 (territorial pair not replacing themselves).

Description of the structural characteristics of NSO habitat and delineation of the range of habitat conditions corresponding to essential activities such as nesting, roosting, and foraging is a critical element of developing guidelines for evaluating the likelihood of incidental take. Determination of the amount of suitable habitat that must be retained in order to avoid incidental take of NSO is strongly influenced by the range of forest conditions that are classified as suitable habitat. The HFP models of Franklin *et al.* (2000), Olson *et al.* (2004), and Dugger *et al.* (2005) contain a limited number of habitat variables and relatively coarse definitions of NSO habitat, and therefore must be supplemented with additional information on forest structural parameters that support classification of forest habitat as suitable for nesting and foraging. Because the structural attributes of habitat immediately surrounding nests are easily quantified, data supporting classification of nesting habitat are readily available (see section III.C). Foraging habitat, on the other hand, is more variable and spatially extensive, requiring intensive radio-telemetry studies to measure use of various habitat conditions by NSO. In recent studies by the National Council for Air and Stream Improvement (NCASI), correlations between habitat data from detailed forest inventories and nocturnal locations of radio-tagged NSO and California spotted owls were used to estimate resource selection function (RSF) models (Irwin et al. 2007a,b) that quantify complex relationships between the owls and their environment. These models allow evaluation of the relative use of specific forest structural variables, such as tree size class distribution and stand density, by foraging NSO. The studies of Irwin *et al.* (2007), combined with other telemetry studies (Solis and Gutierrez 1990), provide the basis of our definitions of suitable foraging habitat for NSO in the Northern Interior Region.

Criticism of the THP review process is frequently focused on the use of "thresholds" that simplify complex gradients of habitat quality into a single value (e.g., 40% suitable habitat within 1.3 mile radius, or 185 ft^2 of basal area). The FWS has long recognized that many different combinations of habitat structure and amount may support a viable NSO territory; evaluation of these combinations by technical experts has been our primary role in technical assistance. However, to maintain consistency and incorporate new information it is necessary to implement unambiguous habitat standards and criteria (i.e., thresholds) that delineate conditions under which take is deemed unlikely. Thresholds do not represent arbitrary lines through consistent data sets; rather, they represent the preponderance of evidence derived from careful evaluation of the results and conclusions of many published studies, supplemented by data sets from credible sources.

Derivation of habitat thresholds from published studies consists of two consecutive steps. First, we consider the relationship or trend between habitat features and spotted owls. For example, most studies show that habitat use by foraging NSO is positively correlated with increasing tree size. These consistent, statistically significant relationships then serve as the foundation for subsequent choice of habitat values that correspond with viable NSO territories. We emphasize habitat parameters that receive disproportionate use by NSO, or are correlated with fitness. In this second step, we evaluate the pattern and distribution of data from a wide range of sources and attempt to identify ranges of values that correspond to consistent use. Deriving the central tendencies within complex, inconsistent data is a difficult task, and often requires input from the researchers responsible for published studies.

Despite consistent patterns of habitat selection by NSO, structural conditions of forest habitats occupied by NSO are highly variable, particularly in the diverse conifer-hardwood forests of the Klamath Province. We recognize that habitat retention guidelines must incorporate the range of habitat conditions used by NSO for nesting, roosting, and foraging, while at the same time ensuring that habitat conditions are not degraded to the point where significant impairment of breeding, feeding, and sheltering occurs. The FWS guidelines achieve this balance and provide a robust method for evaluating the likelihood of take because they describe a range of habitat conditions representing the central tendency for high-quality nesting habitat, nesting roosting habitat, foraging habitat, and low-quality foraging habitat that may provide prey resources (Fig. I.A.1).

Canopy	100%	80%		60%	40%
WHR size[4]	← 4 →				
WHR density	← D →			← M →	

[1] Square feet per acre, [2]Quadratic Mean Diameter of trees >5”dbh, [3] Trees per acre greater than 26” diameter at breast height, [4] California Wildlife Habitat Relationships System

This process must be distinguished from the simple application of “minimum habitat standards” that correspond to the lowest denominator of observed habitat use. To illustrate this, Figure I.A.1 depicts the relationship between California Wildlife Habitat Relationships system (WHR) class 4M and relative use of habitat by NSO. The FPRs classify 4M stands as suitable for nesting, roosting, and foraging by NSO. Although 4M encompasses a wide range of stand conditions, some of which may be suitable as foraging habitat, it largely consists of stand conditions rarely used by NSO. For this reason, the use of existing minimum habitat standards such as those currently in the FPRs may result in take of NSO and are insufficient for programmatic use in take avoidance reviews of THPs.

B. Evidence indicating that regulatory guidance in the current Forest Practice Rules is not adequate to avoid incidental take of NSO

New information available

The current FPRs governing habitat retention for NSOs were developed in 1992 and predate much of the published research used in the FWS guidelines. In particular, studies correlating habitat and NSO fitness measures, and radio-telemetry studies of habitat use by foraging NSO (Irwin *et al*. 2007b) provide information directly applicable to evaluation of timber harvest-related impacts to NSO. During the past decade, the FWS has incorporated the results of new research into Technical Assistance on a plan by plan basis. However, with the February 2008 return of THP review to CALFIRE, the large number of recently published studies requires that a full synthesis of current knowledge be conducted and incorporated into updated take evaluation guidelines. This synthesis, and the habitat retention guidelines that it supports, are presented in section III of this report.

FWS experience in technical assistance process

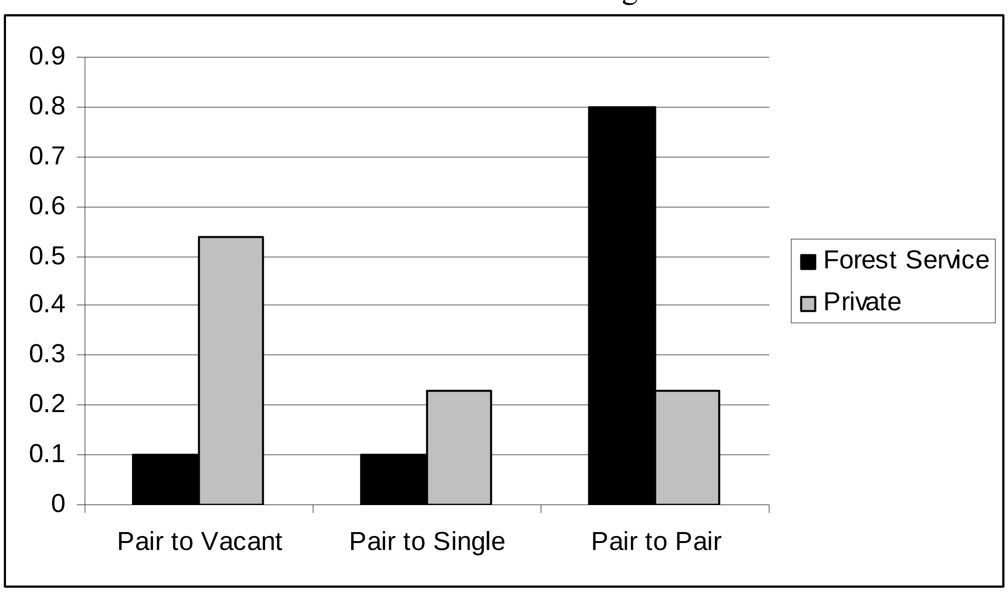
The FWS' primary source of information regarding habitat conditions and NSO status on industrial timberlands in the Northern Interior Region has been our review of

THPs. In the THP review process, FWS staff carefully evaluated historical NSO records and results of current surveys conducted in the plan area, as well as the habitat data provided in support of the THP. In cases where timber harvest was proposed in close proximity to an NSO activity center, the FWS evaluated habitat conditions in the field. The THP review process was conducted on a plan-by-plan basis, which does not permit systematic assessment of habitat conditions and NSO status across an entire ownership. However, our combined experience with hundreds of THPs indicates that the cumulative effects of repeated entries within many NSO home ranges has reduced habitat quality to a degree causing reduced occupancy rates and frequent site abandonment. In a large proportion of technical assistance letters to CALFIRE and industrial timberland owners during the past five years, we noted the lack of NSO responses at historic territories, and described habitat conditions considered inadequate to support continued occupancy and reproduction. This highlights the need for refined, objective criteria to determine the likelihood of NSO take when assessing THPs.

Analysis indicating loss of territories under Forest Practice Rules

To quantify the pattern of territory loss identified during the technical assistance process, we compared results of protocol surveys conducted at verified NSO territories supporting at least one year of occupancy by paired owls on Forest Service lands (N=196) with similar data from private timberlands (N=75) in Shasta and Trinity counties. The data set consisted of activity center status records in the California Department of Fish and Game's Spotted Owl Database (CDFG-NSO database), supplemented with territory locations and recent survey records received during technical assistance. We first evaluated the validity of activity center records in the CDFG-NSO database, and eliminated 18 sites on private lands due to lack of verification of status. The remaining 57 private-land activity centers had verified NSO status in at least one year between 1989 and 2007; 44 of these sites had supported pairs during at least one year. Of these verified pair sites, 54% declined from pair status to no response, and an additional 23% declined from pair status to a territorial single owl during subsequent protocol surveys (Figure I.B.1). On Forest Service-administered lands, 80% of pair sites did not change status during the same time periods. While we recognize that annual variation in survey effort and results at this relatively coarse scale of resolution may influence this type of analysis, the strong differences in trends observed on private versus federal lands supports the contention that management on private timberlands is creating habitat conditions that do not support sustained occupancy by NSO.

Figure I.B.1. Status of valid historical northern spotted owl activity centers (pair sites only) when resurveyed after 5-10 years. Data are from U.S. Fish and Wildlife Service technical assistance records and USFS monitoring records



Section II: Summary of the FWS NSO Take Evaluation Guidelines

The FWS guidelines provide a step-by-step process for evaluation of the likelihood of incidental take posed by proposed THPs (Appendix A). The steps include: (1) verifying the accuracy of NSO activity center location and status; (2) reviewing survey coverage and results to determine whether protocol has been met; and (3) evaluating the quantities and quality of habitat to be retained at each NSO home range potentially affected by the proposed THP. To assist the reader, this section briefly summarizes the analysis areas, habitat quantities, and habitat definitions used in step (3) of the FWS guidelines. See Appendix A for the full take avoidance analysis guidance provided to CALFIRE.

The FWS guidelines specify three spatial scales that form appropriate analysis areas for evaluation of habitat at NSO home ranges. The fourth analysis area, the 'outer core' represents the area between the core area and the total home range area (Table II.1). Within each analysis area, the FWS guidelines describe the quantities of habitat that must be retained in each of four functional habitat categories to avoid incidental take of NSO. These categories are: (1) high-quality nesting/roosting habitat; (2) nesting/roosting habitat; (3) foraging habitat; and (4) low-quality foraging habitat (Table II.2). Descriptions of the stand structural attributes corresponding to each functional habitat category are given in Table II.3. Table II.4 provides additional considerations for use in prioritizing habitat areas for retention.

Table II.1: Spatial scales used to evaluate habitat conditions at northern spotted owl activity centers in the Northern Interior Region

Analysis Area	Radius	Area
Nest Site	1000 feet	70 acres
Core Area	0.5 mile	502 acres
Outer Ring	0.5 – 1.3 mile	2,908 acres
Home Range	1.3 miles	3,410 acres

Table II.2: Minimum quantities of habitat to be retained within four functional habitat types to avoid incidental take of northern spotted owls on private timberlands in the Northern Interior Region

Analysis Area	Functional Habitat Type				
	High-quality NR	Nesting/ Roosting	Foraging	Low-quality Foraging	Total Suitable
Core area	100 acres	150 acres	100 acres	50 acres	300 acres
Outer 'ring'			655 acres	280 acres	935 acres
Home range (total)	100 acres	150 acres	755 acres	330 acres	1335 acres

Table II.3: Values for selected stand structural parameters used to classify nesting/roosting and foraging habitat for northern spotted owls in the Northern Interior Region

Parameter	Functional Habitat Type			
	High-quality NR	Nesting/Roosting	Foraging	Low-quality Foraging
Basal area	≥ 210 ft^2 /acre	Mix ranging from 150 to ≥180 ft^2 /acre	Mix ranging from 120 to ≥180ft^2 /acre	Mix ranging from 80 to ≥120ft^2 /acre
Quadratic mean diameter	≥ 15 inches	≥ 15 inches	≥ 13 inches	≥ 11 inches
Large trees per acre	≥ 8	≥ 8	≥ 5	NA
Canopy closure	≥ 60%	≥ 60%	≥ Mix ranging from 40 to 100%	≥ 40%

Table II.4: Guidelines for prioritizing habitat to be retained to avoid incidental take of northern spotted owls on private timberlands in the Northern Interior Region

Tree Species composition	Mixed conifer stands should be selected over pine-dominated stands
Abiotic considerations	
Distance to nest	Nesting/roosting and foraging habitat closest to identified nest trees, or roosting trees if nest unknown
Contiguity	Nesting/roosting and foraging habitat within the 0.5 mile radius must be as contiguous as possible
	Minimize fragmentation of foraging habitat as much as possible
Slope position	Habitats located on the lower 1/3 of slopes provide optimal microclimate conditions and increased potential for intermittent or perennial water sources
Aspect	Habitats located on northerly aspects provide optimal vegetation composition and cooler microclimates
Elevation	Habitat should be at elevations < 6000 feet, lower elevations are preferred

Section III: Scientific Basis for NSO Take Evaluation Guidelines

A. Fundamentals of spotted owl habitat relationships

Northern spotted owls exhibit clear, consistent patterns of habitat association, and these associations must provide the foundation of habitat management guidelines. In the 1990 *Conservation Strategy for the Northern Spotted Owl,* the Interagency Scientific Committee (Thomas *et al.* 1990) stated that:

"With the exception of recent studies in the coastal redwoods of California, all studies of habitat use suggest that old-growth forests are superior habitat for northern spotted owls. Throughout their range and across all seasons, spotted owls consistently concentrated their foraging and roosting in old-growth or mixed-age stands of mature and old-growth trees....Structural components that distinguish superior spotted owl habitat in Washington, Oregon, and northwestern California include: a multilayered, multispecies canopy dominated by large (>30 inches dbh) conifer overstory trees, and an understory of shade-tolerant conifers or hardwoods; a moderate to high (60-80 percent) canopy closure; substantial decadence in the form of large, live coniferous trees with deformities- such as cavities, broken tops, and dwarf mistletoe infections; numerous large snags; ground cover characterized by large accumulations of logs and other woody debris; and a canopy that is open enough to allow owls to fly within and beneath it."

Fifteen years later, the conclusions of the Interagency Scientific Committee were echoed in the *Scientific Evaluation of the Status of the Northern Spotted Owl* (Courtney *et al.* 2004), who found that the habitat attributes identified by Thomas *et al.* (1990) remain important components of NSO habitat. Notably, positive relationships were found with the aforementioned attributes whether the samples of owl and random locations were within old-growth forest, non-old growth forest, National Parks, public land, private land, or an Indian Reservation. In 2008, the *Recovery Plan for the Northern Spotted Owl* (USFWS 2008) again reiterated the association of NSO with older forest conditions, stating; "Spotted owls generally rely on older forested habitats (Carroll and Johnson 2008) because such forests contain the structures and characteristics required for nesting, roosting, and foraging." A major advance in our understanding of NSO habitat relationships from Thomas et al. (1990) to the present is that we now have a much better understanding of the spatial scale of habitat selection (Hunter et al. 1995), Meyer et al. 1998, Zabel et al. 2003) and relationships of habitat to owl fitness (Franklin et al. 2000, Dugger et al. 2005).

III.B: Analysis Areas

Management guidelines for territorial organisms are typically spatially explicit; that is, they apply to an area corresponding to the movements and activity patterns of the individuals occupying a territory. Spotted owls are territorial raptors that range widely in search of prey but are 'anchored' during the breeding season to a nest site (central-place forager). Evaluations of NSO habitat are usually conducted at two spatial scales; the home range and core areas. The home range is the "area traversed by the individual in its normal activities of food gathering, mating, and caring for young" (Burt 1943:351). Within home ranges, areas receiving concentrated use, typically surrounding the nest site and favored foraging areas, are called core areas. Because the size and pattern of NSO space use are typically unknown, estimates of use areas are derived from radio-telemetry studies. The analysis areas employed in the FWS guidelines are based on a subset of estimates that describe the outer perimeter of NSO activity areas, thus incorporating the areal extent most likely to contain important resources. In this section we review and summarize information related to home range size and patterns of space use within home ranges by NSO.

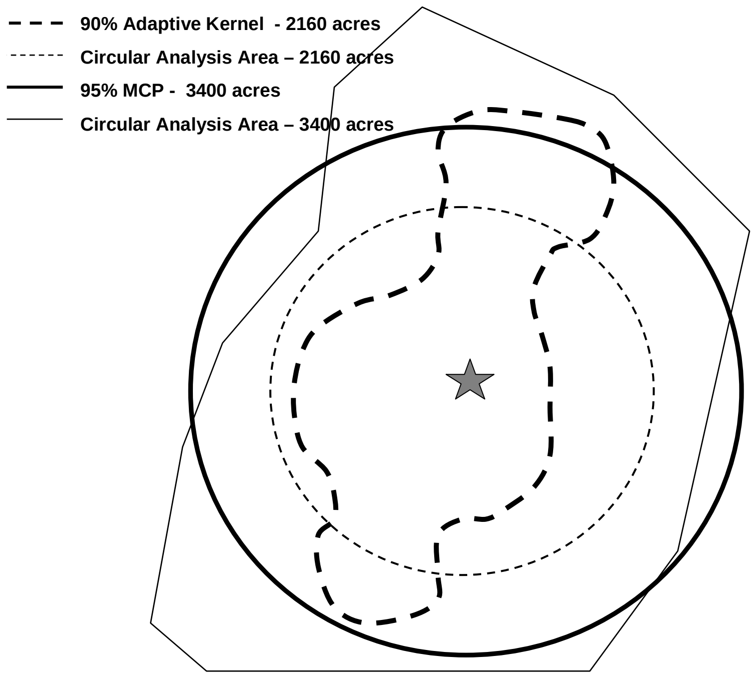
Home Range (1.3-Mile-Radius, 3,410-Acre) Analysis Area

The FPR guidelines for avoiding take of NSOs during timber operations in the Klamath Province indicate the amount of habitat to be retained within 1.3 miles of activity centers. The size of this area was originally based on estimated median annual home range sizes for NSO pairs in northern California, Oregon, and Washington (Thomas *et al.* 1990, USFWS 1992). There are numerous analytical techniques for estimating home range sizes based on animal locations (reviewed in Powell 2000). One of the most commonly used classes of home range estimators is the minimum convex polygon (MCP). Because MCP consists of a single polygon encompassing all or the majority of telemetry locations, this method may be viewed as providing a representation of the area *containing* the home range, including unused and infrequently used areas (Powell 2000, Laver and Kelly 2008). Generally biased large, MCP home range estimates provide relatively conservative values on which to base the size of habitat-analysis areas. Other home range estimators such as utilization distributions (e.g., kernel density estimates: see Powell 2000) de-emphasize areas less frequently used and typically yield smaller home range estimates that, when converted into circular analysis areas, may exclude distant, but potentially important, patches of habitat (see Figure 2.b.1). At the upper end of utilization distributions (e.g.; 90-100%), however, kernel estimates may resemble MCP polygons and circular analysis areas (Anthony and Wagner 1999).

Estimates of home range size are also important for developing management prescriptions and evaluating impacts of human activities on NSO. For the purpose of quantifying habitat and the impact of proposed modification of habitat, median home range estimates from radio telemetry studies are transformed into circular 'analysis areas' that are used as surrogates for actual home ranges (Fig. 2.b.1). Based on the median MCP home range estimate for NSO pairs in the Klamath Province, the FWS currently uses a circular analysis area of 1.3 mile radius (3,398 acres; Thomas *et al.* 1990, USFWS 1992). While this practice provides a practical and uniform method for quantifying NSO habitat, circular analysis areas will generally not correspond directly with areas actually used by NSO. Landscape pattern, both in terms of topographic features and vegetation pattern; prey distribution, abundance and availability; as well as distribution and/or abundance of competitors and predators are all likely to influence NSO territory and home range shape (Anthony and Wagner 1999).

Our understanding of space use by NSO is limited by lack of comparability among published studies due to variation in estimation methods, duration and seasonality of data collection, and whether estimates are for individuals or pairs. By looking for commonalities among studies and using a "strength of evidence" approach, however, we can evaluate whether the available information provides broadly modal values that are useful for conservation planning. Because the primary purpose of this review is to evaluate appropriate spatial scales for evaluation of effects to territorial paired NSO, we have focused on conservative estimates of year-round (annual) space use by NSO pairs.

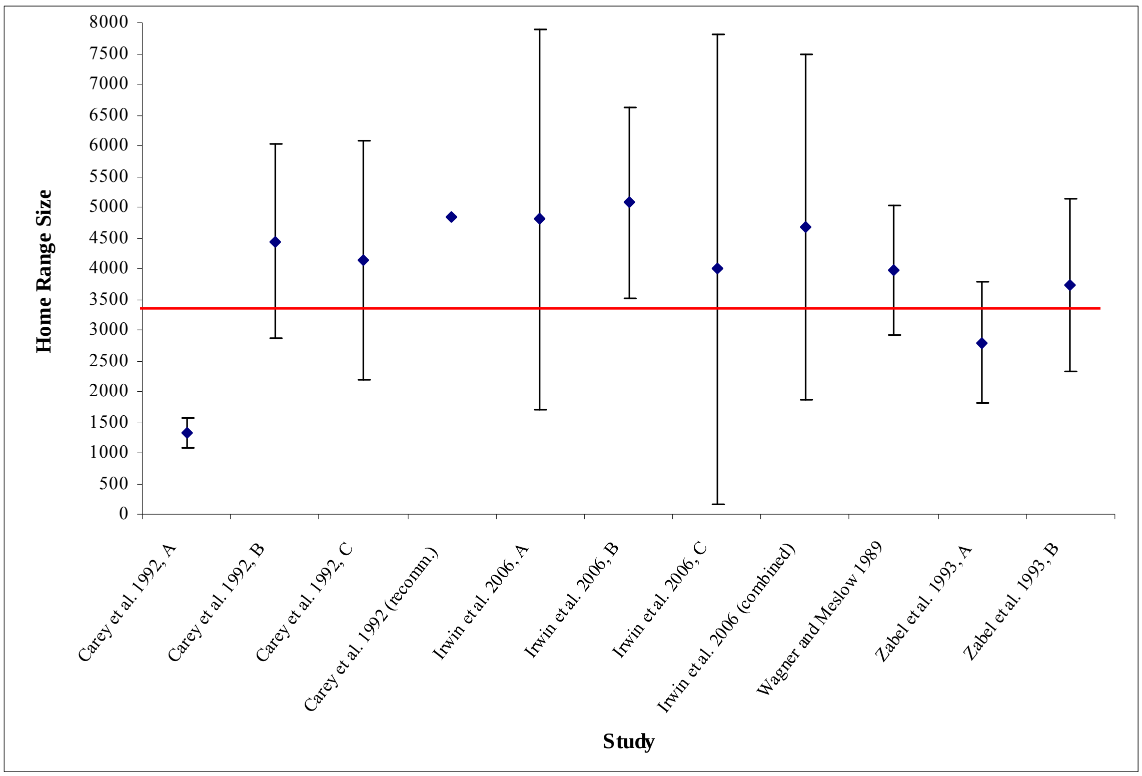
Figure III.B.1: Comparison of MCP and adaptive kernel home range estimates with corresponding circular analysis areas at an actual northern spotted owl home range.



The sizes of NSO home ranges are influenced by a variety of factors, including geographic differences in diets and habitat characteristics (Carey *et al.* 1992, Zabel *et al.* 1995). Therefore, we restricted our assessment of the validity of the 1.3-mile-radius analysis area to home range studies conducted within the Klamath Province. Because the outer analysis area should be large enough to include habitat needed to meet all major life history requirements and should accommodate areas important to both members of most pairs, we largely restricted our evaluation to studies that provided MCP estimates of the sizes of home ranges used year-round by pairs or paired individuals.

Home range studies conducted in the Klamath Province after the FPR guidelines were formulated support the use of a 1.3 mile radius analysis area, as this distance is encompassed by the confidence intervals of nearly all the home range studies we compiled. (see Figure III.B.2). Carey *et al.* (1992) found that the sizes of NSO pairs' home ranges were related to the type of forest and the degree of forest fragmentation (Table III.B.1). Pairs' home ranges in clumped, old forest were substantially smaller than the 1.3-mile-radius analysis area, whereas those in fragmented forest were somewhat larger than the analysis area. The authors suggested that management areas should be slightly larger than 1.3 miles, however, to encompass oblong-shaped home ranges. Zabel *et al.* (1993) provided estimates of 21 pairs' home ranges in two different study areas in the region (see Table III.B.2). They did not report the sizes of pairs' annual home ranges, but the average sizes of pairs' nonbreeding season home ranges were similar to the size of the FWS guidelines' outer analysis area. Pairs' annual home ranges would likely be larger than these values because their breeding- and nonbreeding-season home ranges probably do not completely overlap. In a different study, the mean cumulative pair MCP home range size for 9 pairs in the Medford, Oregon area was 3,971 acres (SD=1,063 acres), which is also similar to the 1.3-mile radius analysis area (Wagner and Meslow 1989). A fourth study by Irwin et al. (2006) showed greater mean home range sizes for 3 study areas in the region than the 1.3-mile radius analysis area used in the existing FWS guidelines (see Table III.B.3). The FWS recognizes that because of differences in methodology between these studies and those originally used to support the 1.3-mile radius analysis area (see Thomas *et al.* 1990, USFWS 1992), the results cannot be rigorously compared (see Powell 2000, Laver and Kelly 2008). Nonetheless, mean MCP values for home range area from more recent studies suggests that the outer analysis area should be somewhat larger than the 1.3-mile (3,410-acre) guideline (Figure III.B.2). We elected to retain the current guideline because, 1) the high degree of variability in MCP estimates in Figure III.B.2 does not compel us to reject the home range estimate in our existing guidelines in exchange for any particular alternative size, and 2) disproportionately high use of habitats closer to nest sites by NSO (see core areas, below) leads us to emphasize habitat conditions closer to nests, rather than expanding home range area.

Figure III.B.2: Mean Minimum Convex Polygon home range sizes (acres) for northern spotted owls in the Klamath Province, CA and OR. Error bars represent ±1 standard deviation. Horizontal line shows the size of the Fish and Wildlife Service guidelines' outer analysis area (3,410 acres).



Carey et al. 1992 = pairs' annual home ranges, A = Klamath Mountains, clumped forest, B = Klamath Mountains, fragmented forest, C = Umpqua, fragmented forest; Irwin et al. 2006 = paired-individuals' annual home ranges, A = Hilt, B = Medford, C = Yreka; Zabel et al. 1993 = pairs' nonbreeding-season home ranges, A = Mad River, B = Ukonom.

Core Area (0.5-Mile-Radius, 500-Acre) Analysis Area

The FPR guidelines for avoiding take of NSO during timber operations specified the amounts of habitat to be retained within 0.7 mile (986 acres) of activity centers. The 0.7-mile-radius scale was adopted in the FPR guidelines based on a study by Thomas *et al.* (1990), who found that circles of this size surrounding NSO nest sites contained significantly more suitable habitat compared with random circles. This study, however, only illustrated the importance of suitable habitat, rather than the amount of habitat required by NSO or the appropriate scales for evaluating and managing habitat (Bart 1995). The results of studies conducted after the FPR guidelines were formulated (see below) have indicated that a 0.5-mile-radius (500-acre) area around activity centers is a more appropriate scale at which to evaluate the amounts of habitat required by breeding NSO in the Klamath Province. These studies provide three primary lines of support for the core area size used in the FWS guidelines; distribution of locations of radio-telemetered NSO, territorial spacing of NSO, and studies comparing relative habitat selection at different scales.

Resources such as food and breeding and resting sites are patchily distributed in heterogeneous landscapes, such as those prevalent within the Klamath Province. In such landscapes, animals are likely to disproportionately use areas that contain relatively high densities of important resources (Powell 2000). These disproportionately used areas are referred to as core areas. One of the most influential studies of wildlife core areas was focused on NSOs in northern California (Bingham and Noon 1997). Although this study's sample size was small, it used an unusually rigorous method for determining the sizes of core areas (Powell 2000). Bingham and Noon (1997) noted that the combined size of NSO pair members' core areas is probably more meaningful than the sizes of individuals' core areas. Bingham and Noon (1997) estimated core areas by evaluating the ratio of total home range area to the area encompassing different adaptive kernel utilization distributions (UD), and found that individual NSO in northern California spent 60 to 75% of their time in their core areas, which comprised only 21 to 22% of their home ranges. The mean core area size for NSO pairs in the Klamath Province was 411 acres (166 ha; SE=26 ha; range=168-455 acres [68-184 ha]; n=7 pairs). Bingham and Noon (1997) also recommended that management guidelines attempt to meet the area requirements of most individuals in a population by accounting for variability in core area size; for example, by using the mean core area size plus one standard error. The addition of one standard error to the mean size of pairs' core areas totaled 475 acres (192 ha) for the Klamath Province data set. NSO core areas had diverse shapes due to variation in the distribution of foraging and roosting locations (Bingham and Noon 1997). However, assuming a circular shape for the purposes of evaluating and managing habitat, an area this size would have a radius of 0.49 mile. Carey and Peeler (1995) found remarkably similar results outside the Klamath Province, in southern Oregon.

We evaluated home range estimates from other studies in the Klamath Province in light of these patterns. By approximating Bingham and Noon's (1997) methodology, we evaluated kernel estimates in Irwin et al. (2004; Table 2) to estimate core area size (only 50%, 75% and 95% UD estimates were available). The 75 percent fixed kernel estimate accounted for 21 to 27 percent of the total (95%) home range, and the 75 percent adaptive kernel accounted for 23 to 30 percent, suggesting that a UD somewhat lower than 75 percent would yield core area estimates very similar to those obtained by Bingham and

Noon (1997). The addition of one standard error to individuals' mean 50 percent and 75 percent kernel density home range estimates from three different study areas in the province suggested that 500-acre analysis areas would include much of the important habitat for most breeding NSOs (Irwin *et al.* 2004, Table 2.b.4). Application of the same criteria to the results of a telemetry study in southwestern Oregon suggested that pairs used somewhat larger core areas than in other parts of the Klamath Province (Anthony and Wagner 1999, Table 2.b.5). Much of this study area is comprised of a checkerboard of public lands and industrial timberlands (Anthony and Wagner 1999, Dugger *et al.* 2005). To the extent that the amounts, quality, or contiguity of habitat have been reduced on these timberlands due to timber harvesting, NSO in this area may have larger area requirements than in parts of the province with less harvesting (Carey *et al.* 1990, 1992, Zabel et al. 1992, 1995).

The territorial spacing of NSO provides additional support for using a 0.5-mile-radius core area to evaluate and manage habitat for NSO in the Klamath Province. An individual's territory is thought to be the portion of the home range that both contains important resources and is economically defensible (Meyer *et al.* 1998). Therefore, average territory size provides a useful scale at which to evaluate core area habitat.

Wildlife biologists frequently use half the mean or median nearest neighbor distance to estimate the size of the defended portions of home ranges, or the portions of home ranges that are used exclusively by resident pairs (e.g., Reynolds and Joy 1998). Half the mean and median nearest neighbor distances for nesting NSO near Willow Creek were 0.49 mile (0.79 km: Hunter *et al.* 1995) and 0.44 mile (0.71 km: Franklin *et al.* 2000), respectively.

A third line of support for using a 0.5-mile-radius area for evaluating and managing habitat is provided by studies that modeled the habitat relationships of NSOs in the Klamath Province. Two studies in the region found that habitat within a 0.5-mile radius of nests differed more strongly from the general landscape compared with larger areas around nests (Hunter *et al.* 1995, Meyer *et al.* 1998, Zabel et al. 2003). While these results do not necessarily indicate that NSO are most selective of habitat at the 0.5-mile-radius scale, they do show that evidence of habitat selection by NSO is weaker at scales larger than this. Stronger support for the validity of assessing and managing habitat at the 0.5-mile-radius scale is provided by studies that modeled habitat-based fitness (Franklin *et al.* 2000, Dugger *et al.* 2005) and presence (Zabel *et al.* 2003) for NSO in the region. These studies found that important NSO-habitat relationships were well-captured at scales of 0.44 to 0.50 mile around activity centers.

III.C: Quantity, Distribution, and Configuration of Habitat

The FPR take-avoidance guidelines required that 40% of the 1.3-mile-radius analysis area and 50% of the 0.7-mile-radius analysis area be retained as suitable habitat. The FWS guidelines kept the 40% requirement because it is consistent with the results of research in the Klamath Province. However, the FWS guidelines require greater concentration of habitat near the nest or activity center than did the FPR guidelines. This concentration occurs through: (1) a decrease in the size of the inner analysis area (from 0.7- to 0.5-mile radius; see *Analysis Areas*) and (2) requirement that part of the total amount of foraging habitat (see *Habitat Definitions*) in the home range be retained within the inner analysis area. These changes are supported by studies conducted in the Klamath Province after the FPR guidelines were formulated.

Several types of information are available for evaluating the quantities, distribution, and configuration of habitat that must be retained in order to avoid take of NSO. The strongest type of information relevant to evaluation of take relates the fitness of NSO to characteristics of their habitat (Franklin *et al.* 2000, Olson *et al.* 2004, Dugger *et al.* 2005). Habitat-based fitness, or habitat fitness potential (HFP), is "the fitness conferred on an individual occupying a territory of certain habitat characteristics" (Franklin *et al.* 2000:558). HFP is a function of both the survival and reproduction of individuals within a given territory. Habitat-based modeling that accurately predicts the presence ("occupancy") of breeding NSO (Zabel *et al.* 2003) is another important tool for evaluating the species' habitat relationships. This modeling assumes that NSO gravitate toward areas likely to confer high fitness but does not directly relate habitat characteristics to the survival and reproduction of owls. Descriptions of areas around nests, and comparisons between them and random areas, are additional sources of information for investigating NSO-habitat relationships. This approach provides information about the habitat associations and preferences of NSO but must be cautiously considered because it does not relate habitat descriptions to the fitness of owls. For example, the average quantity of habitat around a sample of NSO nests could be higher than what is available around random locations, but still be lower than what is required for persistence of individuals or the population.

Comparisons among habitat studies can be problematic because researchers often define habitat differently and use different source data to classify vegetation (see Table III.C.1). Nonetheless, all studies in the Klamath Province have found that NSO exhibit strong relationships with older, more structurally complex, conifer-dominated forest classes. The concordance of these findings enabled the FWS to evaluate the guidelines relative to the quantities, distributions, and configurations of older forest within analysis areas. Spotted owls also forage within intermediate (younger and/or more open) forest classes (see *Habitat Definitions*, below). One study (Zabel *et al.* 2003; see below) found a positive association between NSO in the Klamath Province and moderate amounts of intermediate forest (see Table III.C.1) at the core area scale. This habitat class was based on conditions known to be used by foraging NSO. Other studies in the region have described the proportions of analysis areas comprised of intermediate forest classes but have not found positive associations between them and NSO. These forest classes often included conditions that receive little or no use by NSO, however, and are therefore not directly comparable with foraging habitat as defined by Zabel *et al.* (2003) and the FWS guidelines (see *Habitat Definitions*, below). There is currently no information for evaluating the proportion of intermediate forest that should be retained at the home range scale in order to avoid take of NSO in the Klamath Province.

Table III.C.1: Descriptions of suitable or selected habitat from studies of northern spotted owl-habitat relationships in the Klamath Province

Study	Location	Classification Method	Description of Selected or Suitable Habitat
USFWS 1992, Bart 1995	Washington, Oregon, northern California	research synthesis (various methods)	conifer-dominated forest with a multi-layered canopy, average DBH[1] >30 inches, ≥60% canopy cover, decadence (snags, logs, deformed trees)
Anthony and Wagner 1999	southwestern Oregon	aerial photographs, ground reconnaissance	conifer-dominated forest with a multi-layered canopy, ≥40% canopy cover, decadence, large snags and logs; characterized by trees ≥30 inches DBH and ≥200 yrs
Carey *et al.* 1992	southwestern Oregon	aerial photographs, forest inventory data, ground reconnaissance	multi-layered canopy, average DBH of dominant trees >39.4 inches, large snags and logs
Dugger *et al.* 2005	southwestern Oregon	aerial photographs, ground reconnaissance	conifer or mixed forest, ≥100 yrs; characterized by trees ≥13.8 inches DBH
Franklin *et al.* 2000	northwestern California	satellite imagery	forest comprised of ≥40% conifers, conifer QMD[2] ≥21 inches, hardwood QMD ≥6 inches, canopy cover ≥70%
Gutiérrez *et al.* 1998	northwestern California	satellite imagery	≥30% canopy cover, >50% of conifer basal area comprised of trees ≥21 inches DBH
Hunter *et al.* 1995	northwestern California	satellite imagery	≥30% canopy cover, >50% of conifer basal area comprised of trees ≥21 inches DBH
Meyer *et al.* 1998	western Oregon	aerial photographs	conifer-dominated forest, trees ≥80 yrs and/or multi-layered canopy
Ripple *et al.* 1997	southwestern Oregon	aerial photographs	conifer-dominated forest, average DBH ≥19.7 inches, canopy cover ≥60%
Solis and Gutiérrez 1990	northwestern California	timber type classification	average DBH >20.7 inches
Zabel *et al.* 1993	northwestern California	topographic maps, aerial photographs, and orthophotoquads	stands dominated (in terms of basal area) by trees >20.9 inches DBH; >20% canopy cover of dominant trees and >70% canopy cover of trees >5.1 inches DBH
Zabel *et al.* 2003	northwestern California	modified timber type classification, varied geographically	nesting-roosting habitat: for most locations average DBH ≥17 inches and average conifer canopy cover ≥60%; foraging habitat: in all locations average DBH ≥9.8 inches and average conifer canopy cover ≥40%, additional criteria in some locations

[1] DBH: Diameter at breast height

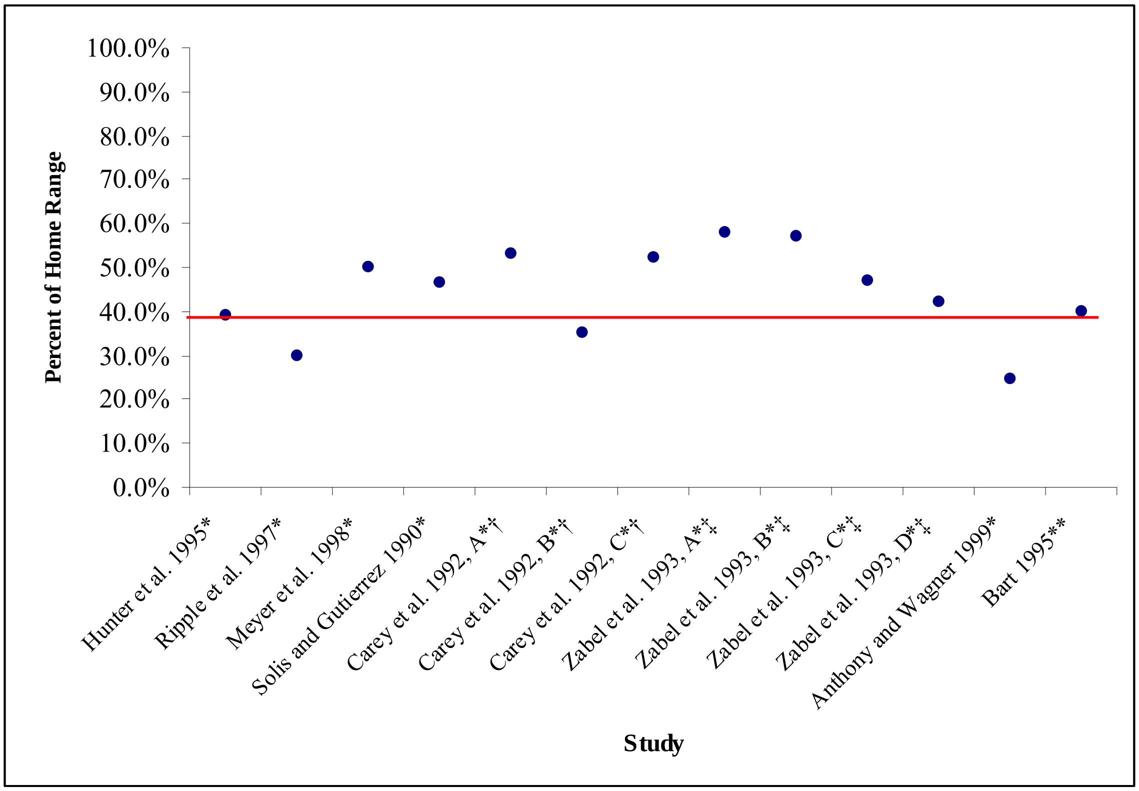
[2] QMD: Quadratic mean diameter

H*ome Range (1.3-Mile Radius)*

Bart (1995) evaluated the 1992 draft recovery plan's (USFWS 1992) requirement that at least 40 percent of the estimated home range be retained as suitable habitat. Using demographic data from throughout the NSOs' range, including the Klamath Province, he calculated that populations are stable when the average proportion of suitable habitat in home ranges is 30 to 50 percent. In a related comment on the FPR take-avoidance guidelines, Bart (1992:3) noted that "…lambda probably reaches 1.0 (stable population) when suitable habitat declines to somewhere between 40 and 55 percent. Since the Service must have good evidence that take did occur, not just that it might have occurred, using a value of 40 percent seems reasonable." Bart's (1992) conclusions continue to be supported by the results of recent research.

Studies have reported a wide range of mean proportions of older forest (ca. 24 - 58 percent; see Figure III.C.1) in home range-sized areas around NSO nests or roosts in the Klamath Province and adjacent areas (Solis and Gutiérrez 1990, Carey *et al.* 1992, Zabel *et al.* 1993, Hunter *et al.* 1995, Ripple *et al.* 1997, Meyer *et al.* 1998, Anthony and Wagner 1999). Variation in proportions of habitat was likely due to multiple factors, particularly differences in habitat classification (see Table III.C.1), but also including sizes of analysis areas and study season (i.e., breeding versus non-breeding), as well as geographic differences in the abundance and quality of habitat. Regardless, the central tendency of these means is about 45 percent; a somewhat higher percentage than the FWS guidelines. We retained the 40 percent threshold, however, because; 1) the FWS guidelines specify amounts of high-quality habitat, rather than a single 'suitable habitat' category, and; 2) FWS guidelines incorporate a higher standard for classifying forest habitat as ‘suitable’ than was used in many of the studies in Figure III.C.1, and; 3).

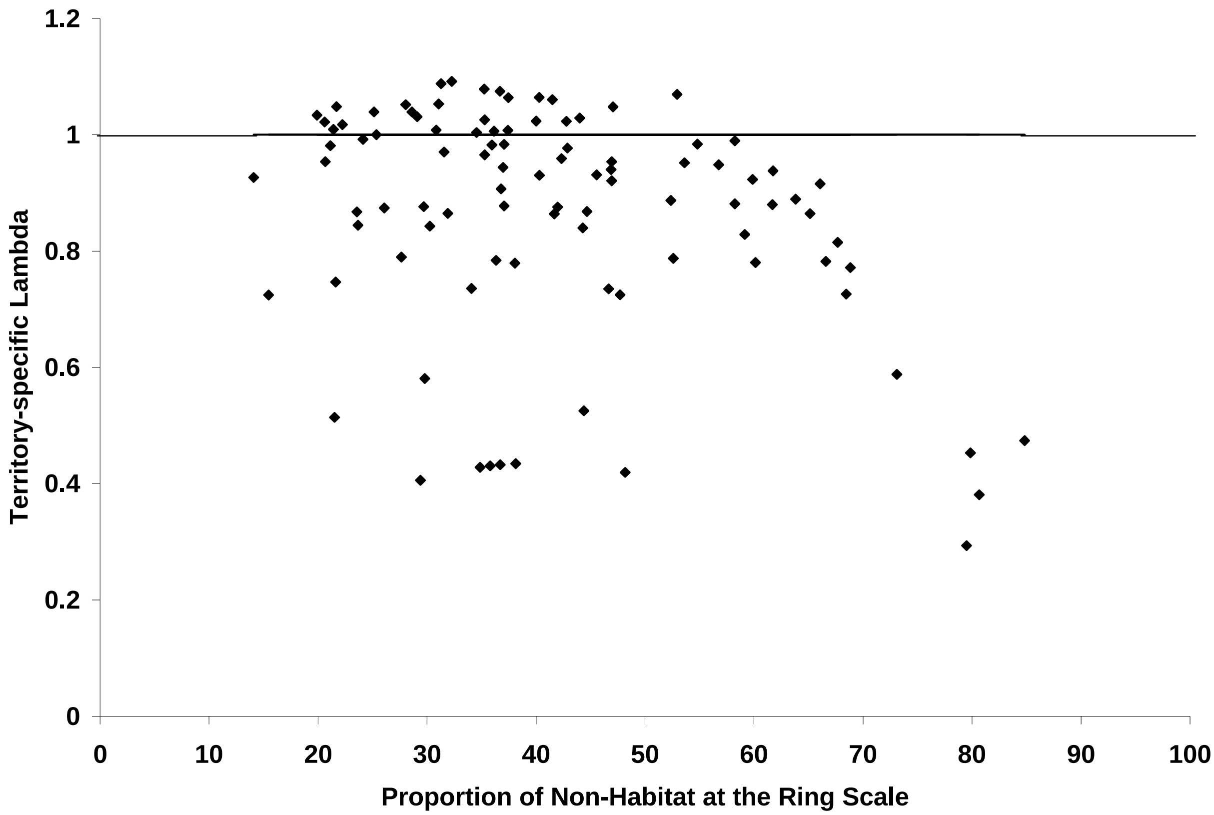
Figure III.C.1: Proportions of older forest (see Table III.C.1) at home range scales around northern spotted owl territory centers in the Klamath Province, CA and OR. Horizontal line shows the proportion of older forest required by the Fish and Wildlife Service guidelines (40 percent).



*Mean proportion. **Recommendation for take-avoidance guidelines. †Carey et al. 1992: A = Klamath Mountains, clumped forest, B = Klamath Mountains, fragmented forest, C = Umpqua, fragmented forest. ‡Zabel et al. 1993: A = Ukonom, breeding season, B = Ukonom, nonbreeding season, C = Mad River, breeding season, D = Mad River, nonbreeding season.

Research in the Klamath Province and adjacent areas indicates that NSO habitat should be concentrated at the core area scale around nests and interspersed with other land cover classes in the rest of the home range. For this reason, the FWS guidelines require retention of a higher proportion of the home range’s total suitable habitat (particularly nesting/roosting habitat) to be within the core area, and allow a wider range of forest conditions in the outer ring. A study in southwestern Oregon showed that HFP was optimal for NSO when the estimated home range beyond the core area (3,430-acre ring) was comprised of large amounts of forest (young, mature, and old classes) and an intermediate amount (ca. 38%) of "nonhabitat" (nonforest, early seral forest, heavily harvested forest) (Dugger *et al.* 2005; see Figure III.C.2). At this scale, HFP was below 1.0 at all territories with >50 percent nonhabitat. A similar study just outside the Klamath Province in southern Oregon found that high survival of NSO usually occurred with large proportions (ca. 70 percent was optimal) of conifer forest (average DBH >9.5 inches) in estimated home ranges (1,747 acres), whereas high reproduction was associated with large amounts of edge between "nonforest" (average diameter at breast height (DBH) <9.5 inches) and other vegetation classes (Olson *et al.* 2004). These findings suggest that HFP is highest when home ranges consist of large amounts of both forest and forest-edge. Zabel *et al.* (2003) found that the best large-scale (2,224-acre) model for probability of occupancy by NSO in northwestern California was an intermediate amount of old forest (≥24 inches DBH and ≥70 percent canopy cover) edge. Thus, both the demography and presence of NSO in the Klamath Province appear to be positively associated with an intermediate amount of horizontal heterogeneity at the home range scale.

Figure III.C.2: Association between habitat fitness potential (territory-specific lambda) and proportion of "nonhabitat" (nonforest, early seral stages, older forest receiving timber harvest entries removing >40 percent basal area in the portion of the estimated home range outside the estimated core area (3,430-acre ring) in southwestern Oregon (Dugger *et al.* 2005).



Core Area (0.5-Mile Radius)

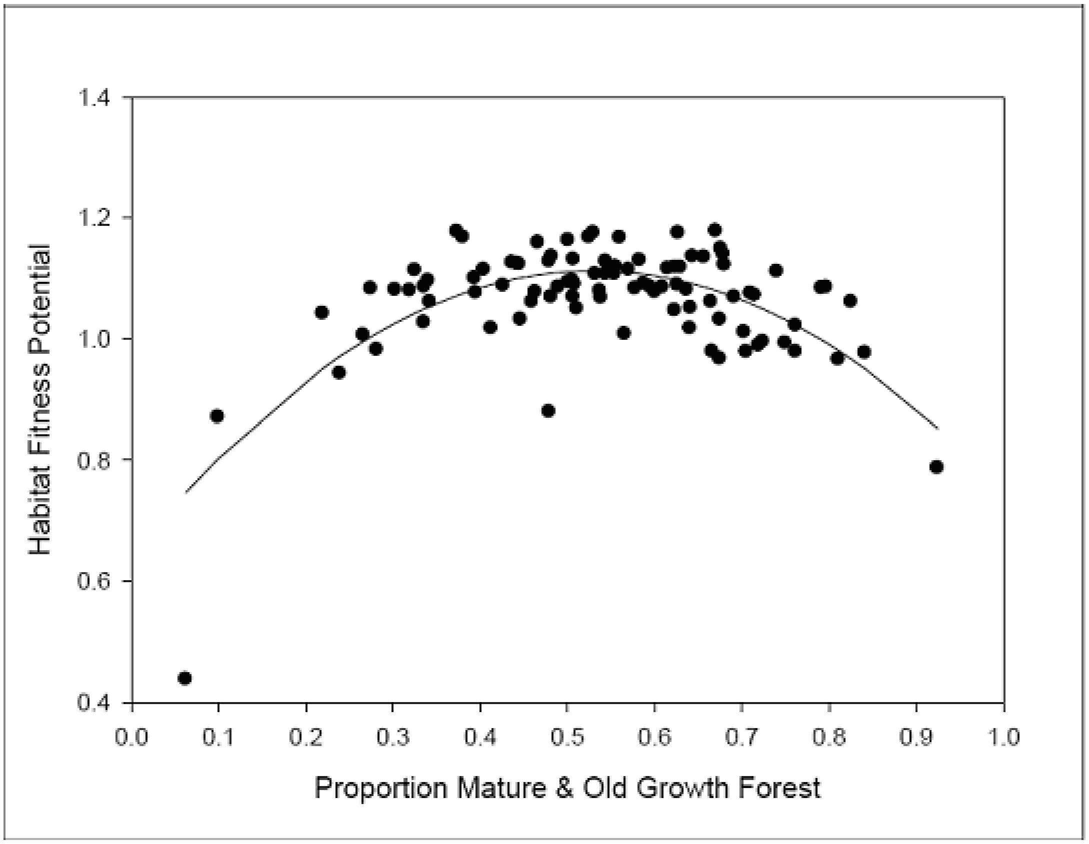
The disproportionate importance of habitat conditions within NSO core areas is indicated by the species' concentrated use of areas close to the territory center (see *Analysis Areas* and *Habitat Definitions*). The core area's relevance has also been demonstrated by strong associations between habitat patterns and the demography (Franklin *et al.* 2000, Dugger *et al.* 2005) and occurrence (Zabel *et al.* 2003) of NSO.

The results of two rigorous demographic studies of NSO in the Klamath Province (Franklin *et al.* 2000, Dugger *et al.* 2005) provide strong, consistent inferences regarding the relationship between habitat conditions and measures of NSO fitness such as adult survival and HFP at the core area scale. Although the habitat-based fitness models of Franklin *et al.* (2000) and Dugger *et al.* (2005) differ somewhat, both studies indicated that HFP for NSO in the Klamath Province was most likely to be ≥1 when at least 50% of the estimated core area was comprised of older forest (see Table III.C.1 for habitat criteria). An HFP of ≥1 indicates that a territory has the characteristics required for breeding females to replace themselves or contribute a surplus to the population (Franklin *et al.* 2000).

Franklin *et al.* (2000) found that territory-specific adult survival was strongly associated with the amounts of interior older forest in addition to the amount of edge between older forest and other vegetation types (see Table 7 in Franklin *et al*. 2000) at the core area scale (390 acres, 158 ha). Interior older forest was the amount of older forest 328 feet (100 m) from an edge and is not equivalent to the simple amount of older forest within a core. Interestingly, HFP declined overall when the core area contained more interior old forest. This was apparently due to a tradeoff between habitat characteristics associated with survival (amount of interior habitat and length of habitat edge) and reproduction (amount of habitat edge). High quality territories typically had core areas comprised of large patches of older forest with convoluted edges. Estimates of the amount of interior older forest that correlated with HFP >1 were provided to the FWS by Dr. Franklin (personal communication, September 19, 2005). The minimum proportion of interior older forest corresponding to HFP >1 was 41 percent; addition of the older forest area within the 328-foot "edge buffer" yielded a proportion of 62 percent ("total core": Franklin 1997). Based on this evaluation, Dr. Franklin recommended that 60 percent of the core area be comprised of older forest (Franklin, personal communication, September 19, 2005). The FWS guidelines incorporate the apparent positive influence of moderate amounts of edge by 1) requiring that retention of high-quality habitat be concentrated at the core scale and 2) specifying amounts of older forest and foraging habitat in the core.

Data sets used in Franklin *et al.* (2000) were recently re-analyzed to evaluate the relationship between HFP and the simple proportion of older forest within NSO core areas (Franklin 2006). The results of this analysis, proposed in Appendix D of the 2007 Draft Recovery Plan for the Northern Spotted Owl (USFWS 2007), indicated a quadratic relationship between HFP and older forest, with optimum HFP occurring when 53 percent of the estimated core area consisted of older forest (Franklin *et al.* 2000; Figure III.C.3). More than half (55 percent) of the high-quality (HFP $\geq$1) territories had core areas comprised of 50 to 65% older forest. This pattern is consistent with the previously described recommendations of Dr. Franklin and the habitat retention guidelines developed by the FWS.

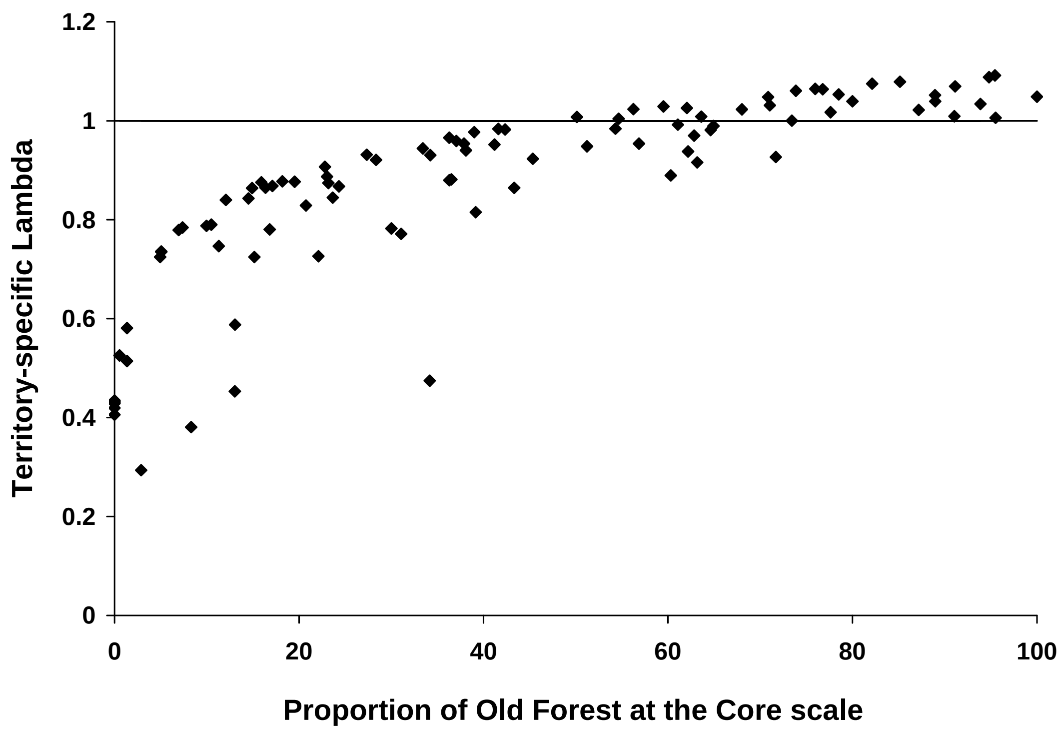
Figure III.C.3: Relationship between habitat fitness potential for northern spotted owls and proportion of older forest (see Table III.C.1) within 0.44 mile of territory centers in northwestern California (courtesy A. Franklin)



Because roughly 29 percent of high-quality territories (HFP ≥1) (Figure III.C.3) contained less than 50 percent old forest, some have suggested that a substantially lower habitat retention guideline would be adequate to avoid incidental take in timber harvest operations. Use of Franklin (2006) as the sole means of support for habitat retention guidelines is inappropriate (Franklin 2007) however, because the model estimating survival based on simple amounts of older forest was not well-supported and had only 3 percent of the weight in the model set (as opposed to 42.7 percent for the best-supported model which included interior old forest and amount of edge; see Table 7 in Franklin *et* *al.* 2000). Use of the simple amount of older forest for evaluating take of NSO is inappropriate because it ignores the model selection process used in Franklin *et al.* (2000), which found that simple amounts of older forest alone did not explain variation in survival nearly as well as amounts of interior older forest and edges (Franklin 2007). Nichols and Pollock (2008) reviewed the use of HFP in the draft NSO Recovery Plan and concurred with Franklin (2007), stating that plots based on a single variable (percent old forest) instead of multiple covariates in the model of Franklin *et al.* (2000) are potentially misleading. Consequently, the analysis using solely percent old forest was deleted from the final 2008 NSO Recovery Plan, and was not used by the FWS to develop recent NSO habitat retention guidelines.

In a similar study in southern Oregon, Dugger *et al.* (2005) found that HFP was positively related to the proportion of older forest in the estimated core area (413 acres, 167 ha), although it became decreasingly sensitive to increased proportions (see Figure III.C.4; Dugger, unpub. data). Roughly 72 percent of core areas with HFP greater than 1.0 had more than 50 percent older forest; whereas cores with HFP less than 1.0 never contained more than 50 percent older forest. In contrast to the conclusions of Franklin *et al.* (2000), the correlation of HFP with proportion of older forest in the estimated core area was roughly linear; HFP did not decline at high levels of older forest. It is unclear why these studies found differences in the nature of the NSOs' relationships with quantities of older forest in the core area. Possible reasons for this dissimilarity include differences in the availability and quality of habitat in the study areas and in the studies' classifications of habitat (see Table III.C.1). For example, the area studied by Dugger *et al.* (2005) was strongly fragmented by industrial timberlands in a checkerboard pattern, whereas the area studied by Franklin *et al.* (2000) was dominated by less-intensively managed federal lands. Regardless, both studies found that high quality territories typically had core areas comprised of at least 50 percent older forest.

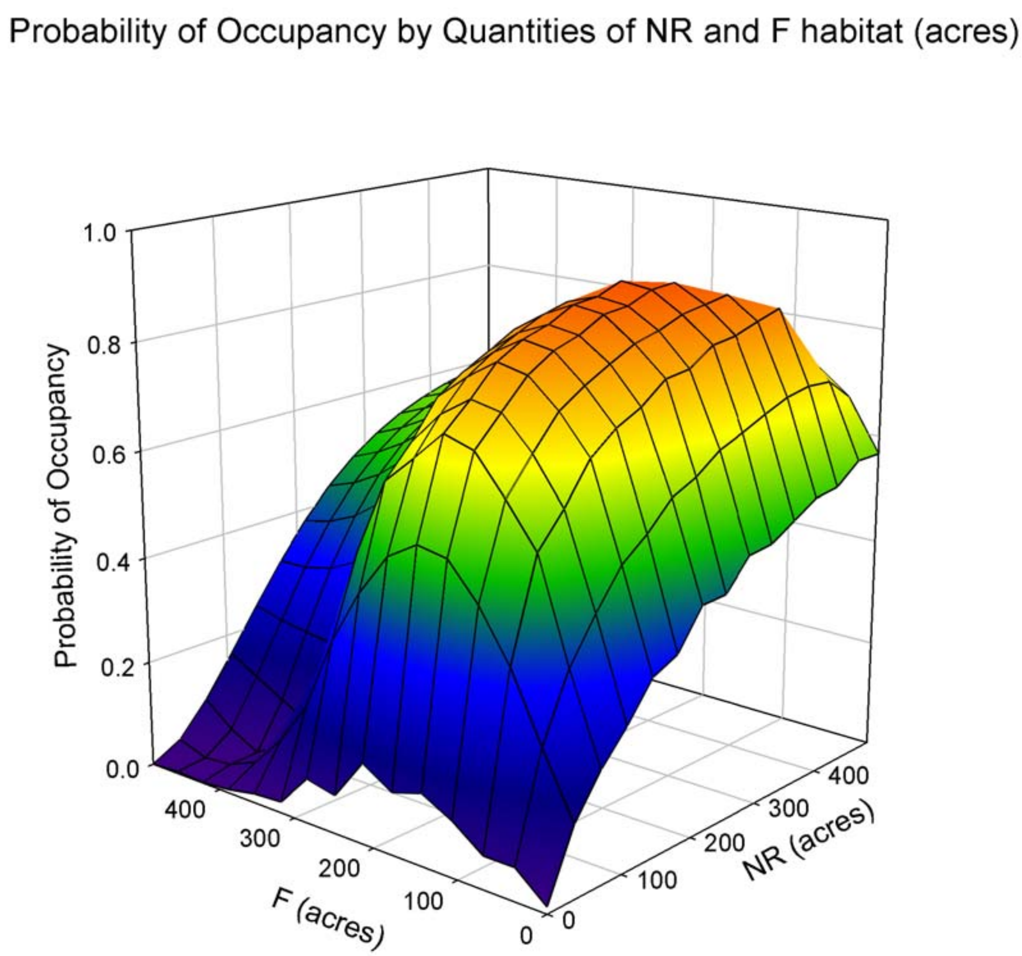
Figure III.C.4: Relationship between habitat fitness potential (territory-specific lambda) for northern spotted owls and proportion of older forest (see Table III.C.1) within 413 acres around territory centers in southwestern Oregon (courtesy K. Dugger)



Zabel *et al.* (2003) modeled the probability of occupancy for NSO in the Klamath Province based on habitat conditions at the core area scale (500 acres). The overall best model in this study indicated that the probability of NSO occurring in a given location was positively, albeit diminishingly, influenced by increased amounts of nesting-roosting habitat and by intermediate amounts of foraging habitat at the core area scale (see Table

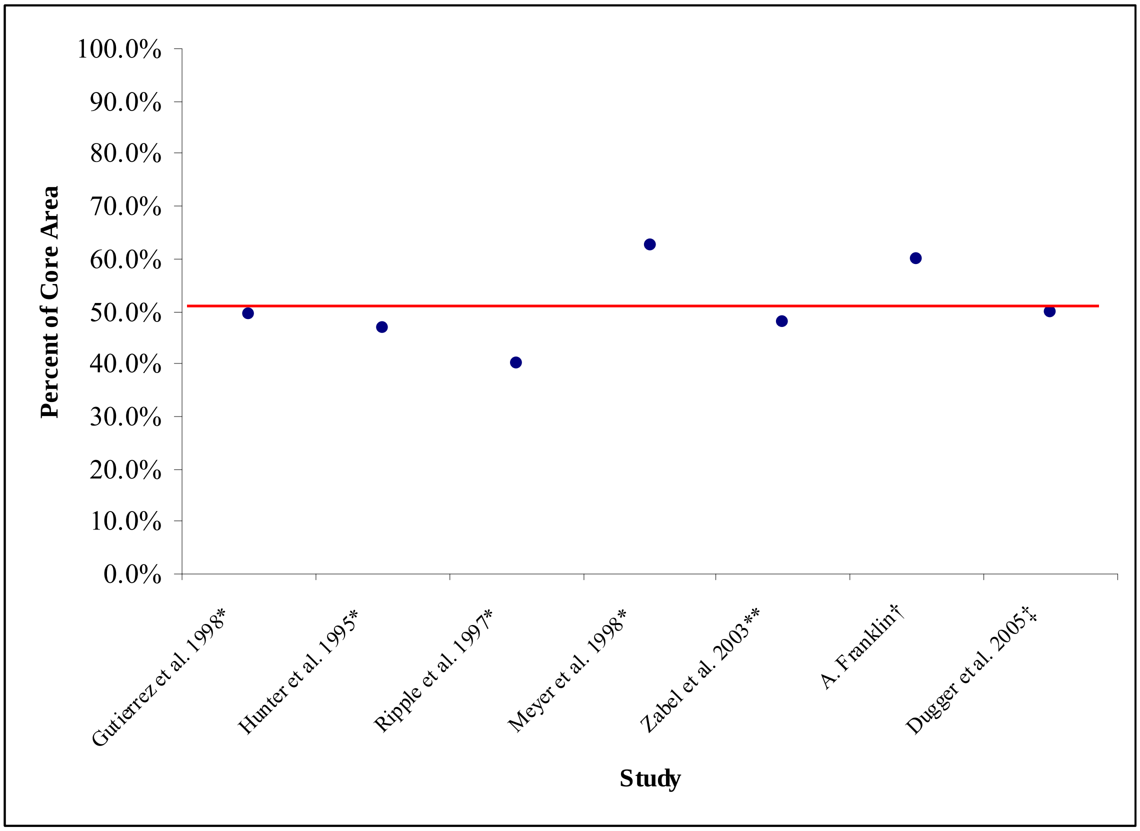
III.C.1 for habitat definitions). The highest probability of occupancy occurred when the core area scale consisted of 60 to 70 percent nesting-roosting habitat and 30 to 40 percent foraging habitat (see Figure III.C.5). The averages for all combinations of habitat associated with a high probability (≥0.70) of occupancy were 48 percent nesting-roosting habitat and 28 percent foraging habitat.

Figure III.C.5: Probability of northern spotted owl occupancy in the Klamath Province associated with amounts of nesting-roosting (NR) and foraging (F) habitats (see Table III.C.1) at the 500-acre (200 ha) scale (Zabel *et al.* 2003)



Researchers have reported a wide range of mean proportions of older forest (ca. 35-60 percent; see Figure III.C.6) at the core area scale around NSO nests in the Klamath Province and adjacent areas (Hunter *et al.* 1995, Ripple *et al.* 1997, Gutiérrez *et al.* 1998, Meyer *et al.* 1998). It is difficult to assess how much of this variation was due to differences in ecological setting, spatial scale, habitat classification, and individual variation among owls. Nonetheless, the central tendency of these results was roughly 50-60 percent, which is consistent with the FWS guidelines' requirement for proportion of nesting and roosting habitat (see *Habitat Definitions*) in the core area (see Figure III.C.6). The mean proportions of older forest at core area scales were higher than those around locations chosen for comparison (random or "unused" locations). Thus, NSO in the Klamath Province appear to select home ranges with large amounts of older forest concentrated around suitable nest locations.

Figure III.C.6: Proportions of older forest (see Table III.C.1) at core area scales around northern spotted owl territory centers in the Klamath Province, CA and OR. Horizontal line shows the proportion of older forest required by the FWS guidelines (50 percent)



*Mean proportion. **Mean proportion associated with ≥70% probability of occupancy. †Recommendation based on the combined proportions of interior and edge-buffer older forest associated with a habitat fitness potential greater than 1 (Franklin et al. 2000). ‡Approximate proportion of older forest associated with a habitat fitness potential of at least 1.

Taken together, the results of studies conducted in the Klamath Province support the conclusion that at least 50 percent of the core area should consist of older forest. Older forest is more likely than other vegetation classes to provide NSO with suitable structures for perching and nesting, a stable, moderate microclimate at nest and roost sites, and visual screening from both predators and prey (see *Habitat Definitions*).

Franklin *et al.* (2000) found that survival and HFP were highest when older forest occurred as large patches in the core area. Larger patches of forest likely buffer NSO from wind and heat associated with forest-opening edges (Chen *et al.* 1995) and predators and competitors associated with open or fragmented forest (e.g., great horned owls [*Bubo virginianus*]: Johnson 1993). Modeling by Franklin *et al.* (2000) also indicated that a balance of interior older forest and edge habitat in the core area is important to NSO in the region. The value of habitat edges for NSO might be related to the availability of woodrats and other prey species associated with more open, early-seral vegetation. The positive influence of large-bodied prey species such as woodrats on NSO reproductive success has been described in northwestern California (White 1996). However, habitat edges in the Franklin *et al.* study occurred wherever habitat was juxtaposed with other land cover classes, and was not necessarily related to the presence of woodrat habitat. In fact, the survival and reproduction of NSO did not appear to be influenced by woodrat habitat in the core area. Zabel *et al.* (2003) found that probability of occupancy by NSO was highest when the core area scale contained some foraging habitat, as well as nesting-roosting habitat. This result suggests that horizontal heterogeneity in the core area should be partially provided by a range of forest conditions suitable for use by NSO, dominated by older forest conditions, (see *Habitat Definitions*, below), not simply the juxtaposition of suitable and unsuitable habitat.

III.D: Habitat Definitions:

Determination of the amount of suitable habitat that must be retained in order to avoid incidental take of NSO is strongly influenced by the range of forest conditions that are classified as suitable habitat. The HFP models of Franklin *et al.* (2000), Olson *et al.* (2004), and Dugger *et al.* (2005) contain a limited number of habitat variables and relatively coarse definitions of NSO habitat, and therefore must be supplemented with additional information on forest structural parameters that support classification of forest habitat as suitable for nesting and foraging. Description of the structural characteristics of NSO habitat and delineation of the range of habitat conditions corresponding to essential activities such as nesting, roosting, and foraging is a critical element of developing guidelines for evaluating the likelihood of incidental take. Because the structural attributes of habitat immediately surrounding nests are easily quantified, data supporting classification of nesting habitat are readily available (see section III.C).

Foraging habitat, on the other hand, is more variable and spatially extensive, requiring intensive radio-telemetry studies to measure use of various habitat conditions by NSO. In recent studies by the National Council for Air and Stream Improvement (NCASI), correlations between habitat data from detailed forest inventories and nocturnal locations of radio-tagged NSO and California spotted owls were used to estimate resource selection function (RSF) models (Irwin *et al.* 2007a,b) that quantify complex relationships between the owls and their environment. These models allow evaluation of the relative use of specific forest structural variables such as tree size class distribution and stand density by foraging NSO. The studies of Irwin *et al.* (2007a, b), combined with other telemetry studies (Solis and Gutiérrez 1990), provide the basis of our definitions of suitable foraging habitat for NSO.

NSO are generally associated with structurally complex conifer or mixed-conifer forests containing dense, multilayered canopies and significant components of large-diameter trees and decadence in the form of deformed trees, snags, and down wood (Thomas *et al.* 1990, Gutiérrez 1996, Courtney *et al.* 2004, USFWS 2008). Variation in seral stage association has been reported for individuals within study areas and for populations in different study areas (Gutiérrez 1996). However, extensive use of younger forests by spotted owls tends to be reported in unusually productive forest types in coastal areas (Folliard *et al.* 1993, Thome *et al.* 1999) or in stands containing structural complexity retained from previous stands (Blakesley *et al.* 1992, Zabel *et al.* 1993, Carey and Peeler 1995, Irwin *et al.* 2000). In particular, NSO have been shown to nest and forage successfully in young redwood forests; in such areas their densities are among the highest on record (Diller and Thome 1999). Young redwood forests have also been associated with high reproduction in spotted owls (Thome et al. 1999). The ability of NSO to successfully occupy young redwood forests has been attributed to resource availability; young forests have been found to produce the highest abundance of woodrats in Douglas-fir/tanoak forests (Sakai and Noon 1993), and in the redwood/Douglas-fir zone, woodrats were most abundant in stands 5 to 20 years of age (Hamm et al. 2007: USDA Forest Service Gen. Tech. Rep. PSW-GTR-194). Ward et al. (1998) described the benefit of an energy rich woodrat diet; and White (1996) describes the positive influence of woodrat consumption on nesting success. The value of younger forest to NSO in the drier portions of the Klamath Province is poorly understood, whereas numerous studies in the Klamath Province and adjacent regions have demonstrated that NSO selectively use older, denser forest at a variety of spatial scales (e.g., Solis and Gutiérrez 1990, Bart and Forsman 1992, Blakesley *et al.* 1992, Carey *et al.* 1992, Hunter *et al.* 1995, Ripple *et al.* 1997, LaHaye and Gutiérrez 1999, Zabel *et al.* 2003) and that such forest is positively associated with measures of reproduction and survival (e.g., Ripple *et al.* 1997, Meyer *et al.* 1998, Franklin *et al.* 2000, Olson *et al.* 2004, Dugger *et al.* 2005).

Although spotted owls are generally associated with and preferentially select older, denser forest, suitable habitat for the species can be viewed as a continuum of structural conditions. Owls tend to use parts of this continuum more frequently than others, and to focus their activities within certain parts of it for meeting particular life history needs. The FWS has classified this continuum into habitat categories based on the conditions' primary function and apparent quality for NSO (nesting/roosting or foraging habitat, high or low quality habitat; see Table III.D.1 and Figure III.D.1). The FWS recognizes that conditions within a habitat category may be used by NSO to meet multiple life history needs; for example, NSO may forage in nesting/roosting habitat or roost in foraging habitat. We also acknowledge that rigorous classification of habitat quality requires an understanding of the relationships between habitat conditions and the demography of NSO. However, because NSO are mobile animals with large home ranges, most studies have used low-resolution vegetation data and broad habitat categories to explore their habitat relationships (see Table III.C.1). These studies have greatly improved our understanding of NSO-habitat relationships but provide limited insight into the specific structural conditions used by owls.

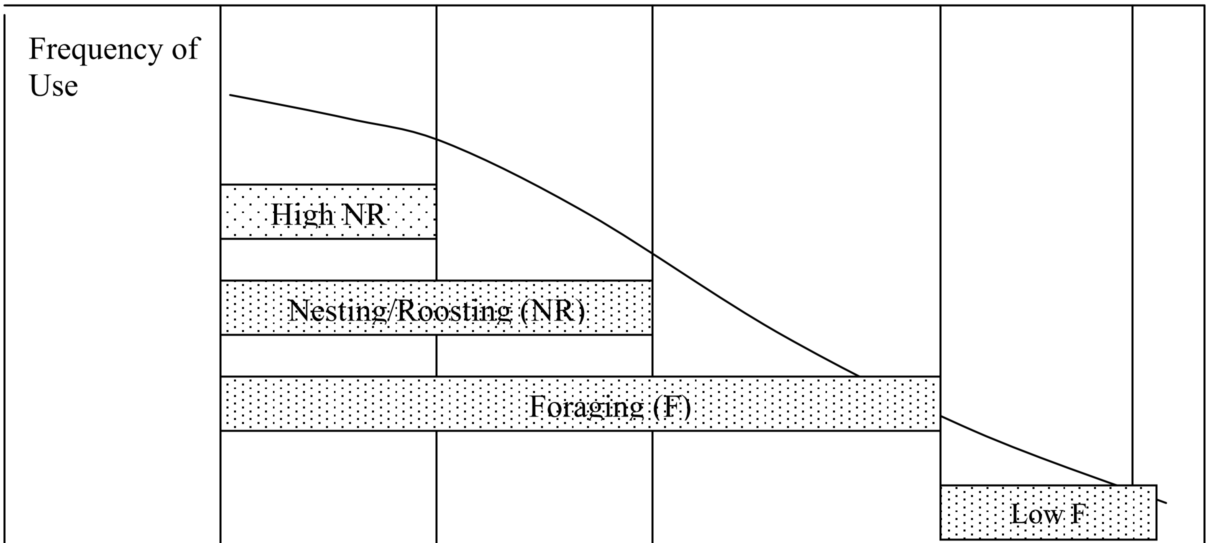
Table III.D.1: Values for selected structural parameters used in the Fish and Wildlife Service guidelines to classify nesting/roosting and foraging habitat for northern spotted owls.

Habitat category	Tree Size (QMD)[1]	Basal Area[2]	Trees > 26"dbh	Canopy closure
High nesting/roosting	≥ 15"	≥ 210 ft^2	8 per acre	≥60%
Nesting/roosting	≥ 15"	150–180+ ft^2	8 per acre	≥ 60%
Foraging	≥ 13"	120-180+ ft^2	5 per acre	≥ 60%
Low foraging	≥ 11"	80-120+ ft^2		≥ 40%

1: Quadratic Mean Diameter (inches) of trees > 5" diameter
2: Square feet per acre, trees > 5"

A few studies have provided plot-level descriptions of areas used by NSO. Habitat definitions in the FWS guidelines are primarily based on the statistical distributions of habitat parameters correlated with use by owls in these studies. Yet, the average conditions in small study plots around owl locations may poorly represent the inherent variability of stands and landscapes in owl territories. Therefore, the FWS guidelines distribute habitat categories in terms of ranges of values within analysis areas, rather than as stand averages. This approach ensures that a range of suitable habitat conditions is well-distributed at appropriate spatial scales, without being unrealistically or unreasonably prescriptive.

Figure III.D.1: Conceptual model of northern spotted owl habitat functions and associated forest structural conditions.



Basal Area	300+	200	150	120	80
QMD[1]	20”		15”	13”	11”
TPA > 26”[2]	50		8	5	
Canopy[3]	100%		60%		40%
Structure	Large tree/dense	Large/open to medium/dense		small/dense to open/brushy	

1: QMD= quadratic mean diameter of trees > 5 inches dbh
2: TPA>26”= trees per acres of trees >26 inches dbh
3: Canopy= percent cover of overstory trees

The FWS guidelines use a suite of structural metrics to classify NSO habitat (basal area, quadratic mean diameter, large-diameter [>26 inches DBH] trees per acre, and canopy cover) (Table III.D.1). We chose these metrics because they describe different aspects of stand structure that appear to be important to NSO and because they are commonly used by silviculturists to evaluate forest conditions. The FWS discourages the use of broad vegetation classification categories for defining habitat for NSO in the Klamath Province. These classification schemes are inappropriate for defining habitat in take-avoidance guidelines because they encompass broad ranges of vegetation parameters that often do not correspond to habitat used by NSO. For example, habitat class 4M in the CWHR system (average DBH 11 - 24 inches and average canopy cover 40-59 percent) might describe anything from infrequently-used foraging habitat to nesting and roosting habitat. Furthermore, use of broad habitat classification schemes can mask the effects of habitat modification. For example, timber harvests could remove important habitat elements (e.g., snags, deformed trees, dense groups of large trees) while maintaining the minimum average canopy cover and tree diameter values in a given habitat category and masking the loss of habitat quantity and quality.

Habitats Used for Nesting and Roosting

The 2008 NSO Recovery Plan (USFWS 2008:50) stated that: "Features that support nesting and roosting typically include a moderate to high canopy closure (60 to 90 percent); a multi-layered, multi-species canopy with large overstory trees (with diameter at breast height [dbh] of greater than 30 inches); a high incidence of large trees with various deformities (large cavities, broken tops, mistletoe infections, and other evidence of decadence); large snags; large accumulations of fallen trees and other woody debris on the ground; and sufficient open space below the canopy for spotted owls to fly." The validity of applying this rangewide habitat definition to the Klamath Province has been supported by numerous studies in and adjacent to the region (e.g., Solis and Gutiérrez 1990, Blakesley *et al.* 1992, Carey *et al.* 1992, Hershey *et al.* 1998, LaHaye and Gutiérrez 1999), including on private timberlands (Self *et al.* 1991, SPI 1992, Farber and Crans 2000).

The characteristic structure of nesting/roosting habitat probably serves a variety of functions for NSO. NSO may partly favor older, more decadent forest for nesting because it frequently contains suitable nest structures. Nests are usually located in older, larger-diameter, deformed, decadent, or diseased trees containing cavities or platforms (Forsman *et al.* 1984, Hershey *et al.* 1998, LaHaye and Gutiérrez 1999, North *et al.* 2000). Northern spotted owls may also nest and roost in older, denser forest because it tends to provide a more moderate, stable microclimate compared with other kinds of forest. NSO are less able to dissipate body heat than other owls and appear to compensate by nesting and roosting in relatively cool, humid sites (Barrows 1981, Ganey *et al.* 1993, Ting 1998, Weathers *et al.* 2001). NSO also appear to use dense, multilayered canopies for protection from cold, wet weather (Forsman *et al.* 1984, North *et al.* 2000). Northern spotted owls may also prefer nesting and roosting in denser forest because it provides visual screening from predators (Carey 1985, Buchanan *et al.* 1995).

High-quality nesting/roosting habitat

As defined by the FWS guidelines, high-quality nesting/roosting habitat occurs where structural conditions resemble or exceed those of most observed NSO nest sites in northern California (see Table III.D.2). To date, no Klamath Province study has directly compared plot-level vegetation data for nest and roost sites to the demography of NSO, so it is unknown if the average structural conditions used by owls in the region are associated with high reproduction and survival. Therefore, a definition of high-quality nesting/roosting habitat must account for variability in habitat-use patterns among individuals by ensuring that the range of habitat values associated with owl use are well-represented, rather than prescribing a single criterion based on mean values.

Nesting/roosting habitat

The FWS' definition of nesting/roosting habitat is similar to high-quality nesting/roosting habitat, but is intended to reflect both variability in the structure of sites used by nesting and roosting owls and the variability typical of forest stands or patches encompassing denser nest and roost sites (see Table III.D.1and III.D.2). The FWS guidelines' requirement for a mix of basal areas in nesting/roosting habitat allows land managers some operational flexibility but also discourages homogenization of stands during harvesting. Although it is more stringent than that used in the FPR guidelines, the FWS guidelines provide definitions of habitats used for nesting and roosting that consistent with the range of conditions found at many spotted owl nest cores on private timberlands.

Table III.D.2: Mean structural characteristics of areas used by spotted owls for nesting, roosting, and foraging (rounded to the nearest whole number). The habitat variables are basal area (BA), quadratic mean diameter (QMD), large trees per acre (TPA), and canopy cover (CC)

Foraging Habitat

Foraging habitat encompasses nesting and roosting habitat but includes a broader range of structure and might not support successful nesting by NSO (Gutiérrez 1996, USFWS 2008). Foraging NSO generally use older, denser, and more complex forest than expected based on its availability, but they also use younger forest (Solis and Gutiérrez 1990, Carey *et al.* 1992, Zabel *et al.* 1993, Carey and Peeler 1995, Anthony and Wagner 1999, Irwin *et al.* 2007b). The FWS guidelines incorporate this structural variability by specifying retention of habitat in four functional categories of habitat suitable for NSO. High-quality nesting/roosting and nesting/roosting habitat provide the upper range of stand structure selected by foraging NSO; foraging habitat encompasses a broad range of structure, and low-quality foraging habitat includes younger and more open habitats that may be important for prey production (Tables III.D.1 and III.D.2; Figure III.D.1). Northern spotted owls may prefer older, denser forest for foraging because it often contains both abundant prey and suitable structural characteristics for hunting. Several important prey species, including flying squirrels (*Glaucomys sabrinus*) and western red-backed voles (*Clethreionomys californicus*) tend to be most abundant in older, denser forest (Carey *et al.* 1992; Waters and Zabel 1995, 1998). Other important prey species, such as woodrats, have been found to be most abundant in young sapling stands (Sakai and Noon 1993), but can also reach high abundances in dense, old forest (Carey *et al.* 1992, Sakai and Noon 1993). Spotted owls usually hunt by listening and scanning for prey from elevated perches (Forsman *et al.* 1984). Dense, multilayered forest might provide owls with hunting perches at a variety of canopy levels (North *et al.* 1999). Dense vegetation might also visually screen foraging NSO from predators and prey

(Carey 1985, Buchanan *et al.* 1995). Conversely, spotted owls require space for flying, which could place an upper limit on the understory density of suitable habitat (Irwin *et al.* 2007b).

Descriptions of habitat structure used by foraging NSO are typically based on studies employing radio telemetry to monitor owl movements. While the habitats associated with nocturnal telemetry locations are commonly termed 'foraging locations', some researchers point out that the owl locations simply indicate the distribution of movements, and may not correspond to sites and habitats actually used by actively foraging NSO. During radio telemetry studies in northwestern California, Diller (unpub. data), found that owls moved frequently during monitoring periods (7.5 minutes/perch for 6 males; 17.0 minutes/perch for 4 females), suggesting that the process of triangulating azimuths for each location was unlikely to detect a specific site used for foraging. Conversely, owls in this study also were stationary for long periods of time, possibly resting, preening, or other activities not associated with active foraging. For these reasons, the FWS recognizes that our descriptions of NSO foraging habitat likely represent the range of habitat conditions used by owls at night, and may not represent the specific habitat qualities of sites where NSO successfully obtain prey.

There are currently no published plot-based descriptions of NSO foraging habitat in the Klamath Province. We therefore strongly considered the results of both unpublished studies of NSO and a published study of California spotted owls (*Strix occidentalis occidentalis*, CSOs) in the northern Sierra Nevada (Irwin *et al.* 2007b) while formulating these habitat definitions. Much of the CSO study was conducted in a mixed-conifer/hardwood forest similar to forest types used by NSO in the Klamath Province.

Although spotted owls often selectively foraged in older forest, these telemetry studies show that they also use a relatively wide range of forest structure (Irwin *et al*. 2004, 2007).

The range of forest structure specified in the FWS guidelines is also based on the distribution of habitat use by foraging NSO in the Klamath Province. Analysis of radio-telemetry data from NSO in southern Oregon (L. Irwin, unpublished data) indicates that roughly 46 percent of nocturnal (foraging) locations occurred in nesting/roosting habitat (basal area ≥210 ft^2/acre), and 76 percent occurred in stands classified as foraging, nesting, and roosting habitat (Figure III.D.2). Only 14% of locations were in stands classified as low-quality foraging habitat. Thus, the functional habitat categories specified in the FWS guidelines capture about 90 percent of the observed distribution of actual use by NSO, but also require retention of the full range of structural conditions corresponding to nesting, roosting, and foraging.

In addition to the structural characteristics addressed in the FWS guidelines, studies have indicated that certain conifer species such as Douglas-fir, as well as hardwoods and dead woody materials are important features of spotted owl foraging habitat (North *et al.* 1999, Irwin *et al.* 2000, Glenn *et al.* 2004, Irwin *et al.* 2007).

Figure III.D.2: Distribution of basal area at inventory plots near nocturnal telemetry locations for northern spotted owls in the Medford area of the Klamath Province (L. Irwin, unpublished data). This figure shows some of the range of basal area values used for foraging; it is does not show selection or avoidance of particular values since available conditions were not described.

Abiotic Habitat Characteristics

Habitat selection by breeding NSO is strongly influenced by spatial and topographic features such as proximity to nest, distance to water, slope position, and elevation. Termed 'abiotic considerations' in the FWS guidelines, these factors act to influence the habitat value of forest stands, and subsequently the importance of retaining habitat based on landscape position as well as stand structure. Abiotic considerations are explicitly incorporated into the FWS guidelines through a prioritization system that ranks habitat retention areas based on distance to nest, contiguity, slope position, aspect, and elevation.

Because the guidelines for abiotic considerations are less prescriptive than the guidelines for stand structure, they are more easily applied during habitat evaluations on a case by case basis.

Habitat selection by breeding NSO is strongly associated with proximity to the nest, as well as with vegetation characteristics (Carey and Peeler 1995, Rosenberg and McKelvey 1999, Glenn *et al.* 2004, Irwin *et al.* 2007b). Spotted owls appear to be central-place foragers, disproportionately using areas near the nest in order to minimize travel costs and maximize their energetic return from foraging (Carey and Peeler 1995, Rosenberg and McKelvey 1999). Home range studies have also indicated the importance of the territory center to spotted owls (see *Analysis Areas*). Combined, spatial patterns of habitat selection and habitat use suggest that NSO may be more sensitive to reductions of habitat in their core areas than in other parts of their home ranges. The FWS guidelines therefore emphasize retention of habitat at the core area scale.

Topography also appears to influence habitat use by NSO; which use lower slope positions more frequently than higher ones (Forsman *et al.* 1984, Blakesley *et al.* 1992, Hershey *et al.* 1998, LaHaye and Gutiérrez 1999, Irwin *et al.* 2007b). Lower slopes likely provide cooler, more humid microclimates for nesting and roosting and favor growth of the denser forest structure preferred by spotted owls. Furthermore, lower slope positions tend to have less frequent and severe fire regimes, potentially allowing trees to attain greater density, sizes and ages than on higher slopes (Beaty and Taylor 2001, Skinner *et al.* 2006). Spotted owls also appear to prefer areas close to streams, which often occur at the bottoms of slopes (Solis and Gutiérrez 1990, LaHaye and Gutiérrez 1999, Irwin *et al.* 2007b). Areas near streams likely tend to be more productive and have cooler, more humid microclimates than upland areas. Additionally, prey abundance can be high in riparian areas (Carey *et al.* 1992, Anthony *et al.* 2003) and NSO may use streams for drinking and bathing (Forsman *et al.* 1984). Some studies have found that NSO in the Klamath Province selectively use northerly aspects, but others found different patterns or no pattern at all (Solis and Gutiérrez 1990, Blakesley *et al.* 1992, Carey *et al.* 1992, Zabel *et al.* 1993, Farber and Crans 2000). Suitable microclimates for nesting and roosting, and for the vegetation structure preferred by NSO, may occur more frequently on north-facing slopes than on other aspects. However, aspect does not appear to influence vegetation distribution as strongly in some areas as in others (e.g., Zabel *et al.* 1993). Elevation also seems to influence habitat-use by spotted owls (Solis and Gutiérrez 1990, Blakesley *et al.* 1992, Hershey *et al.* 1998, LaHaye and Gutiérrez 1999, Irwin *et al.* 2007b). This might be related both to spotted owls' disproportionate use of lower slope positions and to the influence of elevation on vegetation distribution. The productive vegetation types favored by NSO, such as mixed-evergreen forest, primarily occur at lower elevations in the Klamath Province (Sawyer 2007).

III. E. Conclusions:

The FWS has conducted a thorough review and synthesis of published literature, unpublished data sets, and direct communication with NSO researchers in support of a rigorous process for evaluating the effects of habitat management on NSO. It is important to recognize that the habitat conditions described in the document are intended for use in estimating the likelihood of take of individual NSO under the ESA; they do not represent habitat conditions required for population growth or recovery. The FWS guidelines focus solely on individual NSO territories and do not incorporate larger-scale issues such as connectivity and dispersal habitat, wintering habitat, or longer-term habitat disturbance patterns. The FWS habitat evaluation guidelines that this science review document supports are complex; reflecting the complex nature of forest environments in the Klamath Province and the forest products industry's requirement to retain maximum flexibility to conduct timber harvests in the vicinity of occupied NSO territories.

Appendix A: Full text of U.S. Fish and Wildlife Service Guidance for Evaluation of Take for Northern Spotted Owls on Private Timberlands in California's Northern Interior Region

I. Accuracy of NSO activity center location and status

1) Location
    a. Confirm plotted activity center location accuracy
        i. CDFG Reports 2 and 3
        ii. Data from adjacent landowners
        iii. Recent surveys
    b. Document deviations from CDFG locations
    c. Update habitat analysis maps as necessary

2) Status
    a. Valid site
        i. Review page 11 of protocol to determine
        ii. If not valid, report to CDFG for inclusion in next database update
    b. Current occupancy status
    c. Current reproductive status, if determined

II. Survey Effort

1) Coverage
    a. Surveys of nesting/roosting habitat out to 0.7 miles from THP boundary
        i. Use THP habitat map(s) to verify

2) Protocol survey
    a. Time of day
    b. Spacing between visits
    c. Number of surveys
    d. Survey dates
    e. Time spent at each call point

3) Follow up visit(s)
    a. Confirm that the area searched covers suitable habitat within response location/last known location within a logical distance.
    b. Time of follow up and duration of follow up
    c. Additional night surveys
        i. Review page 10 of protocol

III. Habitat

1) Typing
    a. Verify habitat typing with aerial photos, equivalent imagery, or field visits

b. Changes to typing need to be reflected in the NSO habitat acres table and habitat analysis maps
c. Post harvest typing
    i. Post-harvest habitat typing must agree with the silviculture prescription

2) Definitions
    a. Nesting/roosting
        i. High Quality Nesting/roosting Habitat
            1. Basal Area = 210+ square feet, **and**
            2. ≥ 15" quadratic mean diameter (QMD) , **and**
            3. ≥ 8 trees per acre (TPA) of trees ≥ 26" in diameter at breast height (DBH) , **and**
            4. ≥ 60% canopy closure
        ii. Nesting/roosting Habitat
            1. A mix of basal areas ranging from 150-180+ square feet, **and**
            2. ≥ 15" QMD, **and**
            3. ≥ 8 TPA of trees ≥ 26" DBH, **and**
            4. ≥ 60% canopy closure
    b. Foraging
        i. Foraging Habitat
            1. A mix of basal areas ranging from 120-180+ square feet, **and**
            2. ≥ 13" QMD, **and**
            3. ≥ 5 TPA of trees ≥ 26" DBH, **and**
            4. A mix of ≥ 40%-100% canopy closure
        ii. Low Quality Foraging Habitat
            1. A mix of basal areas ranging from 80-120+ square feet, **and**
            2. ≥ 11" QMD, **and**
            3. ≥ 40% canopy closure

3) Quantities
    a. Within 1000 feet of activity center
        i. Outside breeding season (September 1 through January 31): no timber operations other than use of existing roads
        ii. During the breeding season (February 1 through August 31): no timber operations other than the use of existing, permanent, year-round roads

    b. Within 0.5 mile radius (502 acres) centered on activity center
        i. Retention of habitat should follow Section III. 4 of this document
        ii. At least 250 acres nesting/roosting habitat present, as follows:
            1. 100 acres High Quality Nesting/roosting Habitat, **and**
            2. 150 acres Nesting/roosting Habitat

        –AND–

        iii. At least 150 acres foraging habitat must be present, as follows:
            1. 100 acres Foraging Habitat, **and**
            2. 50 acres Low Quality Foraging Habitat
        iv. No more than 1/3 of the remaining suitable habitat may be harvested during the life of the THP

c. Between 0.5 mile radius and 1.3 miles radius circles centered on activity center
    i. Retention of habitat should follow Section III. 4 of this document
    ii. ≥935 acres suitable habitat must be present, as follows:
        1. At least 655 acres Foraging Habitat, **and**
        2. At least 280 acres Low Quality Foraging, **and**
        3. No more than 1/3 of the remaining suitable habitat may be harvested during the life of the THP

4) Priority Ranking of Habitat Retention Acres
    a. Tree species composition
        i. Mixed conifer stands should be selected over pine dominated stands
    b. Abiotic considerations
        i. Distance to nest
            1. Nesting/roosting and foraging habitat closest to identified nest trees, or roosting trees if no nest trees identified
        ii. Contiguous
            1. Nesting/roosting habitat within the 0.5 mile radius must be as contiguous as possible
            2. Minimize fragmentation of foraging habitat as much as possible
        iii. Slope position
            1. Habitats located on the lower 1/3 of slopes provide optimal micro-climate conditions and an increased potential for intermittent or year-round water sources
        iv. Aspect
            1. Habitats located on northerly aspects provide optimal vegetation composition and cooler site conditions
        v. Elevation
            1. Habitat should be at elevations of less than 6000 feet, though the elevation of some activity centers (primarily east of Interstate 5) may necessitate inclusion of habitat at elevations greater than 6000 feet.

IV. Determination

1) If surveys are inadequate or do not meet the intent of protocol, take determination may not be possible.
2) If habitat typing is inadequate, take determination may not be possible.
3) If NSO home range habitat acres are below desired conditions (Section III. 2, 3, and 4), additional loss of suitable habitat can lead to take.
4) If NSOs are nesting, utilize seasonal restriction within 0.25 mile of nest (February 1 through August 31).
5) If effects are limited to noise disturbance, a modified seasonal restriction may be used from February 1 through July 9

    a. Harvest of unsuitable habitat, with unsurveyed suitable within 0.25 of unit boundary
6) Multiple THPs located within a given NSO territory need to be considered collectively or a take determination may not be possible.

V. TA Letter Contents

1) Date of written TA request
2) Date request received
3) Note if previous TA(s) provided in past
4) Number of acres within THP units
5) Amounts and types of silviculture prescriptions
6) Location of THP
    a. Township, Range, and Section
    b. Meridian
    c. County
7) Identify NSO activity centers returned by CDFG reports
8) Surveys conducted and activity center status
9) Logic behind take determination
    a. Habitat considerations
        i. Acres, quality, and location of suitable habitat pre- and post-harvest
        ii. Effects of timber operations on suitable habitat
            1. Degrade: suitable habitat is harvested but still functions in the capacity it did pre-harvest (i.e. Foraging habitat before harvest functions as foraging habitat post-harvest, nesting/roosting habitat pre-harvest functions as nesting/roosting habitat post-harvest)
            2. Downgrade: pre-harvest nesting/roosting habitat becomes foraging habitat post-harvest
            3. Remove: nesting/roosting or foraging habitat is harvested such that it no longer functions as habitat post-harvest
    b. Proximity of activity center to operations
    c. Survey data
10) Sunset date and seasonal restrictions
    a. If 2 year protocol and surveys are current and negative, additional TA needed if operations not completed by February 1, *YEAR* (review protocol page 3).
    b. If 1 year protocol and surveys are current and negative, additional TA needed if operations not completed by February 1, *YEAR* (review protocol page 3).
    c. If NSOs detected in previous surveys and operations are not complete before February 1, surveys are required to determine location and status of NSOs prior to operations during each breeding season that operations are ongoing.
    d. If no owls within 1.3 miles of THP (CDFG reports) and no suitable habitat within units or 1.3 miles of units, additional technical assistance may not be required.
11) Name of agency person to contact if there questions regarding TA

Re: EPIC Comments on Department of Fish and Wildlife California Endangered Species Act Status Review for the Northern Spotted Owl (*Strix occidentalis caurina*)

Dear Mr. Clipperton and Department Officials:

The Environmental Protection Information Center (EPIC) presents the following comments on the California Department of Fish and Wildlife (CDFW or Department) status review for the Northern Spotted Owl (*Strix occidentalis caurina*) (NSO) pursuant to the California Endangered Species Act (CESA). EPIC appreciates the opportunity to provide the Department with comments and direction as it conducts its review of the status of the NSO in California.

These comments demonstrate the plight of the Northern Spotted Owl in California through the lens of an appropriate review and analysis approach that considers bio-regional differences in NSO behavior, habitat needs, prey base, and forest types. We hope that this information and approach assist the Department in developing its review which recommends listing of the NSO under CESA.

Summary

The Northern Spotted Owl warrants listing under CESA because it meets several of the criteria for listing a species as specified under the Act. Specifically, the NSO warrants listing due to the following factors: 1) past, present, and threatened habitat destruction, modification or curtailment; 2) competition from invasive species; 3) inadequate regulatory mechanisms; and 4) climate change. The preponderance of the best available evidence suggests that these and other factors are contributing to the decline of the NSO throughout all provinces in California.

I. Introduction and Background

Petition History

EPIC submitted a petition to the California Fish and Game Commission (Commission) to list the Northern Spotted Owl as either "threatened" or "endangered" under CESA on September 4th, 2012. At its August 7th, 2013 meeting, the Commission voted to accept EPIC's petition, finding that the petitioned action "may be warranted." At its December 11th, 2013 hearing the Commission adopted findings for its decision, thus initiating a one-year "candidacy" period for the NSO.

CDFW Obligations during "Candidacy" Period

Fish and Game Code section 2074.6(a) requires that within 12 months of the Commission's "candidate" designation, the Department must produce and make publicly available a final written peer-reviewed status report. This report is to be based upon the best scientific information available to the Department. The Department must evaluate whether the petitioned action is warranted, includes a preliminary identification of the habitat that may be essential to the continued existence of the species, and recommends management activities and other recommendations for recovery of the species. "Prior to releasing the final written report, the Department shall have a draft status review report prepared and independently peer reviewed, and upon receiving the peer reviewers' input, shall evaluate and respond in writing to the independent peer review and shall amend the draft status review report as appropriate." *Id*. The revised report shall be posted on the Department's Internet Web site for a minimum of 30 days for public review prior to the Commission's hearing scheduled for final consideration of the petition and listing.

Standard of Evidence

CESA is modeled on the federal ESA (FESA), and the two statutes contain very similar substantive and procedural provisions. For instance, both statutes provide for the listing and protection of threatened and endangered species in a process initiated by a citizen petition. CFGC § 2071 *et seq*., 16 U.S.C. § 1533 *et seq*. At the first step in each process, the decision makers decide whether listing "may be warranted," CFGC § 2074.2, 16 U.S.C. § 1533(b)(3)(A), and at the second step in each process, the decision makers decide whether listing "is warranted." CFGC § 2075.5, 16 U.S.C. § 1533(b)(3)(B). Under CESA, as under FESA, listing decisions must be based on the best available science. CFGC §§ 2072.3, 2074.6; 16 U.S.C. § 1533(b)(1)(A).

California courts have explained that "it is a basic premise of statutory construction that when a state law is patterned after a federal law, the two are construed together." *NRDC v. California Fish & Game Comm.,* 28 Cal.App.4th 1102, 1118 (1994), citing *Moreland v. Department of Corporations*, 194 Cal.App.3d 506, 512-13 (1987). Thus, interpretation of the federal ESA guides CESA. This is particularly applicable here, as case law has determined that scientific certainty is not required for a species to qualify for protected status through listing.

> The [FESA] contains no requirement that the evidence be conclusive in order for a species to be listed. Application of such a stringent standard violates the plain terms of the statute . . . Congress repeatedly explained that it intended to require the FWS to take preventive measures before a species is 'conclusively' headed for extinction. The purpose of creating a separate designation for species which are 'threatened', in addition to species which are 'endangered', was to try to 'regulate these animals before the danger becomes imminent while long-range action is begun.'
>
> The FWS itself has taken the position that it need not, and must not wait for conclusive evidence in order to list a species. For example, in its decision to list the northern spotted owl, it explained that because the agency had 'used the best data available to prepare the proposed rule, it was 'not obligated to have data on all aspects of a species biology prior to reaching a determination on listing'. Moreover, the agency concluded that 'to withdraw the proposal and conduct additional research would not improve the status of the [species] and would not be in keeping with the mandates of the Endangered Species Act.' More recently, the FWS decided to list the California red-legged frog, even though many aspects of the species' status were 'not completely understood', because 'a significant delay in listing a species due to large, long-term biological or ecological research efforts could compromise the survival of the [species].'
>
> Furthermore, Defendants have gone to great lengths to argue that there is a lack of 'scientific certainty' as to various aspects of the [species'] status. The ESA does not, however, require such 'certainty' to justify the listing of a species. To the contrary, the clear intent and purpose of Congress in enacting the ESA was to provide preventive protection for species before there is 'conclusive' evidence that they have become extinct.

Defenders of Wildlife v. Babbitt, 958 F.Supp. 670, 679-81 (D.D.C. 1997) (internal citations omitted).

Accordingly, the Department cannot dismiss the need for listing of the NSO based on a claim of lack of "scientific certainty." Rather, following the U.S. Fish and Wildlife Service's (FWS) lead, the Department should determine whether or not listing is warranted based on the preponderance of available evidence. Like any topic of scientific research, there is scientific uncertainty regarding the status and ecology of NSOs. Nonetheless, the NSO is one of the most thoroughly studied vertebrates in North America and a substantial and compelling body of scientific information about the species is currently available.

Recommended Review Approach

EPIC strongly believes that any approach to conducting a status review for the NSO must be firmly rooted in the species' ecology. As noted by the FWS and leading researchers, the NSO's ecology, status, and threats vary among regions, forest types, and elevation zones (USFWS 2011, 2012; Forsman et al. 2011; Courtney et al. 2004). Any robust status review must also consider the available information on NSO populations, trends, and threats across ownership classes, and indeed down to the individual ownership level. Finally, care must be taken in how the Department weighs the various types and sources of information it receives for consideration. For example, the Department clearly must give greater weight and consideration to long-term peer-reviewed studies related to the NSO in California over unpublished, non-peer-reviewed monitoring reports or raw data from project-level surveys.

II. <u>Status of the Northern Spotted Owl</u>

<u>Range-wide Trends</u>

Forsman et al. (2011) identifies three categories of study to determine NSO trends range-wide. These are fecundity, apparent survival, and population trends. Below is a summary of the findings of Forsman et al. (2011) with respect to study areas range-wide.

TABLE 1: Summary of trends in demographic parameters for northern spotted owls, from 11 study areas 1985-2008, adapted from Forsman et al. (2011).

Study Area	Fecundity	Apparent survival	Population trend
Washington			
Cle Elum	Declining	Declining	Declining
Rainier	Increasing	Declining	Declining
Olympic	Stable	Declining	Declining
Oregon			
Coast Range	Increasing	Declining since 1998	Declining
H.J. Andrews	Increasing	Declining since 1997	Declining
Tyee	Stable	Declining since 2000	Stationary
Klamath	Declining	Stable	Stationary
Southern Cascades	Declining	Declining since 2000	Stationary
California			
Northwestern California	Declining	Declining	Declining
Hoopa	Stable	Declining since 2004	Stationary
Green Diamond	Declining	Declining	Declining

<u>California Trends</u>

A primary purpose of the status review is to determine trends in Northern Spotted Owl abundance, population, distribution, and demographic rates for California. EPIC recommends that the Department conduct its review on a bio-regional level, and at landscape and individual ownership scales. We address some of these factors below.

<u>Range and Distribution</u>

As noted in the petition, historically, the Northern Spotted Owl was found from British Columbia through western Washington, western Oregon, and northwestern California from Siskiyou County south to Marin County (American Ornithological Union 1957, Forsman 1976, Forsman et al. 1984, Gutiérrez et al. 1995). The ranges of the Northern and California subspecies of spotted owls meet at the southern end of the Cascade Range, near the Pit River area in northern California. In California, populations are declining in two of three long-term monitoring sites while numerous historic territories have been lost from interior forests in California. The Revised Recovery Plan for the Northern Spotted Owl states: “Many historical spotted owl site-centers are no longer occupied because spotted owls have been displaced by barred owls, timber harvest, or fires” (U.S. Fish and Wildlife Service 2011) (Petition, at page 7).

Despite this, the Department’s initial petition evaluation (CDFW 2013) states that,

> “Based on information in the Petition and other data that is readily available to the Department for California, there is not evidence to indicate that the distribution of northern spotted owl has changed during the time period of years for which surveying/monitoring of the species distribution has occurred” (CDFW Petition Evaluation, at 6).

While further study is needed to determine the range and distribution of the NSO range-wide and within California, the Department cannot reject listing based on an erroneous standard of “certainty” in the evidence; it must consider the best evidence available at the time of its status review, which instructs that the NSO population is declining in California.

NSO Abundance

With respect to NSO abundance, the Fish and Game Commission’s finding, citing the Department’s petition evaluation determined the following:

> “The petition (pages 12-15) does not include direct information about the population size or abundance of NSO populations in California, nor does it discuss abundance range-wide. The Department deemed the relevant information found in the literature cited in the petition and other scientific documents consulted for its evaluation report to be inconclusive to determine the abundance of NSO range-wide or in California, and concluded that further research and analysis is required to determine the abundance for NSO populations in California. (Evaluation Report, page 6).”

Further study is needed to answer the question of NSO abundance in California. In its initial petition evaluation the Department referenced the NSO database maintained as part of the California Native Diversity Database (CNDDB), and acknowledged that until recently this database has not been regularly maintained (CDFW Petition Evaluation, at page 3). The NSO CNDDB may be a useful tool for estimating owl abundance in California, but its utility is clearly limited. Not only is the database limited by infrequent maintenance, but it is also limited in use due to inadequate survey coverage in many areas.

While the evidence available to the Department regarding the abundance of NSO is inconclusive, there is clear evidence of negative demographic trends in California and rangewide (Forsman et al. 2011). Occupancy rates from Timber Company monitoring reports (e.g., CDFW 2013 errata sheet, page 1) should be considered as part of the body of information available concerning the

NSO's status in California (see below). However, they do not represent an equally rigorous or valid counterweight to peer-reviewed, long-term demographic research.

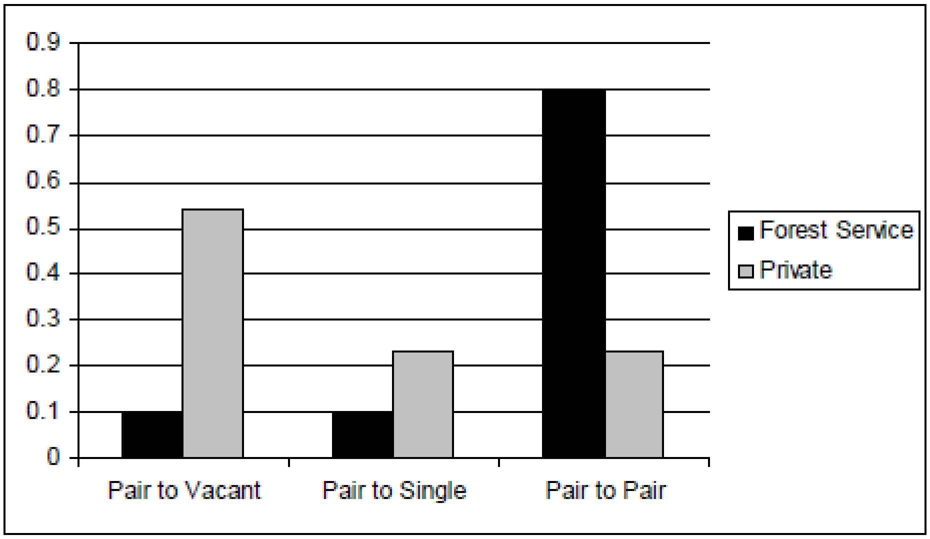
Occupancy trends

The Yreka office of the FWS has completed an extensive analysis of the status of historical spotted owl activity centers on federal and private lands in interior northern California (U.S. Fish and Wildlife Service 2009). The FWS found that extensive losses of owl pairs occurred on private lands, which sharply contrasted with the persistence of owl pairs on federal lands. (U.S. Fish and Wildlife Service 2009: 11-12) stated:

> To quantify the pattern of territory loss identified during the technical assistance process, we compared results of protocol surveys conducted at verified NSO territories supporting at least one year of occupancy by paired owls on Forest Service lands (N=196) with similar data from private timberlands (N=75) in Shasta and Trinity counties. The data set consisted of activity center status records in the California Department of Fish and Game's Spotted Owl Database (CDFG-NSO database), supplemented with territory locations and recent survey records received during technical assistance. We first evaluated the validity of activity center records in the CDFG-NSO database, and eliminated 18 sites on private lands due to lack of verification of status. The remaining 57 private-land activity centers had verified NSO status in at least one year between 1989 and 2007; 44 of these sites had supported pairs during at least one year. Of these verified pair sites, 54% declined from pair status to no response, and an additional 23% declined from pair status to a territorial single owl during subsequent protocol surveys (Figure I.B.1). On Forest Service-administered lands, 80% of pair sites did not change status during the same time periods. While we recognize that annual variation in survey effort and results at this relatively coarse scale of resolution may influence this type of analysis, the strong differences in trends observed on private versus federal lands supports the contention that management on private timberlands is creating habitat conditions that do not support sustained occupancy by NSO" (U.S. Fish and Wildlife Service 2009: 11-12).

The FWS created the figure below to illustrate the results of their analysis.

Figure I.B.1. Status of valid historical northern spotted owl activity centers (pair sites only) when resurveyed after 5-10 years. Data are from U.S. Fish and Wildlife Service technical assistance records and USFS monitoring records



This and other available evidence suggests that NSO site occupancy on private forestlands in interior California is declining.

III. Immediacy of Threats to the Northern Spotted Owl

Past, Present, and Threatened Habitat Destruction, Modification, or Curtailment

The topic of habitat loss must be broken into several categories to address the myriad of factors influencing past, present, and threatened habitat destruction, modification, or curtailment within the species range and in California specifically. We address the following factors affecting NSO habitat loss, modification, and curtailment: 1) timber harvest on public and private lands; 2) stand-replacing fire; and 3) habitat conversion.

Timber Harvest

The 2011 Revised Recovery Plan for the Northern Spotted Owl (U.S. Fish and Wildlife Service 2011) identifies past and present habitat loss due to timber harvest as a primary threat to the species range-wide. After a status review (U.S. Fish and Wildlife Service 1990a), the spotted owl was listed under the Endangered Species Act (ESA) as threatened on June 26, 1990 (U.S. Fish and Wildlife Service 1990b) because of widespread loss of the species' habitat across the spotted owl's range and the inadequacy of existing regulatory mechanisms to conserve the spotted owl. Past habitat loss and current habitat loss are also threats to the spotted owl, even though loss of habitat due to timber harvest has been greatly reduced on Federal lands over the past two decades (U.S. Fish and Wildlife Service 2011). The impacts of ongoing and threatened habitat loss, disturbance, and modification are significant and constitute a fundamental reason for listing.

The 2011 Revised Recovery Plan identified the impacts of timber harvest as a main threat to the NSO.

> "Currently, the most important range-wide threats to the spotted owl are competition with barred owls, ongoing loss of spotted owl habitat as a result of timber harvest, habitat loss or degradation from stand replacing wildfire and other disturbances, and loss of amount and distribution of spotted owl habitat as a result of past activities and disturbances" (U.S. Fish and Wildlife Service 2011).

Data presented in the 2011 Revised NSO Recovery Plan clearly shows substantially higher levels of NSO habitat loss on non-federal versus federal lands since the advent of the Northwest Forest Plan. Table 2-B taken from the Recovery Plan (below) indicates that non federal lands logging in California accounted for 5.8 percent of total habitat lost in California. Range-wide, 14.9% of NSO habitat on private lands within the range of the owl has been lost between 1994/96-2006/2007 to logging. Table B-2 demonstrates that habitat loss, modification, and curtailment continue to occur on both public and private lands in California and range-wide.

Table B-2. Estimated amount of spotted owl nesting and roosting habitat1 at the start of the Northwest Forest Plan (baseline 1994/96[2]) and losses owing to harvest through 2006/7[2], by State and ownership (adapted from Davis and Dugger in press).

Land class	Baseline (1994/96[2])	Harvest	Total Percent loss[3]
Federal reserved			
Washington	2,274,200	7,900	0.3%
Oregon	2,699,600	6,100	0.2%
California	1,214,000	2,500	0.2%
Range-wide total	6,187,800	16,500	0.3%
Federal non-reserved			
Washington	470,200	4,800	1.0%
Oregon	1,561,400	23,800	1.5%
California	634,400	8,700	1.4%
Range-wide total	2,666,000	37,300	1.4%
Non-federal			
Washington	1,258,900	234,200	18.6%
Oregon	1,382,400	301,200	21.8%
California	1,556,700	90,200	5.8%
Range-wide total	4,198,000	625,600	14.9%
Range-wide total	13,052,000	679,400	5.2%

[1] See Davis and Dugger (in press) for description of habitat.
[2] 1996 and 2006 for Oregon and Washington, 1994 and 2007 for California.
[3] Loss is the term used in Davis and Dugger (in press) to describe their data, which is summarized here.

On public lands, federal land management poses many problems for spotted owls. All federal lands within the range of the NSO are currently managed under the provisions of the Northwest Forest Plan (NWFP). The NWFP was adopted in 1994, and it amended land management planning documents for 19 National Forests and seven Bureau of Land Management districts throughout Washington, Oregon and California. The NWFP established a late-successional reserve (LSR) network and specified management standards and guidelines to further the recovery of the NSO.

The 15-year report on the NWFP performance for spotted owls was recently released. It shows that the NWFP is simply not adequate to ensure recovery of the species (Davis et al. 2011). The NWFP was based on overly optimistic assessments of spotted owl demographic performance (Franklin et al. 1999, Anthony et al. 2006). Demographic studies (Franklin et al. 1999, Anthony et al. 2006, Forsman et al. 2011, Davis et al. 2011) have demonstrated that the population declines are at a much greater rate than was anticipated across their range and particularly in Washington. In light of this decline, Forsman et al. (2011) stressed the importance of retaining high quality owl habitat: “[i]n view of the continued decline of Spotted Owls in most study areas, it would be wise to preserve as much high quality habitat (i.e., late-successional forests) for Spotted Owls as possible, distributed over as large an area as possible.”

It is much more difficult to quantify habitat loss, modification, and/or curtailment resulting from timber harvest on private lands than it is on public lands. Currently, there are no entity tracking habitat loss and modification, and there is no data, studies, or other information that addresses the impacts of timber harvest and other forest management practices on the NSO on private lands in California.

In our petition to the Fish and Game Commission, EPIC attempted to quantify habitat loss across some ownerships in California to illustrate that current and threatened habitat loss, modification and/or curtailment was continuing on private lands. In its initial petition evaluation, the Department was critical of our approach, citing inconsistencies in the numbers of acres of habitat removed versus the total acres of specified Timber Harvest Plans (THPs) (CDFW Petition Evaluation, at pages 10-11).

Because there is currently no entity in the State of California tracking the amount of NSO habitat lost, modified, or curtailed as a result of timber harvest activities on private lands, the best available source of information regarding these factors is contained may be individual THPs. We understand and appreciate the limitations of quantifying NSO habitat loss, modification, and/or curtailment by simply analyzing individual THPs. Indeed, information pertaining to the true impacts of timber operations on the NSO provided in THPs is often insufficient to allow for meaningful review of potentially significant impacts. The lack of accountability for habitat loss as a result of timber harvest is another reason why existing regulatory mechanisms are inadequate, and are another reason why listing under CESA is warranted. (See below).

What information is available documents that timber harvest activities in California are in fact destroying, modifying, or curtailing NSO habitat on private lands, and that the cumulative effect of over 150 years of such activities has left the NSO with a landscape that is largely either unsuitable or of very low quality to support stable or increasing rates of NSO occupancy, reproduction and survival.

The FWS's 2009 NSO "take" avoidance guidelines document (U.S. Fish and Wildlife Service 2009) provides the following conclusion regarding the impacts of persistent timber harvest on NSO habitat conditions on private lands:

> "…the strong differences in trends observed on private versus federal lands supports the contention that management on private timberlands is creating habitat conditions that do not support sustained occupancy by NSO." (p 12).

Indeed, in its March 29, 2013 letter of Technical Assistance to CAL FIRE and Sierra Pacific Industries (SPI) (TA 08YRE00-2013-007) the FWS made the following observation about habitat conditions on SPI lands:

> "[The U.S. Fish and Wildlife Service] have determined that SPI's landscape is dominated by habitats considered to provide foraging and quality foraging habitat. Suitable nesting/roosting habitat on SPI managed lands is much more limited." (U.S. Fish and Wildlife Service 2013).

SPI further acknowledges that its lands do not contain any high-quality nesting/roosting habitat in its own THPs, stating:

> "The absence of high quality nesting roosting habitat is largely a result of the USFWS's robust definition of this habitat type that exceeds the habitat conditions of most stands, except those that would traditionally be called "old growth" or primary older forest where no management footprint exists. These stands are not common in areas where historic or past management has been engaged either by Government or private land managers." (SPI THP 2-14-022TRI "Boomer" THP, Section V, page 293).

There are little, if any "primary older forests," or "old growth" forest habitat types available on SPI lands. SPI acknowledges that past management has resulted in the near extirpation of "primary older forests" or "old growth forests" on its property. *Id*. These forest types are clearly identified as preferable habitats for the NSO. As identified in the petition, the best available science shows that relatively large areas of structurally complex, older forests provide the habitat necessary to support viable populations of Northern Spotted Owls (Forsman et al. 2011). Spotted owls generally rely on older forested habitats because such forests contain the structures and characteristics required for nesting, roosting, and foraging, and dispersal.

Past, present and threatened habitat loss due to timber harvest remains a substantial threat to the Northern Spotted Owl in California. Habitat loss is ongoing on both public and private lands, and inadequate regulatory mechanisms exist to curtail this threat. (Please refer to section on inadequacy of regulatory mechanisms below).

Wildfire and Post-Fire Salvage Logging

Two major lines of evidence are available for evaluating effects of wildfire on NSOs: estimated loss of suitable habitat on federal lands (Davis and Dugger 2011) and studies of direct effects of fire on NSO demography, occupancy, and behavior (Bond et al. 2002, Clark et al. 2011, 2013).

Davis and Dugger (2011) estimated losses of suitable nesting-roosting habitat to wildfires and other disturbances on federal lands during 1994/1996 to 2006/2007 (evaluation periods varied among physiographic provinces). During that period some provinces experienced substantial (up to 10.2%) losses of suitable nesting-roosting habitat (Table B-1 [from the 2011 Recovery Plan, Figure 3-12 from Davis and Dugger 2011). These losses were primarily due to large wildfires in dry forests; largely within the Oregon and California Klamath provinces. Wildfires also fragmented suitable nesting-roosting habitat during this period (Figure 3-18 from Davis and Dugger 2011). Loss of 'core' (non-edge) nesting-roosting habitat could negatively affect NSO populations, due to the relationship between NSO fitness and amounts of core old-forest centered on nest trees or activity centers (Franklin et al. 2000, Olson et al. 2004, Dugger et al. 2005).

Table B-1. Spotted owl habitat loss on Federal lands resulting from harvest and natural disturbances from 1994/96[1] to 2006-7[1] (acres) (adapted from Davis and Dugger in press).

Physiographic Provinces	1994/96 acres	Harvest *(%)*[2]	Natural Disturbance			Total Habitat Loss	Total Percent loss[2,3]
			Wildfire	Insects and disease	Total *(%)*[2]		
Olympic Peninsula	763,100	**500** *(0.06%)*	200	0	**200** *(0.03%)*	700	**0.1%**
Eastern WA Cascades	673,600	**8,100** *(1.2%)*	20,000	2,000	**22,000** *(3.3%)*	30,100	**4.5%**
Western WA Cascades	1,283,000	**3,700** (0.3%)	700	400	**1,100** (0.09%)	4,800	**0.4%**
Western WA Lowlands	24,700	**400** *(1.6%)*	0	0	**0**	400	**1.6%**
OR Coast Range	611,200	**3,300** *(0.5%)*	0	0	**0**	3,300	**0.5%**
OR Klamath	985,000	**6,800** *(0.7%)*	93,600	300	**93,900** *(9.5%)*	100,700	**10.2%**
Eastern OR Cascades	402,900	**5,800** *(1.4%)*	17,800	2,300	**20,100** *(5.0%)*	25,900	**6.4%**
Western OR Cascades	2,258,700	**13,900** *(0.6%)*	28,900	1,100	**30,000** *(1.3%)*	43,900	**1.9%**
Willamette Valley	3,400	**100** *(2.9%)*	0	0	**0**	100	**2.9%**
CA Coast	145,400	**300** *(0.2%)*	2,100	100	**2,200** *(1.5%)*	2,500	**1.7%**
CA Cascades	213,200	**6,500** *(3.0%)*	1,800	300	**2,100** *(1.0%)*	8,600	**4.0%**

Range-wide total	8,853,000	**53,800** *(0.6%)*	236,700	8,100	**244,800** *(2.8%)*	298,600	**3.4%**

[1] 1996 and 2006 for Oregon and Washington, 1994 and 2007 for California.
[2] Percent of 1994/96 habitat.
[3] Loss is the term used in Davis and Dugger (in press) to describe their data, which is summarized here.

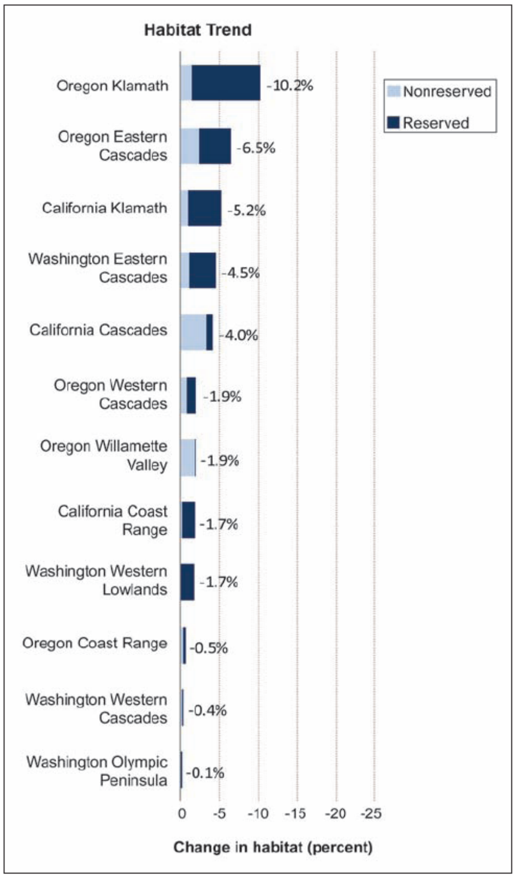

Figure 3-12—Nesting/roosting habitat trends (based on the LandTredr analysis) from 1994/96 to 2006/07 by physiographic province for reserved and nonreserved federal lands.

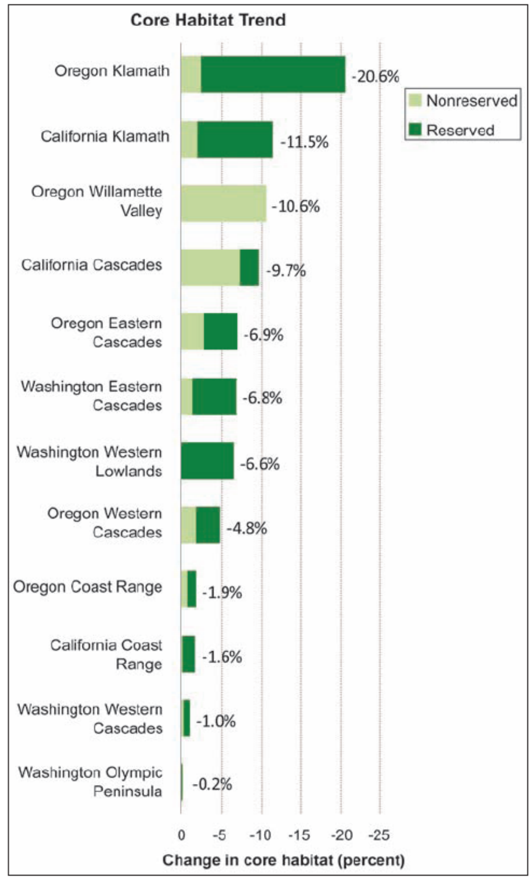

Figure 3-18—Nesting/roosting "core" habitat trends from 1994/96 to 2006/07 by physiographic province for reserved and nonreserved federal lands.

Bond et al. (2002) measured short-term (1 year) survival of 21 spotted owls and productivity of 7 pairs in 11 recently burned territories (4 NSO, 3 California spotted owl, and 4 Mexican spotted owl). Fire burned 83-100% of the area within estimated territories, including known nest and roost areas. Fire severity was mapped for 8 of 11 territories: 6 of these primarily experienced low- to moderate-severity fire and two experience extensive severe fire. The authors re-sighted 18 of 21 (86%) individual owls after the fires and 16 of these (89%) were in their pre-fire territories. These estimate survival and territory fidelity rates are similar to those found in other, longer-term studies of the three spotted owl subspecies. Bond et al. (2002) found 7 pairs in burned areas 1-year post-fire and an average of 1 offspring produced per pair. This level of productivity was higher than those found in other studies. While based on very small sample sizes, this study suggests that, in the very short-term (1-year post-fire) spotted owls may often continue to occupy and breed within territories that have experienced fire; particularly low-to-moderate severity fire.

Clark et al. (2013) examined how fire and subsequent salvage logging affected occupancy dynamics of NSOs in two wildfire areas in southwestern Oregon. First, the authors compared occupancy dynamics before and after the Timbered Rock Fire to those in another area not recently burned by wildfire (South Cascades study area). The burned study area (Timbered Rock) experienced a 64% reduction in site occupancy post-fire, compared with a 25% reduction in the unburned study area (South Cascades) during the same period. These results suggest that wildfire and/or post-fire salvage logging negatively affected site occupancy by NSOs. In the study's second analysis, the authors examined possible relationships between NSO occupancy dynamics and wildfire, post-fire salvage logging, and other habitat conditions in three burned areas (Biscuit, Timbered Rock, and Quartz). They were unable to determine relationships between pre-fire occupancy dynamics and habitat variables but they did find that site occupancy declined in the short-term post-fire. Declines in occupancy did not appear to have been due to salvage logging alone since post-fire site extinction probabilities were highest in the Biscuit Fire study area, in which 13.6% and 17.1% of intermediate-age and older forests experienced moderate and high severity fire, respectively, compared with only 1.6% being salvage logged. Past timber harvesting, high-severity fire, and post-fire salvage logging likely cumulatively contributed to declines in site occupancy in all three burned areas.

In the same study, Clark et al. (2011) estimated annual survival rates for 23 territorial NSOs in three burned study areas (Quartz, Timbered Rock, Biscuit). The remains of 4 of the 5 dead NSOs recovered during the study were severely emaciated, suggesting that the owls died of starvation; possibly due to wildfire and/or salvage logging effects on foraging habitat or prey populations. Estimated annual survival rates for owls located inside the fire perimeters or displaced by the fires and/or post-fire salvage logging were lower than those both in areas just outside the fire perimeters and in an unburned reference study area (South Cascades).

Apparently contradictory results found by these studies may be due to several factors, in addition to the occurrence of salvage logging in one study and not the other. For example, spotted owl populations in the areas studied by Clark et al. (2011) may have been more sensitive to habitat changes than those studied by Bond et al. (2002) because suitable nesting-roosting habitat was more limited due to past intensive timber harvesting and a checkerboard ownership pattern. It is also possible that the study by Bond et al. (2002) was too short to detect a negative effect of wildfire on spotted owls. For example, mortality of trees due to insect attack can take more than a year to occur (Gaines et al. 1997). Furthermore, spotted owls may not immediately respond to habitat changes due to strong fidelity to territories and mates. It is also likely that the studies' discrepant findings were strongly influenced by differences in fire severity. Much of the area studied by Clark et al. (2011) was severely burned and/or salvage logged (approximately 30-40%), while the majority of territories studied by Bond et al. (2002) primarily experienced low- to moderate-severity fire and none were salvage logged. Studies of California and Mexican spotted owls generally support conclusions that large, severe fires can have strong negative effects on spotted owls, whereas the species appears to be resilient to low- to moderate-severity fires (e.g., Keane et al. 2010, 2012).

Land use and Habitat Conversion

Conversion of Northern Spotted Owl habitat to other land uses was not identified as a significant threat to the species in the Revised Recovery Plan. There is, however an emerging and as yet little-understood threat in California—land conversion for cannabis agriculture, both legal and illegal. While there is little actual quantifiable evidence to demonstrate the extent or severity of this threat, it is clear that conversion of forests to agricultural cannabis use, both legal and illegal can fragment and degrade habitat for the NSO. NSO may also be affected when riparian areas are altered due to water diversion for cannabis agriculture.

<u>Competition from Invasive Species</u>

Competition from non-native invasive species has emerged as one of the greatest threats to NSO conservation. The larger and more aggressive barred owl (*Strix varina*) has made its way from eastern North America to the Pacific Northwest, and now into California. According to the Executive Summary for the Final EIS for experimental barred owl removal, the range of the barred owl now completely overlaps with that of the Northern Spotted Owl (U.S. Fish and Wildlife Service 2013).

The FEIS Executive Summary notes that:

> "Although northern spotted owl populations have been declining for many years, the presence of barred owls exacerbates the decline. Recent studies (Olson *et al*. 2005, p. 918; Forsman *et al*. 2011a, pp. 69-70, 75-76) have established negative relationships between barred owl presence and declines in spotted owl population performance across the range of the subspecies. This could result in the extirpation (local extinction) or near extirpation of the northern spotted owl from a substantial portion of their historical range, even if other known threats, such as habitat loss, continue to be addressed." (U.S. Fish and Wildlife Service 2013).

The 2011Revised Recovery Plan summarizes the general findings of the latest science regarding the effects of barred owls on Northern Spotted Owls.

> "Barred owls reportedly have reduced spotted owl site occupancy, reproduction, and survival. Limited experimental evidence, correlational studies, and copious anecdotal information all strongly suggest barred owls compete with spotted owls for nesting sites, roosting sites, and food, and possibly predate spotted owls…. Because the abundance of barred owls continues to increase, the effectiveness in addressing this threat depends on action as soon as possible." (U.S. Fish and Wildlife Service 2011, p. III-62).

Dugger et al. 2011 further summarizes the affects of barred owls on NSO and provides clear recommendations to protect as much habitat as possible to mitigate these effects:

> "We observed increased extinction rates in response to decreased amounts of old forest at the territory core and higher colonization rates when old-forest habitat was less fragmented. Annual site occupancy for pairs reflected the strong effects of Barred Owls on occupancy dynamics with much lower occupancy rates predicted for territories where Barred Owls were detected. The strong Barred Owl and habitat effects on occupancy dynamics of Spotted Owls provided evidence of interference competition between the species. These effects increase the importance of conserving large amounts of contiguous, old-forest habitat to maintain Northern Spotted Owls in the landscape." (Dugger et al. 2011).

The implications for this invasive competition on the Northern Spotted Owl are clear and enormous. Listing of the Northern Spotted Owl under CESA is warranted for this reason alone, not withstanding all the other well-documented threats to the species.

<u>Inadequate Regulatory Mechanisms</u>

The petition at Section D-pages 19-23 describes the inadequacy of regulatory mechanisms range-wide and in California, on both public and private lands. We further discuss the inadequacy of regulatory mechanisms on public and private lands in California.

<u>Public Lands</u>

Federal land management poses many problems for Northern Spotted Owls. All federal lands within the range of the Northern Spotted Owl are currently managed under the provisions of the NWFP. As noted above, the NWFP alone is inadequate to provide recovery for the NSO, and populations are still in decline. (Davis et al. 2011, Franklin et al. 1999, Anthony et all 2006, Forsman et al. 2011).

According to Appendix A of the U.S. Fish and Wildlife Service's consultation for the U.S. Forest Service's Gemmill Thin project, the FWS has provided consultation on U.S. Forest Service Timber Sales within the range of the Northern Spotted Owl since 1994. Between 1994 and October 24, 2013, the FWS has consulted on the proposed removal/downgrade of approximately 708,155 acres (Table A1), or eight percent of the 8.854 million acres of Northern Spotted Owl nesting/roosting habitat estimated by Davis et al. (2011) to have occurred on Federal lands (Table A1). While these changes in suitable Northern Spotted Owl habitat may be consistent with the expectations for implementation of the NWFP, which anticipated a rate of habitat harvested at 2.5 percent per decade on public lands (USFS and BLM 1994a) (U.S. Fish and Wildlife Service 2013), they nonetheless document that habitat loss, modification, and/or curtailment are occurring on public lands, and that the NWFP has not adequately curtailed such habitat modification.

In all, the available evidence suggests that while the NWFP has reduced logging of suitable habitat on public lands, habitat loss and degradation is still occurring, including within the so-called "late-successional reserves." The inadequacies of the NWFP to protect spotted owls and preserve the species habitat constitute a substantial threat to the NSO.

<u>Private Lands</u>

The California Forest Practices Rules (FPRs) are the primary state regulations affecting the management of the Northern Spotted Owl on private lands in California. These regulations implement the Z'berg Nejedley Forest Practices Act of 1973 (Pub. Res. Code § 4511 et seq.).

The FPRs provide a suite of options for landowners to achieve the goal of "take" avoidance (14 CCR 919.9[939.9]). These options (a-g) were adopted by the California Board of Forestry and Fire Protection (Board of Forestry) in the early 1990's in response to the federal listing of the NSO as a "threatened" species under the federal ESA.

In addition to 14 CCR 919.9 [939.9] the FPRs also contain specific criteria to guide CAL FIRE in making a determination that "take" has been avoided (14 CCR 919.10 [939.10]). The FPRs provide that if CAL FIRE determines that "take" will not be avoided, then the Director must disapprove the plan (14 CCR 989.2 (f)).

When the NSO was originally listed, the then-California Department of Fish and Game provided consultation services to landowners and the California Department of Forestry and Fire Protection (CAL FIRE) on individual Timber Harvest Plans (THPs) in hopes of ensuring that "take" would be avoided. The Department of Fish and Game turned the biological review of individual projects to the FWS in 1999. Since that time the CDFW has been largely absent from the review and approval process for individual projects that may impact the NSO. The FWS conducted a process known as "technical assistance" whereby it reviewed individual THPs to ensure "take" avoidance through the lens of the existing FPRs, while augmenting its review with independent agency biological expertise. Although the process of seeking technical assistance falls under 14 CCR 919.9(e) [939.9(e)], the actual criteria for habitat protection and retention standards are contained in 14 CCR 919.9(g) [939.9(g)]. The FWS provided technical assistance through the lens of 14 CCR 919.9(g) [939.9(g)].

In 2009, the FWS ceased providing technical assistance to landowners and CAL FIRE. CAL FIRE thus became solely responsible for ensuring "take" avoidance. In doing so, the Service provided CAL FIRE with a review of the effectiveness of the FPRs to avoid "take" of NSO as defined under the federal Act. The FWS also provided CAL FIRE with a set of alternative "take" avoidance guidelines it believes would be more effective at protecting the NSO than current Rules.

The FWS's guidance document specifically called out the ineffectiveness of existing FPRs. The FWS's overall conclusion was:

> "…our combined experience with hundreds of THPs indicates that **the cumulative effects of repeated entries within many NSO home ranges has reduced habitat quality to a degree causing reduced occupancy rates and frequent site abandonment**. In a large proportion of technical assistance letters to CAL FIRE and industrial timberland owners during the past five years, we noted the lack of NSO responses at historic territories, and described habitat conditions considered inadequate to support continued occupancy and reproduction." (Emphasis added) (p 11).

14 CCR 919.9(g)[939.9(g)] otherwise known as "option "g"" contains prescriptive rules that delineate how much total NSO habitat must be retained following a given timber harvest in order to ensure that "take" is avoided. Habitat has traditionally been described using the definitions found in the FPRs at 14 CCR 895.1. Option "g" does not specify quantities of individual habitat types to be retained and in what configuration. Option "g" also contains disturbance minimization measures that are primarily employed during the breeding season for the NSO.

CAL FIRE advised the Board of Forestry at its March 2013 hearing that option "g"" is out-of-date, and no longer reflects the best available science.

> "…the Department recognizes that frankly Ken [Hoffman] knows we have been working with him prior to retirement in the Service and we have recognized the problems with option "g" for quite some time and even before we were handed the full brunt of the responsibility back in 2008 we had heard from the Service that option "g" was really not adequate." (Shintaku 2013).

Mr. Shintaku agreed with points made at the hearing by EPIC that option "g" is obsolete and inadequate:

> "…so first of all CAL FIRE agrees with EPIC in terms of the obsolete nature of option "g".... so really where we are today is what we are calling "g-plus".... what that means is we recognize "g" is not going to get it done, but the rules specifically say an RPF only has the choices "a"-"g" in order to address a spotted owl in a THP, so because the RPF has to say I am using option "g," coupled with the fact that we know option "g" is obsolete that forces the Department into what I would consider a full-blown CEQA analysis; we have to make sure that significant impacts, cumulative impacts and take are all addressed in the plan, and we just use the "g" vehicle to get that done." (Shintaku 2013).

The U.S. Fish and Wildlife Service (2009) identified several failings in the standard provisions and application of option "g." These include inadequate habitat retention standards and out dated habitat definitions. Regarding the existing FPR Northern Spotted Owl habitat definitions contained at 14 CCR 895.1 the Service stated:

> "...use of [California] W[ildlife] H[abitat] Relationship[s] habitat definitions in the FPRs is unlikely to avoid take. This is because the WHR types considered to be NSO habitat (4M & 4D) are widely variable, and at the lowest end of size class/density are typically poor habitat or non-habitat." (1-24-08 e-mail from Brian Woodbridge to CAL FIRE's Chris Browder).

The FWS expounded on the inadequacies of the FPR definitions:

> "Service staff in the Yreka Fish and Wildlife Office believe that application of the FPRs **typically does not avoid or reduce the likelihood of take of NSO**. This is because the habitat definitions and retention standards in the FPRs represent minimum values that are below the habitat parameters associated with reasonable levels of territory occupancy, survival, and reproduction by NSO."(ibid)(Emphasis added).

The following tables summarize the differences between the FPR NSO habitat definitions and the definitions recommended by the FWS:

FWS Interior				
	Basal Area	**TPA 26"+**	**Canopy closure**	**QMD (DBH)**
HQNR	210	> 8	>60%	>15"
N/R	150-180	>8	>60%	>15"
F	Mix ranging 120-180	>5	Mix 40-100%	>13"
LQF	Mix ranging 80-120		>40%	>11"

Forest Practice Rules		
	Canopy closure	**DBH**
N	>60% total (40% dominant and co-dominant)	>11"
R	>40% with high degree of variability	>11"
F	>40% but if more than 80% must be "fly space"	>11" conifer >6" hardwoods

As noted by CAL FIRE's Duane Shintaku, CAL FIRE has recognized the ineffectiveness of option-"g" and has begun to undertake a heretofore undefined review and approval process for THPs utilizing option "g" known only as "g-plus." CAL FIRE is implementing a review and approval process for THPs utilizing option "g" or "g-plus" that has not been vetted by a rulemaking process and that is not specified in regulation. This is contrary to the requirements of the FPRs themselves. 14 CCR 898.1 provides that the provisions of the Forest Practice Act and the FPRs shall be the only criteria employed by the Director when reviewing plans, consistent with Public Resources Code section 4582.7. CAL FIRE is left in the precarious position of recommending that landowners comply with the FWS Guidelines while not being able to require their implementation due to the lack of codified regulations to address the inadequacies of the existing Rules.

The existing evidence provided by the FWS indicates that existing regulatory mechanisms, particularly on private lands, are inadequate and have failed to curtail the downward trend of NSO fecundity, apparent survival, and populations in California. Listing of the NSO under CESA is necessary because the existing regulatory mechanisms are inadequate and because the lack of independent agency biological expertise of the CDFW and the FWS has resulted in CAL FIRE in the precarious position of determining that "take" has been avoided without consultation with the listing agency.

Climate Change

The Revised Recovery Plan acknowledged that climate change has been and will continue to affect forest ecosystems in the range of the Northern Spotted Owl. In preparing the recovery plan, the experts identified disease and the effect of climate change on vegetation as potential and more uncertain future threats. (U.S. Fish and Wildlife Service 2011, at I-8)

Franklin et al. 2000 found that changes in climate alone can affect Northern Spotted Owl life-history traits. Franklin et al. 2000 found:

> "Climate explained most of the temporal variation in life history traits. Annual survival varied the least over time, whereas recruitment rate varied the most, suggesting a ''bet-hedging'' life history strategy for the owl. A forecast of annual rates of population change (l), estimated from life history traits, suggested that Northern Spotted Owl populations may change solely due to climate influences, even with unchanging habitat conditions." (Franklin et al. 2000, Abstract).

According to Franklin et al. 2000, climatic variation is one structured source of temporal variation that may affect avian populations through its influence on life history traits, largely in a density-independent manner (Boyce 1984). Extremes in climatic variation also can function as catastrophic events and have been associated with sudden large scale mortality in avian populations (Tompa 1971, Johnson et al. 1991, Rogers et al. 1991, Smith et al. 1991).(Franklin et al. 2000).

The U.S. Fish and Wildlife Service's Biological and Conference Opinions for the issuance of the Fruit Growers Supply Company Habitat Conservation Plan and Incidental Take Permit briefly summarize the potential impacts of climate change:

> Loarie et al. (2008) projected that up to 66 percent of California's endemic flora would experience >80 percent reductions in range size as a result of anticipated climate changes. While this is a worst-case scenario based on high levels of CO2 emissions in the future, a global climate model with high sensitivity to atmospheric greenhouse gas levels, and no dispersal component, the models ignore several factors that would exacerbate the projected impacts of climate change, including specialization to restricted soil types and the spread of invasive species…
>
> Despite variability in climate change simulations, consistent projections for warmer summers, reduced spring snowpacks, and earlier and more rapid snowmelt suggest that forests in California and the Pacific Northwest will experience longer fire seasons and more frequent, extensive, and severe fires in the future (Flannigan et al. 2000, Lenihan et al. 2003a, Whitlock et al. 2003, McKenzie et al. 2004). (U.S. Fish and Wildlife Service 2012).

The FWS specifically discussed the potential impacts of climate change on NSO in this same document:

> Climate change, a potential additional threat to northern spotted owl populations, is not explicitly addressed in the NWFP. Climate change could have direct and indirect effects on northern spotted owls and their prey. Based upon a global meta-analysis, Parmesan and Yohe (2003) discussed several potential implications of global climate change to biological systems, including terrestrial flora and fauna. Results indicated that 62 percent of species exhibited trends indicative of advancement of spring conditions. In bird species, trends were manifested in earlier nesting activities. Because the northern spotted owl exhibits a limited tolerance to heat relative to other bird species (Weathers et al. 2001), subtle changes in climate have the potential for significant negative effects. However, the direct effects of climate change to the species are unknown. *Id.*

The Department must critically evaluate the potential threats to the Northern Spotted Owl that may result from climate change. Changes in climate are significant factors affecting the survival and enhancement of the Northern Spotted Owl now and into the future. The Department must give serious consideration to the best available evidence related to changes in climate.

IV. Conclusion

The best available information clearly establishes the necessity to list the Northern Spotted Owl under CESA. The best quality information identifies NSO declines in fecundity, apparent survival, population trends throughout the state and throughout the species' range, and the realities of ongoing habitat loss and the incursion of barred owls. The Northern Spotted Owl warrants listing as either a "threatened" or "endangered" species.

We appreciate the opportunity to provide comments to the Department to inform its status review. EPIC will follow this process closely and provide additional comments when the status review is available for public comment. Please do not hesitate to contact me at the number provided below if additional information is required or if there are questions about anything we present here.

Sincerely,

Rob DiPerna

Dear Mr. Clipperton and Department Officials:

Please find attached a short summary comment letter that has been endorsed by numerous conservation groups.

We will be providing more extensive comments as well as supporting material later in the day today.

Thank you for your attention and consideration. Please do not hesitate to contact me at either of the numbers provided below as necessary.

Thank you.

Re: Comments Regarding CDFW Status Review for the Northern Spotted Owl (*Strix occidentalis caurina*)

Dear Mr. Clipperton and Department Officials:

The undersigned conservation organizations submit the following comments on the California Department of Fish and Wildlife Status Review for the Northern Spotted Owl (*Strix occidentalis caurina*) (NSO) pursuant to the California Endangered Species Act (CESA). Please consider these comments as part of the Department's review.

The available evidence supports the conclusion that the Northern Spotted Owl warrants listing as either "threatened" or "endangered" under CESA. The Northern Spotted Owl warrants listing under CESA because it meets several of the criteria for listing a species as specified under the Act. Specifically, the NSO warrants listing due to the following factors: 1) past, present, and threatened habitat destruction, modification or curtailment; 2) competition from invasive species; 3) inadequate regulatory mechanisms; 4) climate change.

The status and trends of NSO in California on both public and private lands show continued declines in NSO fecundity, apparent survival, and population trends (e.g. Forsman et al. 2011). The best available evidence clearly points to habitat loss and the incursion of the invasive and aggressive barred owl among the primary reasons for declines in NSO across the species' range, and in California specifically.

There is ample evidence available to the Department via long-term, independent, and peer-reviewed literature to show that the NSO warrants listing as either "threatened" or "endangered."

Long-term demographic studies such as Forsman et al. 2011 demonstrate that both public and private lands study areas show declines in key indicating factors. It is critical that the Department conduct its review with scientific rigor, and that it appropriately weighs available evidence based on the strengths of said evidence. We encourage the Department to seek and consider evidence of the highest quality and that represents the best available science.

CESA requires the Department to consider the best available information, but does not require certainty in the science or evidence. The Department must, therefore, conduct its evaluation through the lens of the best, most rigorous and most credible evidence.

The Northern Spotted Owl is clearly in decline in California and throughout its range, and is faced with a myriad of threats, and therefore warranting listing as either "threatened" or "endangered" under CESA. We appreciate the opportunity to provide comments to the Department and are happy to answer any questions that the Department may have.

The THP includes enforceable statements of compliance with 14 CCR 939.9(g)(3)&(4).

Table 1 Demonstration of compliance with 14 CCR 939.9(g)(3)&(4)

Habitat within 0.7 mile radius, using USFWS habitat definitions	Pre-harvest acres	Post-harvest acres	Net change	Compliance Requirement 500 acres 14 CCR 939.9(g)(3)
High Quality Nesting habitat*	0	0	0	
Nesting-roosting Habitat	186	186	0	
Foraging habitat	22	22	0	
Low Quality foraging habitat	406	369	-37	
Unsuitable	371	408	37	
Total Owl Habitat	614	577	37	577
Habitat within 1.3 mile radius, using USFWS habitat definitions	**Pre-harvest acres**	**Post-harvest acres**	**Net change**	**Compliance Requirement 1336 acres 14 CCR 939.9(g)(4)**
High Quality Nesting habitat*	0	0	0	
Nesting-roosting Habitat	280	280	0	
Foraging habitat	487	487	0	
Low Quality foraging habitat	1452	1260	-192	
Unsuitable	1176	1368	192	
Total Owl Habitat	2219	2027	192	2027

The following table has been developed using the methodology suggested to CAL FIRE by the USFWS in the document "<u>Important Information for Timber Operations Proposed within the Range of the Northern Spotted Owl"</u> (CAL FIRE, 2008). It is provided to further support the avoidance of "*take*" via *harm*.

Table 2 Demonstration of deficiency with USFWS Guidance

Habitat within 0.5 mile radius	Pre-harvest acres	Post-harvest acres	Net change	Recommend Retention 400 acres
High Quality Nesting habitat*	0	0	0	At least 100
Nesting-roosting Habitat	132	132	0	150
Foraging habitat	8	8	0	100
Low Quality foraging habitat	166	164	-2	50
Unsuitable	196	198	2	
Total Owl Habitat	306	304	2	304
Habitat within 0.5-1.3 mile radius	**Pre-harvest acres**	**Post-harvest acres**	**Net change**	**Compliance Requirement 935 acres**
High Quality Nesting habitat*	0	0	0	
Nesting-roosting Habitat	148	148	0	
Foraging habitat	479	479	0	655
Low Quality foraging habitat	1286	1096	-190	280
Unsuitable	973	1163	190	
Total Owl Habitat	1913	1723	190	1723

* The absence of high quality nesting Roosting habitat is largely a result of the USFWS's robust definition of this habitat type that exceeds the habitat conditions of most stands, except those that would traditionally be called "old growth" or primary older forest where no management footprint exists. These stands are not common in areas where historic or past management has been engaged by either Government or private land managers.

FEDERAL REGISTER

Vol. 77 Tuesday,

No. 233 December 4, 2012

Part II

Department of the Interior

Fish and Wildlife Service

50 CFR Part 17

Endangered and Threatened Wildlife and Plants; Designation of Revised Critical Habitat for the Northern Spotted Owl; Final Rule

DEPARTMENT OF THE INTERIOR

Fish and Wildlife Service

50 CFR Part 17

[FWS–R1–ES–2011–0112; 4500030114]

RIN 1018–AX69

Endangered and Threatened Wildlife and Plants; Designation of Revised Critical Habitat for the Northern Spotted Owl

AGENCY: Fish and Wildlife Service, Interior.

ACTION: Final rule.

SUMMARY: We, the U.S. Fish and Wildlife Service, designate revised critical habitat for the northern spotted owl (*Strix occidentalis caurina*) under the Endangered Species Act. In total, approximately 9,577,969 acres (ac) (3,876,064 hectares (ha)) in 11 units and 60 subunits in California, Oregon, and Washington fall within the boundaries of the critical habitat designation.

DATES: The rule becomes effective on January 3, 2013.

ADDRESSES: The final rule and the associated economic analysis and environmental assessment are available on the Internet at *http://www.regulations.gov* at Docket No. FWS–R1–ES–2011–0112. Comments and materials received, as well as supporting documentation used in preparing this final rule, are available for public inspection, by appointment, during normal business hours, at the U.S. Fish and Wildlife Service, Oregon Fish and Wildlife Office, 2600 SE. 98th Ave., Suite 100, Portland, OR 97266; telephone 503–231–6179; facsimile 503–231–6195.

The coordinates or plot points or both from which the maps are generated are included in the administrative record for this critical habitat designation and are available at *http://www.fws.gov/oregonfwo,* at *http://www.regulations.gov* at Docket No. FWS–R1–ES–2011–0112, and at the Oregon Fish and Wildlife Office (see **FOR FURTHER INFORMATION CONTACT**). The additional tools and supporting information that we developed for this critical habitat designation are available at the Fish and Wildlife Service Web site and Field Office set out above and at *http://www.regulations.gov.*

FOR FURTHER INFORMATION CONTACT: Paul Henson, Field Supervisor, U.S. Fish and Wildlife Service, Oregon Fish and Wildlife Office, 2600 SE. 98th Ave., Suite 100, Portland, OR 97266; telephone 503–231–6179; facsimile 503–231–6195. If you use a telecommunications device for the deaf (TDD), call the Federal Information Relay Service (FIRS) at 800–877–8339.

SUPPLEMENTARY INFORMATION:

Organization of the Final Rule

This final rule describes the revised critical habitat designation for the northern spotted owl under the Endangered Species Act of 1973, as amended (Act) (16 U.S.C. 1531 *et seq.*). The pages that follow summarize the comments and information received in response to the proposed designation published on March 8, 2012 (77 FR 14062), and in response to the notice of availability of the draft economic analysis and draft environmental assessment of the proposed revised designation published on June 1, 2012 (77 FR 32483), describe any changes from the proposed rule, and detail the final designation for the northern spotted owl. To assist the reader, the content of the document is organized as follows:

I. Executive Summary

Why we need to publish a rule. This is a final rule to designate revised critical habitat for the northern spotted owl. Under the Endangered Species Act of 1973, as amended (Act), designations and revisions of critical habitat can only be completed through rulemaking.

We, the U.S. Fish and Wildlife Service (Service), listed the northern spotted owl as threatened on June 26, 1990 (55 FR 26114), because of widespread loss of habitat across its range and the inadequacy of existing regulatory mechanisms to conserve it. We previously designated critical habitat for the northern spotted owl in 1992 and 2008. The 2008 designation (73 FR 47326, August 13, 2008) was subsequently challenged in court. In July 2009, the Federal Government requested voluntary remand of the 2008 revised critical habitat designation. On March 8, 2012, we published in the **Federal Register** a revised proposed critical habitat designation for the northern spotted owl (77 FR 14062). This rule complies with the court-ordered deadline to submit a final revised critical habitat rule for the northern spotted owl to the **Federal Register** by November 21, 2012.

Section 4(b)(2) of the Act states that the Secretary shall designate critical habitat on the basis of the best available scientific data after taking into consideration the economic impact, national security impact, and any other relevant impact of specifying any particular area as critical habitat. The critical habitat areas we are designating in this rule constitute our current best assessment of the areas that meet the definition of critical habitat for the northern spotted owl.

The rule revises our designation of critical habitat in Washington, Oregon, and California. Consistent with the best scientific data available, the standards of the Act and our regulations, we are designating 9,577,969 ac (3,876,064 ha) in 11 units and 60 subunits in California, Oregon, and Washington that meet the definition of critical habitat. The approximate totals by State and comparison to previous designations are outlined below, as follows (note some units and subunits overlap State boundaries; therefore, totals do not add up to 11 units and 60 subunits):

- Approximately 2,918,067 ac (1,180,898 ha) in 4 units and 26 subunits in Washington.
- Approximately 4,557,852 ac (1,844,496 ha) in 8 units and 58 subunits in Oregon.
- Approximately 2,102,050 ac (850,669 ha) in 5 units and 36 subunits in California.
- This designation increases previously designated critical habitat, including the addition of 272,026 ac (110,085 ha) ac of State lands. However, this final critical habitat designation is a decrease from the 13,962,449 ac (5,649,660 ha) identified as meeting the definition of critical habitat in the March 8, 2012 (77 FR 14062) proposed rule.
- We have also excluded areas of State and private land from this designation of critical habitat under section 4(b)(2) of the Act, as explained in the Exclusions section of this rule.

The Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011; hereafter ''Revised Recovery Plan'') recommends that land managers: (1) conserve older forest, high-value habitat, and areas occupied by northern spotted owls; and (2) actively manage forests to restore ecosystem health in many parts of the species' range. In developing this critical habitat designation, we also recognize the importance of the Northwest Forest Plan (NWFP) and its land management strategy for conservation of native species associated with old-growth and late-successional forest, including the northern spotted owl. The designation of areas as critical habitat does not change land use allocations or Standards and Guidelines for management under the NWFP, nor does this rule establish any management plan or prescriptions for the management of critical habitat. However, we encourage land managers to consider implementation of forest management practices recommended in the Revised Recovery Plan to restore natural ecological processes where they have been disrupted or suppressed (*e.g.,* natural fire regimes), and application of ''ecological forestry'' management practices (e.g., Gustafsson *et al.* 2012, entire; Franklin *et al.* 2007, entire; Kuuluvian and Grenfell *et al.* 2012 entire) within critical habitat to reduce the potential for adverse impacts associated with commercial timber harvest when such harvest is planned within or adjacent to critical habitat. In sum, the Service encourages land managers to consider the conservation of existing high-quality northern spotted owl habitat, the restoration of forest ecosystem health, and the ecological forestry management practices recommended in the Revised Recovery Plan that are compatible with both the goals of northern spotted owl recovery and Standards and Guidelines of the NWFP.

The basis for our action. This final critical habitat designation is based on the current status and recent scientific research on northern spotted owl populations. We used the best scientific information available to identify those specific areas within the geographical area occupied by the species at the time it was listed on which are found those physical or biological features essential to the conservation of the species, and which may require special management considerations or protection. For the northern spotted owl, these features include particular forest types that are used or likely to be used by northern spotted owls for nesting, roosting, foraging, or dispersing habitat. In addition, we used the best available information to identify those areas that are otherwise determined to be essential to the conservation of the species.

We relied on the recovery criteria set forth in the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011) to determine what is essential to the conservation of the species; therefore we have identified a habitat network that meets the following criteria:

- Ensures sufficient habitat to support stable, healthy populations across the range, and also within each of the 11 recovery units;
- Ensures distribution of northern spotted owl populations across the range of habitat conditions used by the species;
- Incorporates uncertainty, including potential effects of barred owls, climate change, and wildfire disturbance risk; and
- Recognizes that these protections are meant to work in concert with other recovery actions, such as barred owl management.

To assist us in determining critical habitat, we integrated habitat and demographic information (relating to occupancy, survival, reproduction, and movement) to develop a modeling tool that assesses the distribution of habitat quality and population dynamics across the range, and provides a more accurate picture of where high-quality northern spotted owl habitat exists. This model synthesized more than 20 years of data from on-the-ground demographic surveys, and allowed for analysis of how northern spotted owl populations would fare under different habitat conservation scenarios. We determined what is essential to recovery of the northern spotted owl by evaluating the performance of each potential critical habitat scenario considered against the recovery needs of the owl.

Peer reviewers support our methods. We solicited expert opinions from knowledgeable individuals with scientific expertise that included familiarity with the species, the geographic region in which the species occurs, and conservation biology principles. These peer reviewers generally concurred with our methods and conclusions and provided additional information, clarifications, and suggestions to improve this final rule.

Consistency with Presidential Directive. On February 28, 2012, the President issued a memorandum to the Secretary of the Interior regarding the proposed revised critical habitat for the northern spotted owl, specifically on minimizing regulatory burdens. The Service has fully addressed each of the directives in this memo and has taken steps to comply with this directive, including:

- We conducted and completed, as is the Service's normal practice, an economic analysis on the probable impacts of the proposed revised critical habitat.
- We provided a description of ecological forestry management actions that may be compatible with both northern spotted owl recovery and timber harvest, as recommended in the Revised Recovery Plan for the Northern Spotted Owl. This discussion appears in the following sections of this rule:
    - An Ecosystem-based Approach to the Conservation of the Northern Spotted Owl and Managing Its Critical Habitat
    - Special Management Considerations or Protection
    - Determination of Adverse Effects and Application of the ''Adverse

Modification'' Standard.

We note, however, that this discussion of ecological forestry is provided to Federal, State, local and private land managers, as well as the public, for their consideration as they make decisions on the management of forest land under their jurisdictions and through their normal processes. This critical habitat rule itself does not take any action or adopt any policy, plan, or program in relation to active forest management.

• As per the Service's normal practice, we solicited public review and comment on this rulemaking action, using information thus gained to correct and refine our designation.

• We fully considered exclusion of private lands and State lands from the final revised critical habitat, consistent with the best available scientific and commercial information.

The Service appreciates, and is sensitive to, the potential for regulatory burden that may result from our designation of critical habitat for the northern spotted owl under the Act. Our analysis indicated that the revision of critical habitat could have relatively little incremental effect above and beyond the conservation measures already required as a result of its threatened species status under the Act, and thus is not expected to impose substantial additional regulatory burdens. The Service appreciates, and relies on the many partners we have in conservation, including private landowners, Tribes, States, and local governments, and strongly desires to promote conservation partnerships to conserve, protect, and enhance fish, wildlife, plants, and their habitats for the continuing benefit of the American people.

Costs and benefits. In order to identify and analyze the potential economic impacts of the designation of critical habitat for the northern spotted owl, we worked with a contractor to draft an economic analysis report, which was released in May of 2012 and finalized following consideration and incorporation of public comment. The report looked at a variety of economic activities including timber harvest, wildlife management, road construction, and other forest management activities, but focused primarily on timber management. It concludes that only a relatively small portion of the overall proposed revised designation may result in more than minor incremental administrative costs. It found that potential incremental changes in timber harvests on Bureau of Land Management and U.S. Forest Service lands may occur on approximately 1,449,534 ac (585,612 ha) proposed for designation, or 10 percent of the total lands included in the proposed designation and that there is the potential for 307,308 ac (123,364 ha) of private land to experience incremental changes in harvests, or approximately 2 percent of total lands proposed. No incremental changes in harvests are expected on State lands.

II. Background

It is our intent to discuss only those topics directly relevant to the revised designation of critical habitat in this rule. For further details regarding northern spotted owl biology and habitat, population abundance and trend, distribution, demographic features, habitat use and conditions, threats, and conservation measures, please see the Northern Spotted Owl 5-year Review Summary and Evaluation, completed October 26, 2011, and the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011), completed July 1, 2011. Both of these documents are available on the U.S. Fish and Wildlife Service's Endangered Species Web site at *http://ecos.fws.gov/;* under ''Species Search,'' enter ''northern spotted owl.'' As detailed below, Appendix C of the Revised Recovery Plan is particularly informative, as we used the habitat modeling process it describes as a tool to help identify areas containing the essential physical and biological features or areas that were otherwise essential to the conservation of the northern spotted owl in this revised designation of critical habitat. Furthermore, the recovery criteria for the northern spotted owl, as described in the Revised Recovery Plan (USFWS 2011, pp. I–1 to I–2), helped to discriminate between the various scenarios considered in the modeling process in terms of assessing which of the habitat networks evaluated included what is essential to the conservation of the northern spotted owl in the most efficient configuration possible.

Introduction

The northern spotted owl inhabits structurally complex forests from southwestern British Columbia through Washington and Oregon to northern California. The northern spotted owl was listed under the Act as a threatened species in 1990 because of widespread loss of habitat across its range and the inadequacy of existing regulatory mechanisms to conserve it (55 FR 26114; June 26, 1990). Although the rate of loss of habitat due to timber harvest has been reduced on Federal lands over the past two decades, both past and current habitat loss remain a threat to the northern spotted owl. Despite implementation of habitat conservation measures in the early 1990s, Thomas *et al.* (1990, p. 5) and USDI (1992, Appendix C) foresaw that owl populations would continue to decline for several decades, even with habitat conservation, as the consequence of lag effects at both individual and population levels. However, many populations of northern spotted owls have declined at a faster rate than anticipated, especially in the northern parts of the subspecies' range (Anthony *et al.* 2006, pp. 31–32; Forsman *et al.* 2011, pp. 65, 76). We now know that the suite of threats (detailed below) facing the northern spotted owl differs from those at the time it was listed; in addition to the effects of historical and ongoing habitat loss, the northern spotted owl faces a new significant and complex threat in the form of competition from the congeneric (referring to a member of the same genus) barred owl (USFWS 2011, pp. I–7 to I–8).

During the second half of the 20th century, barred owls expanded their range from eastern to western North America, and the range of the barred owl now completely overlaps that of the northern spotted owl (Gutiérrez *et al.* 1995, p. 3; Crozier *et al.* 2006, p. 761). Barred owls compete with northern spotted owls for habitat and resources for breeding, feeding, and sheltering, and the presence of barred owls has significant negative effects on northern spotted owl reproduction, survivorship, and successful occupation of territories (see Population Status and Trends, below). The loss of habitat has the potential to intensify competition with barred owls by reducing the total amount of resources available to the northern spotted owl and by increasing the likelihood and frequency of competitive interactions. While there are important differences in the ecology between barred owls and northern spotted owls, barred owls select very similar habitat for breeding, feeding, and sheltering, and loss of habitat has the potential to intensify competition between species. While conserving habitat will not completely alleviate the barred owl threat, Dugger *et al.* (2011, pp. 2464–2465) found that northern spotted owl occupancy and colonization rates decreased as both barred owl presence increased and available habitat decreased. Similar to another case in which increased suitable habitat was required to support two potentially competing raptors, these authors concluded that increased habitat protection for northern spotted owls may be necessary to provide for sustainable populations in the presence of barred owls in some areas (Dugger *et al.* 2011, p. 2467). Maintaining high-quality habitat has been important since the northern spotted owl was initially listed as a threatened species in 1990, and this competitive pressure from barred owls has intensified the need to conserve and restore large areas of contiguous, high-quality habitat across the range of the northern spotted owl (Dugger *et al.* 2011, p. 2464; Forsman *et al.* 2011, p. 76; USFWS 2011, Recovery Action 32 [RA32], p. III–67).

It is becoming increasingly evident that solely securing habitat will not be effective in achieving the recovery of the northern spotted owl when barred owls are present (USFWS 2011, p. vi). While conservation of high-quality habitat is essential for the recovery and conservation of the owl, habitat conservation alone is not sufficient to achieve recovery objectives. As stated in the Revised Recovery Plan, ''* * * addressing the threats associated with past and current habitat loss must be conducted simultaneously with addressing the threats from barred owls. Addressing the threat from habitat loss is relatively straightforward with predictable results. However, addressing a large-scale threat of one raptor on another, closely related raptor has many uncertainties'' (USFWS 2011, p. I–8). A designation of critical habitat is intended to ameliorate habitat-based threats to an endangered or threatened species; critical habitat cannot reasonably be expected to fully address other, non-habitat-related threats to the species. In the case of the northern spotted owl, the recovery goal of supporting population viability and demographically stable populations of northern spotted owls will likely require habitat conservation in concert with the implementation of recovery actions that address other, non-habitat-based threats to the species, including the barred owl. In addition, recovery actions include scientific evaluation of potential management options to reduce the impact of barred owls on northern spotted owls (USFWS 2011, Recovery Action 29 [RA29], p. III–65), and implementation of management actions determined to be effective (USFWS 2011, Recovery Action 30 [RA30], p. III–65).

When developing a critical habitat rule, the Service must use the best scientific information available to identify critical habitat as defined in section (3)(5)(A) of the Act, which are (i) the specific areas within the geographical area occupied by the species at the time it was listed that provide the physical or biological features essential for the conservation of the species, and which may require special management considerations or protection, and (ii) specific areas outside the geographical area occupied by the species at the time it was listed that are otherwise determined to be essential to the conservation of the species. However, like most critical habitat designations, this rule addresses elements of risk management, because we must make recommendations and decisions in the face of incomplete information and uncertainty about factors influencing northern spotted owl populations. This uncertainty exists even though the northern spotted owl is among the most thoroughly studied of listed species. We understand a great deal about the habitats the subspecies prefers and the factors that influence its demographic trends. Nonetheless, considerable uncertainty remains, particularly about interactions among different factors that threaten the owl.

In the face of such uncertainty, the Revised Recovery Plan proposes strategies to address the primary threats to the northern spotted owl from habitat loss and barred owls (USFWS 2011, p. I–7). The effects of climate change and of past management practices are changing forest ecosystem processes and dynamics, including patterns of wildfires, insect outbreaks, and disease, to a degree greater than anticipated in the Northwest Forest Plan (NWFP) (Hessburg *et al.* 2005, pp. 134–135; Carroll *et al.* 2010, p. 899; Spies *et al.* 2010, entire; USFWS 2011, p. I–8). At the same time, the expansion of barred owl populations is altering the capacity of intact habitat to support northern spotted owls. Projecting the effects of these factors and their interactions into the future leads to even higher levels of uncertainty, especially considering how the influences of different threats may vary across the owl's large geographical range. It is clear that ecosystem-level changes are occurring within the northern spotted owl's forest habitat.

The development of a critical habitat network for the northern spotted owl must take into account current uncertainties, such as those associated with barred owl impacts and climate change predictions (USFWS 2011, p. III–10). These uncertainties require that we make some assumptions about likely future conditions in developing, modeling, and evaluating potential critical habitat for the northern spotted owl; those assumptions are identified clearly in this rule (see Criteria Used to Identify Critical Habitat, below) and in our supporting documentation (Dunk *et al.* 2012b, entire).

Given the continued decline of northern spotted owl populations, the apparent increase in severity of the threat from barred owls, and information indicating a recent loss of genetic diversity for the subspecies, retaining both occupied northern spotted owl sites and unoccupied, high-value northern spotted owl habitat across the subspecies' range are key components for recovery (USFWS 2011, p. I–9). High-value habitat is defined in the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011) as habitat that is important for maintaining northern spotted owls on landscapes, including areas with current and historic use by northern spotted owls. We refer readers to the glossary (Appendix G) of the Revised Recovery Plan for definitions of forest stand conditions and habitat types discussed in this rule.

Accordingly, in this rule, we have identified areas of habitat occupied at the time of listing that provide the physical or biological features essential to the conservation of the northern spotted owl, and that may require special management considerations or protection. When occupied areas were not adequate to achieve essential recovery goals, we also identified some unoccupied areas as critical habitat for the northern spotted owl only upon a determination that such areas are essential to the conservation of the species (see the second part of the definition of critical habitat in section (3)(5)(a)(ii), which states that critical habitat also includes ''specific areas outside the geographical area occupied by the species at the time of listing in accordance with the provisions of section 4 of this Act, upon a determination by the Secretary that such areas are essential for the conservation of the species.'') However, it is important to note that this revised designation of critical habitat does not include all sites where northern spotted owls are presently known to occur. The habitat modeling that we used, in part, to assist us in developing this revised designation was based primarily on present habitat suitability. While we did also consider the present known locations of northern spotted owls in refining the identified habitat network, not all such sites were included in the revised designation if those areas did not make a significant contribution to population viability (for example, if known sites were too small or isolated to play a meaningful role in the conservation of the species; see Criteria Used to Identify Critical Habitat). This is in accordance with section 3(5)(C) of the Act, which specifies that ''critical habitat shall not include the entire geographical area which can be occupied by the threatened or endangered species.''

Because of the uncertainties associated with the effects of barred owl interactions with the northern spotted owl and habitat changes that may occur as a result of climate change, active adaptive forest management strategies will be needed to achieve results in certain landscapes. Active adaptive forest management is a systematic approach for improving resource management by learning from the results of explicit management policies and practices and applying that learning to future management decisions (USFWS 2011, p. G–1). This critical habitat rule identifies key sources of uncertainty, and the need to learn from our management of forests that provide habitat for northern spotted owls. We have designated a critical habitat network that was developed based on what we determined to be the areas containing the physical and biological features essential for the conservation of the northern spotted owl or are otherwise essential to owl conservation, after taking into consideration information on essential habitats, the current distribution of those habitats, and the best available scientific knowledge about northern spotted owl population dynamics, while acknowledging uncertainty about future conditions in Pacific Northwest forests.

An Ecosystem-Based Approach to the Conservation of the Northern Spotted Owl and Managing Its Critical Habitat

Section 2 of the Act states, ''The purposes of this Act are to provide a means whereby the ecosystems upon which endangered species and threatened species depend may be conserved.'' Although the conservation of the listed species is the specific objective of a critical habitat designation, the essential physical or biological features that serve as the basis of critical habitat are often essential components of the ecosystem upon which the species depends. In such cases, a fundamental goal of critical habitat management is not only to conserve the listed species, but also to conserve the ecosystem upon which that species depends. This is the case with the northern spotted owl.

An ecosystem is defined as a biological community of interacting organisms and their physical environment, or as the complex of a community of organisms and its environment functioning as an ecological unit (Krebs 1972, pp. 10–11; Ricklefs 1979, pp. 31–32, 869). These ecosystem interactions and functions are often referred to as ecological relationships or processes. Thus, to conserve the northern spotted owl as directed by the Act, one must also conserve the ecological processes that occur within the ecological landscape inhabited by the species. These processes—such as vegetation succession, forest fire regimes, and nutrient cycling—create and shape the physical or biological features that form the foundation of critical habitat. The northern spotted owl was initially listed as a threatened species largely due to the loss or degradation of the late-successional forest ecosystems upon which it depends. A complex interaction of physical or biological factors contribute to the development and maintenance of these ecosystems, which in turn provide the northern spotted owl with the environmental conditions required for its conservation and survival, such as large areas of suitable habitat, nest structures, and sufficient prey to sustain interconnected populations of owls across the landscape. A fundamental goal of critical habitat management should thus be to understand, describe, and conserve these processes, which in turn will maintain the physical or biological features essential to the conservation of the species. This ''ecosystem approach'' will ultimately have the highest likelihood of conserving listed species such as the northern spotted owl in the long term (Knight 1998, p. 43).

The U.S. Forest Service, which manages the great majority of areas being designated as revised northern spotted owl critical habitat, has prioritized restoring and maintaining natural ecological function and resiliency to its forest lands (Blate *et al.* 2009, entire; USDA 2010, entire; Tidwell 2011, entire). Active adaptive forest management within critical habitat, as discussed herein for the consideration of land managers, may be fully compatible and consistent with these landscape-level ecosystems. Most importantly, this approach is compatible with the ecosystem-based approach of the Northwest Forest Plan.

Revised critical habitat for the northern spotted owl includes a diverse forest landscape that covers millions of acres and contains several different forest ecosystems and thousands of plant and animal species. It ranges from moist old-growth conifer forest in the western portion, to a mix of conifers and hardwood trees in the Klamath region, to dry, fire-prone forests in the eastern Cascades. Thousands of species occur in these forest ecosystems, including other listed and sensitive species with very specific biological needs. In areas where prescribed management is needed to maintain ecosystem function, such management is often expensive, logistically difficult, and contentious (Thompson *et al.* 2009, p. 29). Many scientists believe a single-species approach to forest management is limited and that land managers need to focus on broader landscape goals that address ecosystem process and future habitat conditions (see, e.g., Thomas *et al.* 2006, p. 286; Boyd *et al.* 2008, p. 42; Hobbs *et al.* 2010, p. 487; Mori 2011, pp. 289–290). The Revised Recovery Plan (USFWS 2011) encourages the application of ecosystem management principles to ensure the long-term conservation of the northern spotted owl and its habitat, as well as other species dependent on these shared ecosystems.

We reference here the recommendations for habitat management as made in the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011). This discussion is provided primarily for consideration by Federal, State, local, and private land managers, as they make decisions on the management of forest land under their jurisdictions and through their normal processes. This critical habitat rule does not take any action or adopt any policy, plan or program in relation to active forest management.

Critical Habitat and the Northwest Forest Plan

It is important to understand the relationship between northern spotted owl critical habitat and the Northwest Forest Plan (NWFP). In brief, the designation of areas as critical habitat does not change land use allocations or Standards and Guidelines for management under the NWFP. Critical habitat for the northern spotted owl was first designated in 1992 (January 15, 1992; 57 FR 1796). Since 1994, the NWFP has also served as an important landscape-level plan that has contributed to the conservation of the northern spotted owl and late-successional forest habitat on Federal lands across the range of the species (Thomas *et al.* 2006, pp. 278–284). The NWFP introduced a system of reserves where conservation of late-successional forest, riparian habitats, northern spotted owls, and other species dependent on older forest would be the priority, and matrix areas where timber harvest would be the goal. The Standards and Guidelines for the NWFP (USDA and USDI 1994) prescribe an ecosystem-based approach to management for the Federal action agencies that manage these lands, and provide guidance for activities conducted on different land use allocations. All Bureau of Land Management and U.S. Forest Service lands identified as northern spotted owl critical habitat in this rule fall under the NWFP, and should be managed consistent with its standards. Here we briefly provide a summary of how our designation of critical habitat has been informed by and relates to forest management under the NWFP.

In developing this critical habitat designation, the Service recognizes the importance of the NWFP as the overarching land management strategy for conservation of the northern spotted owl and other native species associated with old-growth and late-successional forest. The system of reserves within the NWFP is essential for the conservation and development of large areas of late-successional forest across the landscape; however, because the NWFP was designed to benefit multiple species not every acre of the late-successional reserves (LSRs) provide high-quality habitat for northern spotted owls. In addition, barred owls have become increasingly abundant in the Pacific Northwest and likely have a large effect on the continued decline of northern spotted owl populations. With barred owls now sharing the range of the northern spotted owl, conservation of northern spotted owls outside NWFP reserved areas is increasingly important for species recovery.

In our designation of critical habitat on Federal lands, we identified lands that contain the features essential to the conservation of the species including lands both within NWFP reserves and matrix that function as highly valuable northern spotted owl habitat. As noted above, designation as critical habitat does not change these land use allocations or Standards and Guidelines for management under the NWFP, and we fully recognize the ecological functions and land management goals of the different land use allocations as outlined under the NWFP. While the NWFP has been successful in conserving large blocks of late-successional forest (Thomas *et al.* 2006, p. 283, Davis *et al.* 2011, p. 38), concerns have been expressed that it provides less than the anticipated level of commercial timber harvest on matrix lands, does not promote active restoration in areas that may contain uncharacteristically high risk of severe fire (Spies *et al.* 2006, pg. 359; Thomas *et al.* 2006, p. 277), and does not promote development of complex early-seral forest in areas where regeneration harvest has been conducted (Betts *et al.* 2010, p. 2117; Hagar 2007, p. 109; Swanson *et al.* 2011, p. 124) (''seral'' refers to developmental or successional stages of the forest community that influences species composition, i.e., early, mid, late seral stages).

Thomas *et al.* (2006, pp. 284–287) provided three recommendations to improve the NWFP. These recommendations are highly relevant to northern spotted owl critical habitat conservation and management:

1. Conserve old-growth trees and forests on Federal lands *wherever they are found* (emphasis added), and undertake appropriate restoration treatment in the threatened forest types.

2. Manage NWFP forests as dynamic ecosystems that conserve all stages of forest development (e.g., encompassing the range of conditions between early-seral and old-growth), and where tradeoffs between short-term and long-term risks are better balanced.

3. Recognize the NWFP as an integrated conservation strategy that contributes to all components of sustainability across Federal lands.

It is our hope that management of critical habitat for the northern spotted owl will be compatible with these broader landscape management goals articulated by Thomas *et al.* (2006, pp. 284–287). Furthermore, the Standards and Guidelines for the NWFP encourage an ecosystem-based approach to land management (*e.g.,* USDA and USDI 1994, p. A–1, Standards and Guidelines, pp. C–12, C–13). As discussed in the Revised Recovery Plan, recovery of the northern spotted owl will likely require that an ecosystem management approach that includes both passive and active management, to meet a variety of conservation goals that support long-term northern spotted owl conservation, be implemented. We fully support the land use allocation goals and the Standards and Guidelines for management under the NWFP (USDA and USDI 1994) as informed by the recommendations of the Revised Recovery Plan. Some general considerations for managing the threats to the essential physical or biological features for the northern spotted owl are discussed in the *Special Management Considerations or Protections* and *Determinations of Adverse Effects and Application of the ''Adverse Modification'' Standard* sections of this document, below, as well as in the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011, pp. III–11 to III–39).

Forest Management Activities in Northern Spotted Owl Critical Habitat

As stated above, many areas of critical habitat do not require active management, and active forest management within such areas could negatively impact northern spotted owls. We are not encouraging land managers to consider active management in areas of high-quality owl habitat or occupied owl sites; rather, we encourage management actions that will maintain and restore ecological function where appropriate. In some areas, forest stands are not on a trajectory to develop into high-value habitat, ecological processes have been disrupted by human actions, or projected climate change is expected to further disrupt or degrade desired forest conditions. In these areas, land managers may choose to implement active management, as recommended in the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011), to improve ecological health and development of forest conditions more favorable to northern spotted owls and other biodiversity. For example, LSRs are to be managed to protect and enhance old-growth forest conditions (defined in the Revised Recovery Plan as forests that have accumulated specific characteristics related to tree size, canopy structure, snags, and woody debris and plant associations). According to the NWFP Standards and Guidelines (USDA and USDI 1994), no programmed timber harvest is allowed inside the reserves. However, thinning or other silvicultural treatments inside these reserves may occur in younger stands if the treatments are beneficial to the creation and maintenance of late-successional forest conditions. On the east of the Cascades and in Oregon and California Klamath Provinces, additional management activities may be considered both within and outside reserves to reduce risks of large-scale disturbance (NWFP Standards and Guidelines, p. C–12—C–13).

We also recognize that ecological restoration is not the management goal on all NWFP land use allocations (*e.g.,* matrix) within designated critical habitat, and we provide a discussion of options land managers could consider to tailor traditional forest management activities on these lands to consistent with conservation of current and future northern spotted owl habitat (see, *e.g.,* Gustafsson *et al.* 2012, entire; Franklin *et al.* 2007, entire; Kuuluvainen and Grenfell 2012, entire; North and Keeton 2008; Long 2009, entire; Lindenmayer *et al.* 2012; entire). Our discussion of potential management considerations for the northern spotted owl are intended to be fully compatible with the objectives and Standards and Guidelines of the NWFP as informed by the conservation guidelines presented in the 2011 Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011) to provide a means whereby the ecosystems on which northern spotted owls depend will be conserved.

Mimicking natural disturbance regimes, such as fire, is an important strategy in North American forest management (Seymour and Hunter 1999, p. 56; Long 2009, p. 1868; Gustafsson *et al.* 2012, p. 635; Kuuluvainen and Grenfell 2012, entire). This change is occurring in response to: (1) The simplification of forests in terms of structure, age-class diversity, and species composition as a result of management for timber production, and (2) a recognition of fundamental changes in ecosystem function and processes due to land management practices, especially fire and successional patterns (Franklin *et al.* 2002, pp. 402–408; Hessburg *et al.* 2005, pp. 134–135; Drever *et al.* 2006, p. 2291). Although human disturbance is unlikely to precisely mimic natural forest disturbance, it can be used to better maintain the resilience of landscapes and wildlife populations to respond to natural disturbance and climate change (Lindenmayer *et al.* 2008, p. 87). In general, prescriptions (e.g., vegetation management, prescribed fire, etc.) that apply ecological forestry principles to address the restoration and conservation of broader ecological processes in areas where this is needed, while minimizing impacts to structurally diverse or mature and old forest that does not require such management can be compatible with maintaining the critical habitat's essential features in the long term at the landscape scale (USFWS 2011, p. III–14). The Service has recently consulted on these types of management actions in occupied northern spotted owl habitat on Bureau of Land Management (BLM) and U.S. Forest Service (USFS) lands.

Specifically prescribing such management is beyond the scope or purpose of this document, and should instead be developed by the appropriate land management agency at the appropriate land management scale (e.g., National Forest or Bureau of Land Management District) (USDA 2010, entire; Fontaine and Kennedy 2012, p. 1559; Gustafsson *et al.* 2012, pp. 639–641, Davis *et al.* 2012, entire) through the land managing agencies' planning processes and with technical assistance from the Service, as appropriate. Furthermore, we encourage an active adaptive forest management approach, should agencies choose to implement ecological forestry practices, as we continue to learn from continuing research on these methods (see *Research and Adaptive Management,* below).

Some general considerations for managing for the conservation of essential physical or biological features within northern spotted owl critical habitat are discussed in more detail in the *Special Management Considerations or Protections* and *Determinations of Adverse Effects and Application of the ''Adverse Modification'' Standard* sections of this document, below. In sum, vegetation and fuels management in dry and mixed-dry forests may be appropriate both within and outside designated critical habitat where the goal of such treatment is to conserve natural ecological processes or restore them (including fire) where they have been modified or suppressed (Allen *et al.* 2002, pp. 1429–1430; Spies *et al.* 2006, pp. 358–361; Fielder *et al.* 2007, entire; Prather *et al.* 2008, entire; Lindenmayer *et al.* 2009, p. 274; Tidwell 2011, entire; Stephens *et al.* 2009, pp. 316–318; Stephens *et al.* 2012a, p. 13; Stephens *et al.* 2012b, pp. 557–558; Franklin *et al.* 2008, p. 46; Miller *et al.* 2009, pp. 28–30; Fule *et al.* 2012, pp. 75–76). These types of management are encouraged in the NWFP (USDA and USDI 1994, p. C–13). Likewise, in some moist and mixed forests, management of northern spotted owl critical habitat should be compatible with broader ecological goals, such as the retention of high-quality older forest, the continued treatment of young or homogenous forest plantations to enhance structural diversity, heterogeneity and late-successional forest conditions, and the conservation or restoration of complex early-seral forest habitat, where appropriate (Spies *et al.* 2007b, pp. 57–63; Betts *et al.* 2010, pp. 2117, 2126–2127; Swanson *et al.* 2011, entire).

In general, actions that promote ecological restoration and those that apply ecological forestry principles at appropriate scales as described above and in the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011, pp. III–11 to III–41) may be, in the right circumstances, consistent with the conservation of the northern spotted owl and the management of its critical habitat. However, we emphasize that this rule does not take any action or adopt any policy, plan or program in relation to active forest management. The discussion is provided only for consideration by Federal, State, local and private land managers, as well as the public, as they make decisions on the management of forest land under their jurisdictions and through their normal processes.

Research and Adaptive Management

The Service supports the goals of maintaining and restoring ecological function and development of future northern spotted owl habitat. We encourage land managers to consider a stronger focus on ecological forestry in areas where commercial harvest and restoration are planned. We recognize the need to balance both the conservation of current owl sites and the development of future owl habitat. However, a better understanding of how ecological forestry approaches affect owls and their prey is needed. Studies have shown negative effects of commercial thinning and other conventional forestry practices on both northern spotted owls (Forsman *et al.* 1984, pp. 16–17; Meiman *et al.* 2003, p. 1261) and their prey (Waters *et al.* 1994, p. 1516; Luoma *et al.* 2003, pp. 343–373; Wilson 2010, entire).This need was recognized in Recovery Action 11 of the Revised Recovery Plan, which states ''When vegetation management treatments are proposed to restore or enhance habitat for northern spotted owls (e.g., thinnings, restoration projects, prescribed fire, etc.), consider designing and conducting experiments to better understand how these different actions influence the development of northern spotted owl habitat, northern spotted owl prey abundance and distribution, and northern spotted owl demographic performance at local and regional scales.'' Furthermore, the recovery strategy outlined in the Revised Recovery Plan (USFWS 2011) identifies monitoring and research, as well as active adaptive forest management, as important steps in achieving recovery goals.

Given these concerns, and recognizing that appropriate management actions will vary depending upon site-specific conditions, we provide the following suggestions regarding active forest management for consideration by land managers within critical habitat as consistent with the recommendations of the Revised Recovery Plan for the Northern Spotted Owl:

1. Focus active management in younger forest, lower quality owl habitat, or where ecological conditions are most departed from the natural or desired range of variability.

2. In moist forests on Federal lands, follow NWFP guidelines as informed by the Revised Recovery Plan and focus on areas outside of LSRs (i.e., matrix). In dry forests, follow NWFP guidelines and focus on lands in or outside of reserves

that are most ''at-risk'' of experiencing uncharacteristic disturbance and where the landscape management goal is to restore more natural or resilient forest ecosystems (see, *e.g.,* Davis *et al.* 2012, entire; Franklin *et al.* 2008, p. 46).

3. Avoid or minimize activities in active northern spotted owl territories (or the high-quality habitat within these territories).

4. Ensure transparency of process so the public can see what is being done, where it is done, what the goal of the action is, and how well the action leads to the desired goal.

5. Practice active adaptive forest management by incorporating new information and learning into future actions to make them more effective, focusing on how these actions affect northern spotted owls and their prey.

Towards this objective of learning critical new scientific insights from research and adaptive management, we especially encourage research and active adaptive forest management on the seven Forest Service Experimental Forests (H.J. Andrews Experimental Forest, Pringle Falls Experimental Forest, South Umpqua Experimental Forest, and Cascades Head Experimental Forest in Oregon; Wind River Experimental Forest and Entiat Experimental Forest in Washington; and Yurok Redwood Experimental Forest in California) within designated northern spotted owl critical habitat. We acknowledge the specific value and contributions of research done within experimental forests in furtherance of the research and active adaptive forest management objectives in the Revised Recovery Plan. These Experimental Forests have four principal scientific advantages that support the specific kinds of research needed to better understand how management affects and potentially enhances northern spotted owl habitat:

(1) These sites are intended for and enabled to conduct manipulative research to test forest management strategies in a rigorous scientific manner;

(2) They have long-term baseline datasets that enable detailed climate/environmental change assessments;

(3) The sites represent a diversity of forest types within the range of northern spotted owl; and

(4) Experimental forests have been the subject of intensive, long-term study that can serve as a backdrop for new research.

Essential research and active adaptive forest management questions, detailed in the Revised Recovery Plan, that could be conducted on Experimental Forests include (but are not limited to):

(a) What vegetation management treatments best accelerate the development of forest structure associated with northern spotted owl habitat functions while maintaining or restoring natural disturbance and provide greater ecosystem resiliency?

(b) What are the effects of wildland and prescribed fire on the structural elements of northern spotted owl habitat?

(c) Can strategically-placed restoration treatments be used to reduce the risk of northern spotted owl habitat being burned by high severity fire within dry forest ecosystems?

(d) What are the effects of epidemic forest insect outbreaks on northern spotted owl occupancy and habitat use immediately following the event and at specified time periods after treatment?

Sound scientific information represents a vital component of our path to recovery for the northern spotted owl (and almost all threatened or endangered species). We believe it would be counterproductive to inhibit or curtail research that is designed to benefit the northern spotted owl and the ecosystem in which it is found, and therefore support research activities within experimental forests.

The Biology and Ecology of the Northern Spotted Owl

Physical Description and Taxonomy

The northern spotted owl is a medium-sized owl and the largest of the three subspecies of northern spotted owls currently recognized by the American Ornithologists' Union (Gutiérrez *et al.* 1995, p. 2). It is dark brown with a barred tail and white spots on the head and breast, and has dark brown eyes that are surrounded by prominent facial disks. The taxonomic separation of these three subspecies is supported by numerous factors (reviewed in Courtney *et al.* 2004, pp. 3–3 to 3–31), including genetic (Barrowclough and Gutiérrez 1990, p. 739; Barrowclough *et al.* 1999, p. 922; Haig *et al.* 2004, p. 1353; Barrowclough *et al.* 2005, p. 1113), morphological (Gutiérrez *et al.* 1995, pp. 2 to 3), behavioral (Van Gelder 2003, p. 30), and biogeographical characteristics (Barrowclough *et al.* 1999, p. 928).

Distribution and Habitat

The current range of the northern spotted owl extends from southwest British Columbia through the Cascade Mountains, coastal ranges, and intervening forested lands in Washington, Oregon, and California, as far south as Marin County, California. The subspecies is listed as a threatened species under the Act throughout its range (55 FR 26114; June 26, 1990). Within the United States, the northern spotted owl ranges across 12 ecological regions, based on recognized landscape subdivisions exhibiting different physical and environmental features, often referred to as ''physiographic provinces'' (Franklin and Dyrness 1988, pp. 5–26; Thomas *et al.* 1990, p. 61; USDA and USDI 1994, p. A–3). These include the Olympic Peninsula, Western Washington Lowlands, Western Washington Cascades, Eastern Washington Cascades, Oregon Coast Ranges, Western Oregon Cascades, Willamette Valley, Eastern Oregon Cascades, Oregon Klamath, California Klamath, California Coast Ranges, and California Cascades Provinces (based on USDA and USDI 1994, p. A–3). Very few northern spotted owls are found in British Columbia, in the Western Washington Lowlands or Willamette Valley; therefore, the subspecies is restricted primarily to 10 of the 12 provinces within its range.

For the purposes of developing this rule, and based on Appendix C of the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011, pp. C–7 to C–13), we have divided the range of the northern spotted owl into 11 different regions. We used these 11 regions in the habitat modeling that informed this revised designation of critical habitat. The regions used here are more ''owl specific'' than the physiographic provinces used in the past. In addition to regional patterns of climate, topography, and forest communities, which the physiographic provinces also considered, the 11 regions are based on specific patterns of northern spotted owl habitat relationships and prey base relationships across the range of the species. The 11 regions include the North Coast Olympics; West Cascades North; West Cascades Central; West Cascades South; East Cascades North; East Cascades South; Oregon Coast; Klamath West; Klamath East; Redwood Coast; and Inner California Coast Ranges. We additionally grouped these 11 regions into 4 broad ecological zones (West Cascades/Coast Ranges of Oregon and Washington; East Cascades; Redwood; and Klamath and Northern California Interior Coast Ranges). A map of the 11 regions used for the purposes of habitat modeling, as well as the 4 ecological zones, is provided in Figure 1 of this document. We used these 11 regions as the organizing units for our designation of critical habitat, and the 4 ecological zones for the identification of region-specific primary constituent elements (PCEs) for the northern spotted owl.

Northern spotted owls generally rely on older forested habitats because such forests contain the structures and characteristics required for nesting, roosting, and foraging, and dispersal. Forest characteristics associated with northern spotted owls usually develop with increasing forest age, but their occurrence may vary by location, past forest practices, and stand type, history, and condition. Although northern spotted owl habitat is variable over its range, some general attributes are common to the owl's life-history requirements throughout its range. To support northern spotted owl reproduction, a home range requires appropriate amounts of nesting, roosting, and foraging habitat arrayed so that nesting pairs can survive, obtain resources, and breed successfully. In northern parts of the range where nesting, roosting, and foraging habitat have similar attributes, nesting is generally associated with late-seral or old-growth forest in the core area (Swindle *et al.* 1999, p. 1216). In some southern portions of the range, northern spotted owl survival is positively associated with the area of old forest habitat in the core, but reproductive output is positively associated with amount of edge between older forest and other habitat types in the home range (Franklin *et al.* 2000, pp. 573, 579). This pattern suggests that where dusky-footed woodrats (*Neotoma fuscipes*) are the primary prey species, core areas that have nesting habitat stands interspersed with varied types of foraging habitat may be optimal for northern spotted owl survival and reproduction. Both the amount and spatial distribution of nesting, roosting, foraging, and dispersal habitat influence reproductive success and long-term population viability of northern spotted owls.

Population growth can occur only if there is adequate habitat in an appropriate configuration to allow for the dispersal of owls across the landscape. This includes support of dispersing juveniles, as well as nonresident subadults and adults that have not yet recruited into the breeding population. The survivorship of northern spotted owls is likely greatest when dispersal habitat most closely resembles nesting, roosting, and foraging habitat, but owls may use other types of habitat for dispersal on a short-term basis. Dispersal habitat, at a minimum, consists of stands with adequate tree size and canopy cover to provide protection from avian predators and at least minimal foraging opportunities (57 FR 1805, January 15, 1992). In this rule, we consider canopy cover as a vertical measurement of the amount of canopy that would cover the ground.

The three essential functions served by habitat within the home range of a northern spotted owl are:

(1) *Nesting.* Nesting habitat is essential to provide structural features for nesting, protection from adverse weather conditions, and cover to reduce predation risks. Habitat requirements for nesting and roosting are nearly identical. However, nesting habitat is specifically associated with a high incidence of large trees with various deformities (large cavities, broken tops, mistletoe (*Arceuthobium* spp.) infections, and other evidence of decadence) or large snags suitable for nest placement. Additional features that support nesting and roosting typically include a moderate to high canopy cover; a multilayered, multispecies canopy with large overstory trees; large accumulations of fallen trees and other woody debris on the ground; and sufficient open space below the canopy for northern spotted owls to fly (Thomas *et al.* 1990, p. 164). Forested stands with high canopy cover also provide thermal cover (Weathers *et al.* 2001, p. 686) and protection from predators. Patches of nesting habitat, in combination with roosting habitat, must be sufficiently large and contiguous to maintain northern spotted owl core areas and home ranges, and must be proximate to foraging habitat. Ideally, nesting habitat also functions as roosting, foraging, and dispersal habitat.

(2) *Roosting.* Roosting habitat is essential to provide for thermoregulation, shelter, and cover to reduce predation risk while resting or foraging. As noted above, the same habitat generally serves for both nesting and roosting functions; technically ''roosting habitat'' differs from nesting habitat only in that it need not contain those specific structural features used for nesting (cavities, broken tops, and mistletoe platforms), but does contain moderate to high canopy cover; a multilayered, multispecies canopy; large accumulations of fallen trees and other woody debris on the ground; and open space below the canopy for northern spotted owls to fly. In practice, however, roosting habitat is not segregated from nesting habitat. Nesting and roosting habitat will also function as foraging and dispersal habitat.

(3) *Foraging.* Foraging habitat is essential to provide a food supply for survival and reproduction. Foraging habitat is the most variable of all habitats used by territorial northern spotted owls, and is closely tied to the prey base, as described below. Nesting and roosting habitat always provides for foraging, but in some cases owls also use more open and fragmented forests, especially in the southern portion of the range where some younger stands may have high prey abundance and structural attributes similar to those of older forests, such as moderate tree density, subcanopy perches at multiple levels, multilayered vegetation, or residual older trees. Foraging habitat generally has attributes similar to those of nesting and roosting habitat, but foraging habitat may not always support successfully nesting pairs (USDI 1992, pp. 22–25). Foraging habitat can also function as dispersal habitat. The primary function of foraging habitat is to provide a food supply for survival and reproduction.

Because northern spotted owls show a clear geographical pattern in diet, and different prey species prefer different habitat types, prey distribution contributes to differences in northern spotted owl foraging habitat selection across the range. In the northern portion of their range, northern spotted owls forage heavily in older forests or forests with similar complex structure that support northern flying squirrels (*Glaucomys sabrinus*) (Carey *et al.* 1992, p. 233; Rosenberg and Anthony 1992, p. 165). In the southern portion of their range, where woodrats are a major component of their diet, northern spotted owls are more likely to use a variety of stands, including younger stands, brushy openings in older stands, and edges between forest types in response to higher prey density in some of these areas (Solis 1983, pp. 89–90; Sakai and Noon 1993, pp. 376–378; Sakai and Noon 1997, p. 347; Carey *et al.* 1999, p. 73; Franklin *et al.* 2000, p. 579). Both the amount and distribution of foraging habitat within the home range influence the survival and reproduction of northern spotted owls.

Dispersal Habitat and Habitat for Nonresident Owls

Successful dispersal of northern spotted owls is essential to maintaining genetic and demographic connections among populations across the range of the species. Habitats that support movements between larger habitat patches that provide nesting, roosting, and foraging habitats for northern spotted owls act to limit the adverse genetic effects of inbreeding and genetic drift and provide demographic support to declining populations (Thomas *et al.* 1990, pp. 271–272). Dispersing juvenile northern spotted owls experience high mortality rates (more than 70 percent in some studies (Miller 1989, pp. 32–41;

Franklin *et al.* 1999, pp. 25, 28; 55 FR 26115; June 26, 1990)) from starvation, predation, and accidents (Miller 1989, pp. 41–44; Forsman *et al.* 2002, pp. 18–19). Juvenile dispersal is thus a highly vulnerable life stage for northern spotted owls, and enhancing the survivorship of juveniles during this period could play an important role in maintaining stable populations of northern spotted owls.

Successful juvenile dispersal may depend on locating unoccupied suitable habitat in close proximity to other occupied sites (LaHaye *et al.* 2001, pp. 697–698). Dispersing juveniles are likely attracted to conspecific calls, and may look for suitable sites preferentially in the vicinity of occupied territories. When all suitable territories are occupied, dispersers may temporarily pursue a nonresident (nonbreeding) strategy; such individuals are sometimes referred to as ''floaters'' (Forsman *et al.* 2002, pp. 15, 26). Floaters prospect for territorial vacancies created when residents die or leave their territories. Floaters contribute to stable or increasing populations of northern spotted owls by quickly filling territorial vacancies. Where large blocks of habitat with multiple breeding pairs occur, the opportunities for successful recruitment of dispersers and floaters are enhanced due to the within-block production of potential replacement birds (Thomas *et al.* 1990, pp. 295, 307).

Juvenile dispersal occurs in steps (Forsman *et al.* 2002, pp. 13–14), between which dispersing juveniles settle into temporary home ranges for up to several months (Forsman *et al.* 2002, p. 13). Natal dispersal distances, measured from natal areas to eventual home range, tend to be larger for females (about 15 mi (24 km)) than males (about 8.5 mi (13.7 km)) (Courtney *et al.* 2004, p. 8–5). Forsman *et al.* (2002, pp. 15–16) reported dispersal distances of 1,475 northern spotted owls in Oregon and Washington for the period from 1985 to 1996. Median maximum dispersal distance (the straight-line distance between the natal site and the farthest location) for radio-marked juvenile male northern spotted owls was 12.7 mi (20.3 km), and that of female northern spotted owls was 17.2 mi (27.5 km) (Forsman *et al.* 2002, Table 2).

Northern spotted owls can utilize forests with the characteristics needed for nesting, roosting, foraging, and dispersal, and likely experience greater survivorship under such conditions. However, dispersing or nonresident individuals may also make use of other forested areas that do not meet the requirements of nesting or roosting habitat on a short-term basis. Such short-term dispersal habitats must, at minimum, consist of stands with adequate tree size and canopy cover to provide protection from avian predators and at least minimal foraging opportunities.

Population Status and Trends

Demographic data from studies initiated as early as 1985 have been analyzed every 5 years to estimate northern spotted owl demographic rates and population trends (Anderson and Burnham 1992, entire; Burnham *et al.* 1994, entire; Franklin *et al.* 1999, entire; Anthony *et al.* 2006, entire; Forsman *et al.* 2011, entire). The most current evaluation of population status and trends is based on data through 2008 (Forsman *et al.* 2011, p. 1). Based on this analysis, populations on 7 of 11 study areas (Cle Elum, Rainier, Olympic Peninsula, Oregon Coast Ranges, H.J. Andrews, Northwest California, and Green Diamond) were declining (Forsman *et al.* 2011, p. 64, Table 22).

Estimates of realized population change (cumulative population change across all study years) indicated that, in the more rapidly declining populations (Cle Elum, Rainier, and Olympic Peninsula), the 2006 populations were 40 to 60 percent of the population sizes observed in 1994 or 1995 (Forsman *et al.* 2011, pp. 47–49). Populations at the remaining areas (Tyee, Klamath, Southern Oregon Cascades, and Hoopa) showed declining population growth rates as well, although the estimated rates were not significantly different from stable populations (Forsman *et al.* 2011, p 64). A meta-analysis combining data from all 11 study areas indicates that rangewide the population declined at a rate of about 2.9 percent per year for the period from 1985 to 2006. Northern spotted owl populations on Federal lands had better demographic rates than elsewhere, but still declined at a mean annual rate of about 2.8 percent per year for 1985–2006 (Forsman *et al.* 2011, p. 67).

In addition to declines in population growth rates, declines in annual survival were reported for 10 of the 11 study areas (Forsman *et al.* 2011, p. 64, Table 22). Number of young produced each year showed declines at 5 areas (Cle Elum, Klamath, Southern Oregon Cascades, Northwest California, and Green Diamond), was relatively stable at 3 areas (Olympic Peninsula, Tyee, Hoopa), and was increasing at 2 areas (Oregon Coast Ranges, H. J. Andrews) (Forsman *et al.* 2011, p. 64 Table 22).

As noted above, the barred owl has emerged as a greater threat to the northern spotted owl than was previously recognized. The range of the barred owl has expanded in recent years and now completely overlaps that of the northern spotted owl (Crozier *et al.* 2006, p. 761). The presence of barred owls has significant negative effects on northern spotted owl reproduction (Olson *et al.* 2004, p. 1048), survival (Anthony *et al.* 2006, p. 32), and number of territories occupied (Kelly *et al.* 2003, p. 51; Olson *et al.* 2005, p. 928). The determination of population trends for the northern spotted owl has become complicated by the finding that northern spotted owls are less likely to call when barred owls are also present; therefore, they are more likely to be undetected by standard survey methods (Olson *et al.* 2005, pp. 919–929; Crozier *et al.* 2006, pp. 766–767). As a result, it is difficult to determine whether northern spotted owls no longer occupy a site, or whether they may still be present but are not detected. The 2011 Revised Recovery Plan for the Northern Spotted Owl concludes that ''barred owls are contributing to the population decline of northern spotted owls, especially in Washington, portions of Oregon, and the northern coast of California.'' (USFWS 2011, p. B–12).

British Columbia has a small population of northern spotted owls. This population has declined at least 49 percent since 1992 (Courtney *et al.* 2004, p. 8–14), and by as much as 90 percent since European settlement (Chutter *et al.* 2004, p. 6) to a 2004 breeding population estimated at about 23 birds (Sierra Legal Defence [sic] Fund and Western Canada Wilderness Committee 2005, p. 16) on 15 sites (Chutter *et al.* 2004, p. 26). Chutter *et al.* (2004, p. 30) suggested immediate action was required to improve the likelihood of recovering the northern spotted owl population in British Columbia. In 2007, the Northern Spotted Owl Population Enhancement Team recommended to remove northern spotted owls from the wild in British Columbia. Personnel in British Columbia captured and brought into captivity the remaining 16 known wild northern spotted owls. Prior to initiating the captive-breeding program, the population of northern spotted owls in Canada was declining by as much as 35 percent per year (Chutter *et al.* 2004, p. 6). The amount of previous interaction between northern spotted owls in Canada and the United States is unknown (Chutter *et al.* 2004, p. 24). Although the status of the northern spotted owl in Canada is informative in terms of the overall declining trend of the northern spotted owl throughout its range, and consequently the increased need for conservation in those areas where it persists, the Service does not designate critical habitat in foreign countries (50 CFR 424.12(h)).

Life History

Northern spotted owls are a long-lived species with relatively stable and high rates of adult survival, lower rates of juvenile survival, and highly variable reproduction. Franklin *et al.* (2000, p. 576) suggested that northern spotted owls follow a ''bet-hedging'' life-history strategy, where natural selection favors individuals that reproduce only during favorable conditions. For such species, population growth rate is more susceptible to changes in adult survival than to recruitment of new individuals into the population. For northern spotted owls, recent demographic analyses have indicated declining trends in both adult survival and recruitment across much of the species range (Forsman *et al.* 2011, p. 64, Table 22).

Northern spotted owls are highly territorial (Courtney *et al.* 2004, p. 2–7). They maintain large home ranges; however, they actively defend a smaller area, and overlap between the outer portions of the home ranges of adjacent pairs is common (Forsman *et al.* 1984, pp. 5, 17, 22–24; Solis and Gutiérrez 1990, p. 742; Forsman *et al.* 2005, p. 374). Pairs are nonmigratory and remain on their home range throughout the year, although they often increase the area used for foraging during fall and winter (Forsman *et al.* 1984, p. 21; Sisco 1990, p. 9), likely in response to potential depletion of prey in the core of their home range (Carey *et al.* 1992, p. 245; Carey 1995, p. 649; but see Rosenberg *et al.* 1994, entire). The northern spotted owl shows strong year-round fidelity to its territory, even when not nesting (Solis 1983, pp. 23–28; Forsman *et al.* 1984, pp. 52–53) or after natural disturbance alters habitat characteristics within the home range (Bond *et al.* 2002, pp. 1024–1026). A discussion of northern spotted owl home range size and use is included in the Primary Constituent Elements section of this rule.

Prey

Northern spotted owl diets vary across owl territories, years, seasons, and geographical regions (Forsman *et al.* 2001, pp. 146–148; 2004, pp. 217–220). However, four to six species of nocturnal mammals typically dominate their diets (Forsman *et al.* 2004, p. 218), with northern flying squirrels being a primary prey species in all areas. In Washington, diets are dominated by northern flying squirrels, snowshoe hare (*Lepus americanus*), bushy-tailed woodrats (*Neotoma cinerea*), and boreal red-backed voles (*Clethrionomys gapperi*) (Forsman *et al.* 2001, p. 144). In Oregon and northern California, northern flying squirrels in combination with dusky-footed woodrats, bushy-tailed woodrats, red tree voles (*Arborimus longicaudus*), and deer mice (*Peromyscus maniculatus*) comprise the majority of diets (Courtney *et al.* 2004, pp. 41–31 to 4–32; Forsman *et al.* 2004, p. 221). Northern spotted owls are also known to prey on insects, other terrestrial mammals, birds, and juveniles of larger mammals (e.g., mountain beaver (*Aplodontia rufa*) (Forsman *et al.* 2001, p. 146; 2004, p. 223).

Northern flying squirrels are positively associated with late-successional forests with high densities of large trees and snags (Holloway and Smith 2011, p. 671). Northern flying squirrels typically use cavities in large snags as den and natal sites, but may also use cavities in live trees, hollow branches of fallen trees, crevices in large stumps, stick nests of other species, and lichen and twig nests they construct (Carey 1995, p. 658), as well as mistletoe brooms when snags are not abundant (Lehmkuhl *et al.* 2006, p. 593). Fungi (mychorrhizal and epigeous types) are prominent in their diet; however, seeds, fruits, nuts, vegetation matter, insects, and lichens may also represent a significant proportion of their diet (summarized in Courtney *et al.* 2004, App. 4 p. 3–12). Northern flying squirrel densities tend to be higher in older forest stands with ericaceous shrubs (e.g., Pacific rhododendron (*Rhododendron macrophyllum*)) and an abundance of large snags (Carey 1995, p. 654), and higher tree canopy cover (Lehmkuhl *et al.* 2006, p. 591) likely because these forests produce a higher forage biomass. Wilson (2012, pp. i–ii) reported that dense mid-story canopy conditions can also be a limiting factor for flying squirrel abundance. Flying squirrel density tends to increase with stand age (Carey 1995, pp. 653–654; Carey 2000, p. 252), although managed and second-growth stands sometimes also show high densities of squirrels, especially when canopy cover is high (e.g., Rosenberg and Anthony 1992, p. 163; Lehmkuhl *et al.* 2006, pp. 589–591). The main factors that may limit northern flying squirrel densities are the availability of den structures and food, especially hypogeous (below ground) fungi or truffles (Gomez *et al.* 2005, pp. 1677–1678), as well as protective cover from predators (Wilson 2010, p. 115).

For northern spotted owls in Oregon, both dusky-footed and bushy-tailed woodrats are important prey items (Forsman *et al.* 2004, pp. 226–227), whereas in Washington owls rely primarily on the bushy-tailed woodrat (Forsman *et al.* 2001, p. 144). Habitats that support bushy-tailed woodrats usually include early-seral mixed-conifer/mixed-evergreen forests close to water (Carey *et al.* 1999, p. 77). Bushy-tailed woodrats reach high densities in both old forests with openings and closed-canopy young forests (Sakai and Noon 1993, pp. 376–378; Carey *et al.* 1999, p. 73), and use hardwood stands in mixed-evergreen forests (Carey *et al.* 1999, p. 73). Bushy-tailed woodrats are important prey species south of the Columbia River and may be more limited by abiotic features, such as the availability of suitable rocky areas for den sites (Smith 1997, p. 4) or the presence of streams (Carey *et al.* 1992, p. 234; 1999, p. 72). Dense woodrat populations in shrubby areas are likely a source of colonists to surrounding forested areas (Sakai and Noon 1997, p. 347); therefore, forested areas with nearby open, shrubby vegetation generally support high numbers of woodrats. The main factors that may limit woodrats are access to stable, brushy environments that provide food, cover from predation, materials for nest construction, dispersal ability, and appropriate climatic conditions (Carey *et al.* 1999, p. 78), and arboreal and terrestrial cover in the form of large snags, mistletoe, and soft logs (Lehmkuhl *et al.* 2006, p. 376).

Home Range and Habitat Use

Territorial northern spotted owls remain resident on their home range throughout the year; therefore, these homes ranges must provide all the habitat components needed for the survival and successful reproduction of a pair of owls. Northern spotted owls exhibit central-place foraging behavior (Rosenberg and McKelvey 1999, p. 1036), with much activity centered within a core area surrounding the nest tree during the breeding season. During fall and winter as well as in nonbreeding years, owls often roost and forage in areas of their home range more distant from the core. In nearly all studies of northern spotted owl habitat use, the amount of mature and old-growth forest was greater in core areas and home ranges than at random sites on the landscape (Courtney *et al.* 2004, pp. 5–6, 5–13; also see USFWS 2011, Appendix G for definitions of mature and old-growth forest), and forests were less fragmented within northern spotted owl home ranges (Hunter *et al.* 1995, p. 688). The amount of habitat at the core area scale shows the strongest relationships with home range occupancy (Meyer *et al.* 1998, p. 34; Zabel *et al.* 2003, p. 1036), survival (Franklin *et al.* 2000, p. 567; Dugger *et al.* 2005, p. 873), and reproductive success (Ripple *et al.* 1997, pp. 155–156; Dugger *et al.* 2005, p. 871). A more complete description of the home range is presented in Population Spatial Requirements, below.

The size, configuration, and characteristics of vegetation patches within home ranges affect northern spotted owl survival and reproduction, a concept referred to as habitat fitness potential (Franklin *et al.* 2000, p. 542). Among studies that have estimated habitat fitness potential, the effects of forest fragmentation and heterogeneity vary geographically. In the California Klamath Province, locations for nesting and roosting tend to be centered in larger patches of old forest, but edges between forest types may provide increased prey abundance and availability (Franklin *et al.* 2000, p. 579). In the central Oregon Coast Range, northern spotted owls appear to benefit from a mixture of older forests with younger forest and nonforested areas in their home range (Olson *et al.* 2004, pp. 1049–1050), a pattern similar to that found in the California Klamath Province. Courtney *et al.* (2004, p. 5–23) suggest that although in general large patches of older forest appear to be necessary to maintain stable populations of northern spotted owls, home ranges composed predominantly of old forest may not be optimal for northern spotted owls in the California Klamath Province and Oregon Coast Ranges Province.

The northern spotted owl inhabits most of the major types of coniferous forests across its geographical range, including Sitka spruce (*Picea sitchensis*), western hemlock (*Tsuga heterophylla*), mixed conifer and mixed evergreen, grand fir (*Abies grandis*), Pacific silver fir (*A. amabilis*), Douglas-fir (*Pseudotsuga menziesii*), redwood (*Sequoia sempervirens*)/Douglas-fir (in coastal California and southwestern Oregon), white fir (*A. concolor*), Shasta red fir (*A. magnifica* var. *shastensis*), and the moist end of the ponderosa pine (*Pinus ponderosa*) zone (Forsman *et al.* 1984, pp. 15–16; Thomas *et al.* 1990, p. 145). Habitat for northern spotted owls has traditionally been described as consisting of four functional types: Nesting, roosting, foraging, and dispersal habitats. Recent studies continue to support the practical value of discussing northern spotted owl habitat usage by classifying it into these functional habitat types (Irwin *et al.* 2000, p. 183; Zabel *et al.* 2003, p. 1028; Buchanan 2004, p. 1334; Davis and Lint 2005, p. 21; Forsman *et al.* 2005, p. 372), and data from studies are available to describe areas used for these types of activities, so we retain it here to structure our discussion of the physical or biological features of habitat essential to the conservation of the northern spotted owl.

Recent habitat modeling efforts have also accounted for differences in habitat associations across regions, which have often been attributed to regional differences in forest environments and factors including available prey species (USFWS 2011, p. C–7). These recent advances allowed for modeling of northern spotted owl habitat by regions to account for: (1) The degree of similarity between nesting/roosting and foraging habitats based on prey availability; (2) latitudinal patterns of topology and climate; (3) regional patterns of topography, climate, and forest communities; and (4) geographical distribution of habitat elements that influence the range of conditions occupied by northern spotted owls (USFWS 2011, p. C–8). Detailed characterizations of each of these functional habitat types and their relative distribution are described in Physical or Biological Features, below.

Climate Change

There is growing evidence that recent climate change has impacted a wide range of ecological systems (Stenseth *et al.* 2002, entire; Walther *et al.* 2002, entire; Adahl *et al.* 2006, entire; Karl *et al.* 2009, entire; Moritz *et al.* 2012, entire; Westerling *et al.* 2011, p. S459; Marlon *et al.* 2012, p. E541). Climate change, combined with effects from past management practices, is exacerbating changes in forest ecosystem processes and dynamics to a greater degree than originally anticipated under the NWFP. Environmental variation affects all wildlife populations; however, climate change presents new challenges as systems may change beyond historical ranges of variability. In some areas, changes in weather and climate may result in major shifts in vegetation communities that can persist in particular regions.

Climate change will present unique challenges to the future of northern spotted owl populations and their habitats. Northern spotted owl distributions (Carroll 2010, entire) and population dynamics (Franklin *et al.* 2000, entire; Glenn *et al.* 2010, entire; *et al.* 2011a, entire; Glenn *et al.* 2011b, entire) may be directly influenced by changes in temperature and precipitation. In addition, changes in forest composition and structure as well as prey species distributions and abundance resulting from climate change may impact availability of habitat across the historical range of the subspecies. The Revised Recovery Plan for the Northern Spotted Owl provides a detailed discussion of the possible environmental impacts to the habitat of the northern spotted owl from the projected effects of climate change (USFWS 2011, pp. III–5 to III–11).

Because both northern spotted owl population dynamics and forest conditions are likely to be influenced by large-scale changes in climate in the future, we have attempted to account for these influences in our designation of critical habitat by recognizing that forest composition may change beyond the range of historical variation, and that climate changes may have unpredictable consequences for both Pacific Northwest forests and northern spotted owls. This critical habitat designation recognizes that forest management practices that promote ecosystem health under changing climate conditions will be important for northern spotted owl conservation.

III. Previous Federal Actions

The northern spotted owl was listed as a threatened species on June 26, 1990 (55 FR 26114); a description of the relevant previous Federal actions up to the time of listing can be found in that final rule. On January 15, 1992, we published a final rule designating 6,887,000 ac (2,787,000 ha) of Federal lands in Washington, Oregon, and California as critical habitat for the northern spotted owl (57 FR 1796). On January 13, 2003, we entered into a settlement agreement with the American Forest Resources Council, Western Council of Industrial Workers, Swanson Group Inc., and Rough & Ready Lumber Company, to conduct a 5-year status review of the northern spotted owl and consider potential revisions to its critical habitat (*Western Council of Industrial Workers (WCIW) v. Secretary of the Interior, Civ. No. 02–6100–AA (D. Or*). On April 21, 2003, we published a notice initiating the 5-year review of the northern spotted owl (68 FR 19569), and published a second information request for the 5-year review on July 25, 2003 (68 FR 44093). We completed the 5-year review on November 15, 2004, concluding that the northern spotted owl should remain listed as a threatened species under the Act (USFWS 2004, entire). On November 24, 2010, we published in the **Federal Register** a notice initiating a new 5-year review for the northern spotted owl (75 FR 71726); the information solicitation period for this review was reopened from April 20, 2011, through May 20, 2011 (76 FR

22139), and the completed review was signed on September 29, 2011, concluding that the northern spotted owl was appropriately listed as a threatened species.

In compliance with the settlement agreement in the *WCIW* case, as amended, we published a proposed revised critical habitat rule in the **Federal Register** on June 12, 2007 (72 FR 32450). On May 21, 2008, we published a notice announcing the availability of a Recovery Plan for the Northern Spotted Owl (73 FR 29471; May 21, 2008). We also announced the availability of a draft economic analysis on the proposed critical habitat designation and the reopening of the public comment period on the proposed revised critical habitat designation. The 2008 recovery plan formed the basis for the current designation of northern spotted owl critical habitat. We published a final rule revising the critical habitat designation in the **Federal Register** on August 13, 2008 (73 FR 47325).

Both the 2008 critical habitat designation and the 2008 recovery plan were challenged in court in *Carpenters' Industrial Council v. Salazar,* Case No. 1:08–cv–01409–EGS (D.DC). In addition, on December 15, 2008, the Inspector General of the Department of the Interior issued a report entitled ''Investigative Report of The Endangered Species Act and the Conflict between Science and Policy,'' which concluded that the integrity of the agency decision-making process for the northern spotted owl recovery plan was potentially jeopardized by improper political influence. As a result, the Federal Government filed a motion in the lawsuit for remand of the 2008 recovery plan and the critical habitat designation which was based on it. On September 1, 2010, the Court issued an opinion remanding the 2008 recovery plan to us for issuance of a revised plan within 9 months.

On September 15, 2010, we published a **Federal Register** notice (75 FR 56131) announcing the availability of the Draft Revised Recovery Plan for the Northern Spotted Owl, and opened a 60-day comment period through November 15, 2010. On November 12, 2010, we announced by way of press release an extension of the comment period until December 15, 2010. On November 30, 2010, we announced in the **Federal Register** the reopening of the public comment period until December 15, 2010 (75 FR 74073). At that time we also announced the availability of a synopsis of the population response modeling results for public review and comment. The supporting information regarding the modeling process was posted on our Web site (*http://www.fws.gov/oregonfwo/*). Of the approximately 11,700 comments received on the Draft Revised Recovery Plan, many requested the opportunity to review and comment on more detailed information on the habitat modeling process in Appendix C. On April 22, 2011, we reopened the comment period on Appendix C of the Draft Revised Recovery Plan (76 FR 22720); this comment period closed on May 23, 2011. On May 6, 2011, the Court granted our request for an extension of the due date for issuance of the final revised recovery plan until July 1, 2011. We published the notice of availability of the final Revised Recovery Plan for the Northern Spotted Owl in the **Federal Register** on July 1, 2011 (76 FR 38575).

On October 12, 2010, the Court remanded the 2008 critical habitat designation, which had been based on the 2008 Recovery Plan for the Northern Spotted Owl, and adopted the Service's proposed schedule to issue a new proposed revised critical habitat rule for public comment by November 15, 2011, and a final rule by November 15, 2012. The Court subsequently extended the date for delivery of the proposed rule to the **Federal Register** to February 28, 2012. A proposed revision to the designated critical habitat for the northern spotted owl was signed on February 28, 2012 and published in the **Federal Register** on March 8, 2012 (77 FR 14062), with a 3-month public comment period. On May 8, 2012, we announced an extension of the comment period through July 6, 2012 (77 FR 27010). A June 1, 2012 **Federal Register** notice announced the availability of the associated draft economic analysis and draft environmental assessment (conducted under NEPA), and invited the public to comment on these documents through July 6, 2012 (77 FR 32483). We held seven public information meetings and one public hearing. Two public information meetings were held each night in Redding, California, on June 4, 2012; in Tacoma, Washington, on June 12, 2012; and in Roseburg, Oregon, on June 27, 2012. One public information meeting was held in Portland, Oregon on June 20, 2012 and the public hearing was held in Portland, Oregon, on June 20, 2012. On July 20, 2012, the Service sent letters to all potentially affected Counties and State fish and wildlife agencies in Washington, Oregon and California advising them of the additional opportunity to comment until August 20, 2012, to ensure that they were able to thoroughly review and comment on the proposed rule as provided by Section 4(b)(5)(A)(ii) of the Act. In order to allow sufficient time for interagency review, the Court extended the time for delivery of the final rule to the **Federal Register** to November 21, 2012.

IV. Changes From the Proposed Rule

In preparing this final revised critical habitat designation for the northern spotted owl, we reviewed and considered comments from the public, peer reviewers, and other interested parties on the proposed revised designation of critical habitat published on March 8, 2012 (77 FR 14062). We also reviewed and considered comments on the draft environmental assessment and draft economic analysis. As a result of these comments and a reevaluation of the revised proposed critical habitat boundaries, we have made changes in this final designation, as follows:

(1) We responded to peer-review, public, stakeholder, and internal comments on a wide variety of topics to clarify and strengthen the supporting rationale of this final designation, clarify our meanings and descriptions, and to refine specific aspects of the rule to include emerging research or provide additional explanation. Included in these types of changes from the proposed to final rule are the following:

- Clarifications to the language to specify that northern spotted owl occupancy data are not needed or appropriate for an analysis of the effects of an action on northern spotted owl critical habitat.
- Clarifications to the language to more clearly describe the potential management of hazard trees in critical habitat along roadways.
- In the Special Management Considerations section, we reference Recovery Action 10 from the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011), which focuses on retaining existing northern spotted owls on the landscape. We have edited those references to clarify that management of critical habitat and the section 7 evaluation under the Act that management should focus on the habitat's ability to support nesting northern spotted owls instead of focusing on individual northern spotted owls.
- To determine how to conduct those evaluations under section 7 of the Act, the proposed revised critical habitat recommended assessing the impacts of a timber management project in the context of 500 ac (200 ha) around where the impacts would occur. After numerous discussions with section 7 practitioners in different parts of the

range of the species, we are recommending that the effects determination for a section 7 consultation be conducted at a scale consistent with ''the localized biology of the life-history needs of the northern spotted owl (such as the stand scale, a 500-acre (200-ha) circle, or other appropriate, localized scale).'' Please see detailed discussion of the distinction between effects determination and the adverse modification standard in the section *Determinations of Adverse Effects and Application of the ''Adverse Modification'' Standard.*

- We have clarified that our discussion of ecological forestry and active management is intended for land managers to consider when developing management plans or planning projects, as in many areas this approach may be consistent with critical habitat for the northern spotted owl, but that such management is not mandated by the Service and is not required as the result of this rulemaking. We have also clarified this issue in the final rule language by stating that we have made the 16 U.S.C. 1532(5)(A)(i) determination that essential biological and physical features in occupied areas may require special management considerations or protection, but that the rule does not require land managers to implement, or preclude land managers from implementing, such measures.
- We have provided land managers with a discussion of relevant emerging science and greater detail regarding the appropriate application of active management and ecological forestry to benefit forest ecosystem restoration, as recommended in the Revised Recovery Plan for the Northern Spotted Owl. In addition, we received extensive comments regarding the appropriateness of developing diverse early-seral forest at the expense of older forest stands. We have clarified language regarding development of diverse, early-seral forest to indicate that: (1) We do not recommend these actions in older forest stands or areas that currently function as owl habitat; and (2) this type of management is most appropriate where more traditional forestry methods have typically been conducted on matrix lands. As stated in both the proposed rule and in this final rule, our first recommendation for northern spotted owl critical habitat is the conservation of old growth trees and forests on Federal lands wherever they are found, and to undertake appropriate restoration treatment in the threatened forest types.
- We have clarified the relationship between this revised designation of critical habitat for the northern spotted owl and the Northwest Forest Plan. Numerous commenters were concerned that this critical habitat would undermine the Standards and Guidelines of the Northwest Forest Plan, or enable timber harvest activities in Late-Successional Reserves that would not otherwise be permissible. We have added language to the preamble to clarify that the revised designation of critical habitat does not supersede the Standards and Guidelines of the Northwest Forest Plan. Our discussion of potential active management within critical habitat is intended to encourage land managers to consider the range of management flexibility already contained in the Northwest Forest Plan.

(2) In the proposed rule we requested specific information regarding the amount and distribution of northern spotted owl habitat that should be included in the designation. We refined the designation based on input from peer-review, public comment, and comments from Federal land management agencies, combined with further evaluation of modeled population response to the potential revisions of the critical habitat network, and including the following.

(A) Formal comments from the Forest Service requested that we consider large numbers of specific areas to be removed from, or added to, critical habitat, submitted to us in the form of GIS data. This proposal would have greatly reduced matrix lands in moist forest areas (Western Cascades, Oregon Coast Range, and North Coast Olympics) and eliminated Adaptive Management Areas and Experimental Forests from critical habitat. In addition, BLM requested removal of approximately 300,000 acres of selected BLM lands in western Oregon. We evaluated a new map of relative habitat suitability (Composite 8, as described in our Modeling Supplement, Dunk *et al.* 2012b) that incorporated all of these requested changes. Population modeling results for Composite 8 indicated that many of the lands proposed for removal were essential to conservation of the northern spotted owl because the rangewide population declined by 39 percent and population risk increased by 44 percent. To bring the spotted owl population results back up to levels comparable to proposed critical habitat, the final critical habitat designation includes areas recommended by those agencies for elimination (and that had been removed in our test of Composite 8) because we determined they are essential to the conservation of the species. To increase efficiency and ensure that the designation included only occupied habitat containing the features essential to conservation or habitat that is otherwise essential to the species' conservation, we further refined the boundaries of some subunits by moving the boundaries to include more high-value habitat while simultaneously and less lower-value habitat in the network. To the greatest degree possible, wherever possible we removed matrix lands and incorporated habitat in LSRs in this process.

(B) In response to peer review comments about connectivity and population issues we identified specific areas providing high-suitability habitat that were required to better achieve population objectives in specific lower-performing modeling regions. The additional areas consisted solely of Federal lands, primarily USFS LSR lands, that were essential to provide connectivity between populations in the Oregon Coast Ranges and adjacent regions with larger spotted owl populations, as pointed out in peer review and public comments, and supported by results of population modeling. In many cases, areas added were specifically identified by the USFS or BLM as lands that should be added to compensate for removal of other, lower value lands. To the degree possible, we attempted to situate additions within LSRs and balanced additions by removing lower-quality areas in matrix land allocations. In some cases, additions were made to balance areas removed in (A) above. No additional State or private lands were designated in this process, and all areas are within the critical habitat units as described in the proposed rule.

The changes described in (A) and (B) above had the desired effect of bringing population results back up to levels similar to proposed critical habitat, while simultaneously reducing the area of matrix and lower-quality habitat in the designation thus ensuring that only essential habitat is designated. Overall, about 318,296 acres of BLM and USFS lands were removed from critical habitat, 74 percent (236,887 acres) of which were matrix lands of relatively lower value to northern spotted owls.

(C) We identified and removed lands based on information we received during the public comment period indicating that they did not meet the definition of critical habitat. In general, lands removed had recently lost their ability to function as northern spotted owl habitat either through stand-replacing wildfire or through timber harvest conducted after 2006 (the date of our most recent comprehensive vegetation layer). When such lands were identified, we removed them from critical habitat because they were unlikely to support northern spotted owls, and did not contain the PCEs or could not be otherwise considered essential.

(D) We further refined the critical habitat boundaries to better conform to identifiable landscape features or administrative boundaries, and to improve consistency with our goal of prioritizing high value Federal lands to include in critical habitat while removing relatively lower value lands in all ownerships. The USFS provided a number of specific suggestions in their public comment for this type of refinement. Overall, these refinements resulted in a small net reduction of critical habitat area.

(E) Correcting ownership boundary errors identified in peer-review and public comment. When the underlying land ownership was corrected, we determined that some lands originally labeled as private lands were in fact Federal or State lands.

In the State of Washington, in response to public comment and upon further review using the underlying aerial photo imagery from the 2011 National Agricultural Imagery Program (NAIP) and Ruraltech's 2007 forestland parcel data, we determined that the vast majority of Small Forest Landowner parcels we examined had either highly fragmented, little, or no northern spotted owl habitat currently present. Based on the combination of parcel size, current habitat conditions, and spatial distribution, we concluded that private lands identified as Small Forest Landowner parcels in the State of Washington do not provide the PCEs for northern spotted owls, nor are they essential to the conservation of the species; thus, these areas do not meet the definition of critical habitat, and we have removed them from the final designation of critical habitat.

Also in the State of Washington, we corrected ownership of Washington Department of Fish and Wildlife (WDFW) lands. In the proposed rule, we identified 1,752 ac (709 ha) as under the ownership of WDFW. In this rule, we have corrected this acreage to 8,328 ac (3,370 ha). This correction reflects a land transfer between WDFW and the Washington Department of Natural Resources, as well as a mistaken usage of a mineral rights GIS layer instead of a landownership layer.

Additional changes that were made were minor and included corrections of mapping errors, removing lower value areas that were inadvertently included, or correctly identifying administrative boundaries. Changes in total area are detailed in Table 1, below, and are shown by land ownership.

TABLE 1—LANDS IN THE PROPOSED REVISED CRITICAL HABITAT DETERMINED NOT TO CONTAIN THE PHYSICAL AND BIOLOGICAL FEATURES ESSENTIAL TO CONSERVATION OF THE NORTHERN SPOTTED OWL OR NOT OTHERWISE ESSENTIAL TO ITS CONSERVATION AND THEREFORE NOT INCLUDED IN FINAL CRITICAL HABITAT

State	Ownership	Acres	Hectares
Washington	USFS	11,864	4,793
Oregon	USFS	55,788	22,538
	BLM	62,862	25,396
	STATE	14,114	5,702
California	USFS	64,114	25,902
	BLM	17,152	6,929
Total		225,894	91,261

(3) We have exempted 14,313 ac (5,782 ha) of Department of Defense lands at Joint Base Lewis-McChord in Washington from critical habitat for the northern spotted owl, in accordance with section 4(a)(3) of the Act (see Exemptions). These lands comprised subunit NCO–3 in the proposed revision of critical habitat, and represented the only entirely unoccupied unit of critical habitat proposed for the northern spotted owl.

(4) In the proposed revised rule (77 FR 14062; March 8, 2012), we identified numerous areas under consideration for exclusion from the final designation, and solicited public comment on whether the benefits of exclusion of these lands would outweigh the benefits of inclusion, for example, based on active conservation agreements or conservation plans. We did a thorough evaluation of all the areas identified in the proposed rule, as well as others identified through our review and through information received from the public, and found that the benefits of exclusion for many of these areas outweighed the benefits of inclusion in critical habitat and that excluding these areas will not lead to the extinction of the species. Therefore, the Secretary is exercising his discretion to exclude specific areas covered under conservation agreements, programs, and partnerships under section 4(b)(2) of the Act (see Exclusions section of this document). The total area excluded from the final critical habitat designation under section 4(b)(2) of the Act are given in Table 2, below, again shown by land ownership.

TABLE 2—AREAS EXCLUDED FROM FINAL CRITICAL HABITAT UNDER SECTION 4(b)(2) OR EXEMPTED UNDER SECTION 4(a)(3) OF THE ACT

TABLE 2—AREAS EXCLUDED FROM FINAL CRITICAL HABITAT UNDER SECTION 4(b)(2) OR EXEMPTED UNDER SECTION 4(a)(3) OF THE ACT—Continued

State (Ownership)	Proposed area (ac)	Proposed area (ha)	Final area (ac)	Final area (ha)	Excluded or exempted (ac)	Excluded or exempted (ha)
PRIVATE	1,091,747	441,066	0	0	1,091,747	441,066
Grand Totals	13,962,449	5,640,829	9,577,969	3,876,064	4,271,291	1,725,553

(* Please note that no private lands in Oregon were proposed or included in this final designation.)

Note the difference in area between the proposed and final rules will not align exactly with the sum total of areas removed because they did not meet the definition of critical habitat and areas excluded or exempted from the final designation. Some minor discrepancies in area are due to mapping errors in the proposed designation have been corrected here, and may not be readily apparent through simple addition or subtraction of the total areas identified under various land categories. For example, the proposed rule mistakenly identified 16,031 ac (6,487 ha) of lands under the ownership of SDS and Broughton Lumber Companies in Washington as under consideration for exclusion. The accurate area included within the proposed critical habitat was, in fact, 2,035 ac (824 ha), and it is that area, which was excluded from this final designation, reflected in this final rule. The difference of nearly 14,000 ac (5,655 ha) will not be reflected in the difference between areas proposed and areas excluded in the final rule, as it was not really in the proposed critical habitat to begin with (and thus, was not excluded).

The number of subunits in the final critical habitat designation have changed as a result of exclusions under section 4(b)(2) or exemptions under section 4(a)(3). There were 11 critical habitat units and 63 subunits in the proposed rule. Eleven critical habitat units and 60 subunits comprise the final designation. In the North Coast Olympics, subunit NCO–3, composed entirely of Department of Defense lands at Joint-Base Lewis McChord, was exempted from the final designation under section 4(a)(3) of the Act (see Exemptions). In the Redwood Coast Region, subunits RDC–3 and RDC–4 were made up of private lands excluded under section 4(b)(2) of the Act (see Exclusions).

(5) Not all areas identified for potential exclusion in the proposed revised rule were excluded from the final designation. Based on the best available scientific information, we have found that the benefits of excluding other areas proposed or considered for exclusion do not outweigh the benefits of including them in the designation for the reasons discussed below. Therefore, the Secretary has determined not to exercise his discretion to exclude these lands. These areas are identified in Table 3 and are discussed further, below.

TABLE 3—LANDS THAT WERE PROPOSED FOR EXCLUSION, OR OTHERWISE CONSIDERED FOR EXCLUSION, WHICH ARE RETAINED IN THE FINAL CRITICAL HABITAT DESIGNATION FOR THE NORTHERN SPOTTED OWL

Type	State	Landowner	Acres	Hectares
State Lands	WA	Washington Department of Fish and Wildlife Lands [1]	8,328	3,370
State Lands	OR	Oregon Department of Forestry	212,798	86,116
State Lands	CA	California State Forests	49,760	20,137
	CA	Local Government Lands [2]	20,684	8,371
Total			291,570	117,994

(a) State, County, and Municipal Lands Not Excluded.

California

We retained a relatively limited area of State, County, and municipally owned or managed lands in California. Retained areas include lands managed as State Forests, County Parks, and a Municipal Water District. No habitat conservation plans (HCPs) or sage harbor agreements (SHAs) are currently in place on these lands. Most of these lands are in areas that have repeatedly been identified as critical to maintaining linkages among northern spotted owl populations in California. These State and County lands play an essential conservation role in this area of limited Federal ownership. Retaining these lands in the critical habitat designation promotes movement of northern spotted owls, and maintains the potential for genetic interchange. Including these lands would increase the awareness of State, County and local agencies about the status of and threats to spotted owls, the conservation actions needed for recovery, and the essential conservation role this habitat plays. It also increases the potential for educating visitors to State Forests and County Parks and Open Space areas about northern spotted owl conservation needs. Excluding these lands would have little impact on regulatory burdens because (a) current management of these lands is generally consistent with maintenance of habitat values, limiting the potential for adverse effects to critical habitat, and (b) management activities typically do not involve a Federal nexus. Therefore, the Secretary has chosen not to exclude the following California State, County, or municipal lands from the final designation of critical habitat for the northern spotted owl:

California Demonstration State Forests—Two California State Forests are included in the final critical habitat designation: (1) Jackson Demonstration State Forest (DSF), within subunit 2 in the Redwood Coast CHU in Mendocino County, California; and (2) Las Posadas DSF within subunit 6 of the Interior Coastal California CHU in Napa County, California. The California Department of Forestry and Fire Protection (CALFIRE) requested that the Jackson DSF be excluded from the final critical habitat designation for the northern spotted owl.

CALFIRE developed the Las Posadas DSF Management Plan (California Department of Forestry and Fire Protection, 1992) for the Las Posadas DSF and characterizes current management on the forest as ''custodial.'' Goals for fish and wildlife under the plan include maintenance of the ''* * * Forest's status as one of the last relatively undisturbed fish and wildlife habitats in Napa County.'' However, the management plan is quite dated, having been approved in 1992. There is acknowledgment of the presence of northern spotted owl activity sites in the management plan, but no specific provisions for owl management or conservation actions in the plan. There have been no publicly-available amendments or updates to the plan since its enactment in 1992 and the timeframe in which any revisions to the plan may take place is uncertain. The designation of critical habitat on these lands would perform an important educational function in highlighting their essential role in owl conservation as the State updates its plan and conducts management activities. Habitat within the plan area is not typical forested habitat often associated with the northern spotted owl but includes oak woodlands and grasslands in this southern part of the species range and represents a unique ecological setting for the species; the educational benefit of including this area in critical habitat is therefore high, as landowners may not be aware that the northern spotted owl inhabits this atypical habitat type. After reviewing the information available, we find that the benefits of including these areas as critical habitat will assist in maintaining linkages and movement among and between northern spotted owl populations, and heightening the awareness and educating visitors of the conservation role this habitat plays for recovery of the northern spotted owl. As a result we are not excluding the areas designated as critical habitat within the Las Posadas DSF.

CALFIRE has also developed a management plan for the Jackson DSF (Jackson Demonstration State Forest Management Plan (dated January 2008) and CALFIRE has requested that the area be excluded from the final designation. In their request for exclusion CALFIRE stated that the designation of the Jackson DSF as critical habitat was unnecessary given: (1) Extensive conservation planning and environmental assessment has already been completed for the area; (2) the designation would potentially have negative impacts on the mission of the Jackson DSF on implementing restoration and research projects; (3) that the draft economic analysis for the proposed critical habitat concluded that the designation would not affect timber harvest on State lands; and (4) designation does not provide meaningful wildlife benefits any different from those already in place.

The Service responds, as follows, to the four elements in CALFIRE'S request for exclusion. (1) While there are efforts by CALFIRE in the development of a forest management plan and environmental assessment for the Jackson DSF, the plan does not specifically provide for northern spotted owl conservation. We believe that the Jackson DSF Management Plan (CALFIRE, 2008) could provide potential benefits to the northern spotted owl, in that there is a high likelihood that land allocations stated in the plan, along with the long-term desired conditions for forest composition will improve habitat over time. However, we find that: (a) Existing management direction in the Plan relating to the northern spotted owl is vague; (b) the stated conservation policy for the owl is limited to a take-avoidance strategy; and (c) while CALFIRE collects monitoring data on northern spotted owl activity sites on a continuous basis, there is no apparent strategy for evaluating that information or applying it to the benefit of the species. The only overt policy statement in the 2008 Plan regarding the northern spotted owl states that ''* * * forest management objectives * * * are to maintain or increase the number and productivity of nesting owl pairs through forest management practices that enhance nesting/roosting opportunities and availability of a suitable prey base.'' The terms ''maintain'' and ''increase'' are not supported with measurable standards or targets; and there are no remedial measures or mechanisms in the 2008 Plan that are triggered by a decrease in activity sites or demographic productivity. The northern spotted owl conservation strategy in the 2008 Plan is predicated on take-avoidance (CALFIRE 2008, pp. 109 and 267). Take avoidance alone is not a sufficient conservation strategy and it will not necessarily satisfy CALFIRE's direction to maintain or increase owl activity sites or demographic performance. If there are local variations in the ''true'' optimal forest conditions that support owl occupancy, strict adherence to the take-avoidance provisions may not be satisfactory and occupancy rates may decrease, and there are no corrective mechanisms in the 2008 Plan to account for this possibility. This dual problem of the suitability and occupancy of activity sites is further complicated by barred owl intrusion, and likewise is not addressed by total reliance on a take-avoidance strategy. In addition, in the monitoring chapter for the 2008 Plan we find that there is continuous monitoring of northern spotted owl activity sites (CALFIRE 2008, p. 149), but it is not spelled out in detail. (For example, it does not include the detail and adaptability (i.e., adaptive management provisions) as are specified for instream conditions and fisheries (CALFIRE 2008, pp. 153–154). In addition, the 2008 Plan does not appear to contain guidance on how to process, evaluate, and interpret the continuous data that is currently being collected on northern spotted owl activity sites, or on how to apply that information to agency decision-making in the event that activity sites and demographic performance are not maintained or increased under the existing management direction. In summary, although the 2008 Jackson DSF Management Plan can potentially produce positive long-term outcomes for the northern spotted owl, it contains an incomplete conservation plan for the species.

(2) We do not agree with CALFIRE's contention that the designation would potentially have negative impacts on its ability to implement restoration and research projects. The fact that a Federal agency (i.e., U.S. Forest Service) is a research cooperator does not, by itself, create a section 7 nexus. The Service contacted the senior Forest Service scientist connected with the research program at Jackson DSF who described the Forest Service research activities as simply a scientific examination of the State's proposed actions. At this time, we see no Federal regulatory mechanism in connection with the Jackson DSF's existing cooperative research program that would trigger consultation under section 7 of the Act. Therefore, we believe any regulatory burden from designation would be minimal.

(3) The Service agrees with CALFIRE's observation, in their July 6, 2012 correspondence, that the economic analysis rightly concluded that critical habitat designation would have no effect on Jackson DSF harvest levels. The only potential effect on harvest schedules would occur if Federal permits or grants-of-funds were connected to the harvest activity.

(4) We disagree with CALFIRE's position that ''designation would

provide no meaningful wildlife benefits from those already in place.'' Our response to item 1, above, indicates that there are potentially meaningful informational benefits that may assist implementation of the existing Jackson DSF Management Plan. We believe designating these lands as critical habitat would serve a very important informational function as the management plan is implemented; it would highlight the fact that this habitat is essential to the conservation of the northern spotted owl.

While acknowledging that the 2008 Management Plan contains many features that have the potential to benefit the northern spotted owl over the long term, and also recognizing that there several remediable omissions in that Plan, the Secretary has elected not to exclude Jackson Demonstration State Forest from critical habitat designation under section 4(b)(2) of the Act because we believe that the educational and informational benefits of inclusion outweigh the benefits of exclusion.

Mount Tamalpais Municipal Watershed of the Marin Municipal Water District—We are not excluding the Mount Tamalpais Watershed (Watershed) from critical habitat designation. The Watershed (18,500 ac (7,487 ha)) is administered by the Marin Municipal Water District (MMWD) in Marin County, California. The Watershed is flanked on all sides by public parks, county-administered open space areas, grazing land, and residential areas within the triangle formed by U.S. Highway 101, California State Route 1 and Sir Francis Drake Boulevard. The MMWD currently does not operate under a conservation plan such as an HCP or SHA.

A key management consideration for the MMWD is the practical need to limit sediment delivery thereby extending the service life of the five reservoirs within the Watershed (Kent, Alpine, Bon Tempe, Lagunitas, and Phoenix Lakes). To that end, the policy of the MMWD is to maintain land in a natural condition and limit human activities to those that have the least impact on the Watershed. Within specified constraints, permitted public activities include hiking, bicycling, horseback riding, fishing and picnicking. Camping, swimming and boating are prohibited. There is limited public motor vehicle access into the Watershed on Panoramic Highway, Ridgecrest Boulevard and the Fairfax-Bolinas Road. These roads mostly access scenic vistas and day use areas around the reservoirs. The remainder of the road network in the Watershed is dedicated for firefighter access and administrative use, and is closed to public motor vehicles. The MMWD has produced several current management plans addressing specific subject areas, including public access, vegetation management, road and trail management, and long term fire and fuels management. Several elements in those plans are compatible with long-term northern spotted owl conservation. However, there is no explicit discussion about long-term owl management in any of the MMWD's planning documents. The upcoming Vegetation Management Plan (projected in 2013) may provide additional information that is relevant to northern spotted owl habitat management. We are not aware of any substantial benefits to excluding these areas from critical habitat and find that there would be significant educational benefits to including them in the designation in that it would highlight the significance this area has for northern spotted owl conservation in future planning efforts.

Marin County Parks and Open Space Department—We have included in the designation six Open Space Preserves (OSPs) totaling 3,626 ac (1,467 ha) administered by the Marin County (California) Parks and Open Space Department (Department). We have designated three contiguous OSPs adjacent to the Mount Tamalpais Watershed and south of the communities of Lagunitas and Fairfax including Gary Giacomini (1,476 ac (597 ha)), White Hill (390 ac (158 ha)), and Cascade Falls (498 ac (202 ha)). We have also designated three contiguous OSPs adjacent the Watershed and west of the community of Corte Madera including Baltimore Canyon (193 ac (78 ha)), Blithedale Summit (899 ac (364 ha), and Camino Alto (170 ac (69 ha). The Parks Department currently does not operate under a conservation plan such as an HCP or SHA.

Park management emphasizes non-motorized public use. Five of the six OSPs are served only by fire roads that are closed to public motor vehicle access. The exception is the Camino Alto OSP which is flanked on the east by a public street. Several land management elements in the park system strategic plan (Marin County Parks and Open Space Department, 2008) are compatible with northern spotted owl. However, there is no explicit discussion about long term owl management in this planning document. We are not aware of any substantial benefits to excluding these areas from critical habitat and find that there would be significant educational benefits to including them in the designation.

Sonoma County Regional Parks Department—Lands within Hood Mountain Regional Park, administered by the Sonoma County (California) Regional Parks Department (SCRPD), are included in the designation in subunit 6 of the Interior California Coast CHU. The proposed critical habitat designation includes all, or portions of, four assessor's parcels totaling 460 ac (186 ha) within the park boundary. The SCRPD does not operate under an HCP or SHA.

Hood Mountain Regional Park is minimally roaded; the Sonoma County General Plan of 2008 indicates a modest program of trail construction and management within the countywide regional parks system. Public information materials, along with maps showing the local road network, and the types and locations of facilities within Hood Mountain Regional Park, indicate that the SCRPD is emphasizing non-motorized recreation and protection of undeveloped land. Through public information sources in Sonoma County, we located a mission statement for the SCRPD but were unable to find any planning or guidance documents to indicate how the regional parks system would be managed over the long term. The absence of planning direction and the reasons for inclusion are similar to those for the Marin Municipal Water District and for the Marin County Parks and Open Space Department. We are not aware of any substantial benefits to excluding these areas from critical habitat and find that there would be significant educational benefits to including them in the designation.

Oregon

In Oregon, we considered excluding 228,733 ac (92,565 ha) of State lands managed by the Oregon Department of Forestry (ODF). These lands contain both demographically productive sites for northern spotted owls and provide connectivity linkages among northern spotted owl populations in the Oregon Coast and North Coast-Olympic Modeling Regions. These lands are not currently managed under any sort of conservation plan or agreement with the Service, but are managed by ODF for multiple benefits including commodity production.

The State of Oregon has indicated that the designation of their lands as critical habitat would have ''virtually no impact—positive or negative * * *'' on either the management of their lands or their ability to pursue HCPs, SHAs or other conservation agreements (ODF *in litt.*). This is because there is rarely a Federal nexus that would trigger Service regulatory authority, such as the section

7 consultation process and the adverse modification analysis. Thus, there would be little negative impact of including State lands in the critical habitat designation.

Inclusion of these lands in the critical habitat designation highlights their essential conservation role and provides opportunities for educating visitors to these areas, nearby landowners, and ODF about the potential conservation contribution of these lands to northern spotted owls. If ODF were to pursue some sort of conservation agreement, this critical habitat designation would provide a blueprint not only for the lands that would be essential to include in such an effort but also the types of management that would be appropriate there. If ODF does not pursue such an effort this designation clearly indicates the value of these lands for the conservation of the northern spotted owl. We believe the value of the information included in the designation would provide an opportunity for management direction that focuses on benefits to the species.

Because we are unaware of any negative impacts of including these ODF lands, the benefits of exclusion do not outweigh the benefits of inclusion for these lands, and the Secretary has chosen not to exercise his discretion to exclude these State of Oregon lands from the final designation.

Washington

In Washington we proposed or considered excluding 226,869 ac (91,811 ha) of State lands managed by the Washington Department of Natural Resources (225,013 ac; 91,059 ha), Washington State Parks (104 ac; 42 ha), and Washington Department of Fish and Wildlife (8,328 ac; 3,370 ha). We excluded the lands managed by the Washington Department of Natural Resources from the final designation based on their HCP, and excluded 104 ac (42 ha) of State Parks and Department of Fish and Wildlife Lands (see Exclusions). We retained 8,328 ac (3,370 ha) of State-owned lands managed by the State Department of Fish and Wildlife for wildlife habitat in the final designation. No conservation agreements are currently in place on these lands, but some could be covered by an HCP which is currently under development. Most of these lands are located in the central Cascades in an area that has repeatedly been identified as critical to maintaining linkages among spotted owl populations in Washington. These State lands play an essential conservation role in this area of limited or checkerboard Federal ownership. Retaining these lands in the critical habitat designation promotes movement of northern spotted owls between the northern and southern Cascades Range, as well as between the western and eastern slopes of the Cascades. Including these State lands would increase the awareness of State agencies about the essential conservation role these lands play and the conservation actions needed for recovery. Excluding these lands would impose little regulatory burden because (a) management of these lands is consistent with maintenance of habitat values, limiting the potential for adverse effects to critical habitat, and (b) management activities typically do not involve a Federal nexus. Therefore, the Secretary has chosen not to exercise his discretion to exclude lands managed by the Washington Department of Fish and Wildlife from the final designation of critical habitat for the northern spotted owl.

Summary of Changes From the Proposed Rule

The areas identified in this final rule constitute a revision from the areas we designated as critical habitat for the northern spotted owl in 2008 (August 13, 2008; 73 FR 47326), which was a revision of the areas we initially designated as critical habitat for the northern spotted owl in 1992 (January 15, 1992; 57 FR 1796; see Changes from Previously Designated Critical Habitat, below). This final rule supersedes and replaces both of these earlier designations. The changes to the proposed revised critical habitat designation identified above result in a final designation of 9,577,969 ac (3,876,064 ha), a decrease of 4,197,484 ac (1,689,072 ha) from the 13,962,449 ac (5,649,660 ha) identified as meeting the definition of critical habitat in the March 8, 2012 (77 FR 14062) proposed rule (Table 4, below).

TABLE 4—DIFFERENCES BETWEEN PROPOSED AND FINAL REVISED CRITICAL HABITAT. TOTALS MANY NOT SUM DUE TO ROUNDING (ROUNDED TO NEAREST 100 UNITS). SMALL DIFFERENCES BETWEEN THE PROPOSED AND FINAL REVISED CRITICAL HABITAT THAT ARE NOT NOTED AS ADDITIONS OR DELETIONS ARE THE RESULT OF CORRECTIONS OF THE GIS MAP AND ROUNDING ERROR

Total	13,962,449	5,640,829	9,577,969	3,876,064

V. Changes From Previously Designated Critical Habitat

In 2008, we designated 5,312,300 ac (2,149,800 ha) of Federal lands in California, Oregon, and Washington as critical habitat for the northern spotted owl (73 FR 47326; August 13, 2008). In this revision, we are designating 9,577,969 ac (3,876,064 ha) as critical habitat for the northern spotted owl. We have revised the designation of critical habitat for the northern spotted owl to be consistent with the most current assessment of the conservation needs of the species, as described in the 2011 Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011, Appendix B). In this final designation, 4,085,808 ac (1,653,468 ha) are the same as in the 2008 designation. Of the current designation, 5,679,162 ac (2,298,275 ha) are lands not formerly designated in 2008, and 1,229,119 ac (497,405 ha) of lands that were included in the former designation are not included here, for reasons detailed below.

This revision of critical habitat represents an increase in the total land area identified from previous designations in 1992 and 2008. This increase in area is due, in part, to: (a) The unanticipated steep decline of the northern spotted owl and the impact of the barred owl, requiring larger areas of habitat to maintain sustainable spotted owl populations in the face of competition with the barred owl (e.g., Dugger *et al.* 2011, p. 2467); (b) the recommendation from the scientific community that the conservation of more occupied and high-quality habitat is essential to the conservation of the species (Forsman *et al.* 2011, p. 77); (c) the need to provide for redundancy in northern spotted owl populations, by maintaining sufficient suitable habitat for northern spotted owls on a landscape level in areas prone to frequent natural disturbances, such as the drier, fire-prone regions of its range (in other words, ''back-up'' areas of habitat so that owls have someplace to go if their habitat burns or trees die due to insect infestation, etc.) (Noss *et al.* 2006, p. 484; Thomas *et al.* 2006, p. 285; Kennedy and Wimberly 2009, p. 565); and (d) in contrast to the previous critical habitat designation, the inclusion of some State lands in areas where Federal lands are not sufficient to meet the conservation needs of the northern spotted owl.

The new delineation of areas determined to provide the physical or biological features essential for the conservation of the northern spotted owl, or otherwise determined to be essential for the conservation of the species, was based, in part, on an improved understanding of the forest characteristics and spatial patterns that influence habitat usage by northern spotted owls which were incorporated into the latest population evaluation and mapping technology. The modeling process we used to evaluate alternative critical habitat scenarios differed fundamentally from the conservation planning approach used to inform the 1992 and 2008 designations of critical habitat for the northern spotted owl. These past designations relied on *a priori* (predefined) rule sets derived from the best scientific information and expert judgment available at that time regarding the size of reserves or habitat conservation blocks, target number of spotted owl pairs per reserve or block, and targeted spacing between reserves or blocks (USFWS 2011, p. C–4), which we then assessed and refined based on local conditions. This revised designation reflects our use of a series of spatially explicit modeling processes to determine those specific areas where biological features are essential to the conservation of the northern spotted owl, and in the case of unoccupied habitat, to determine the areas that are otherwise essential to the conservation of the owl, as described in Criteria Used to Identify Critical Habitat. These models enabled us to compare potential critical habitat scenarios in a repeatable and scientifically accepted manner (USFWS 2011, p. C–4), using current tools that capitalize on new spatial information and algorithms (rule sets to solve problems) for identifying the most efficient habitat network containing what is essential for conservation.

The areas designated are lands that were occupied at the time of listing and that currently provide suitable nesting, roosting, foraging, or dispersal habitat for northern spotted owls, or that are otherwise essential to the conservation of the species. However, as noted above, not every site of known owl occupancy, either at present or at the time of listing, is included in the designation. We did not include owl sites if they were isolated from other known occurrences or in areas of marginal habitat quality such that they were unlikely to make a significant contribution to the conservation of the species, and therefore were not considered to provide the essential features.

The critical habitat network development and evaluation strategy we used attempted to maximize the efficiency of the network by prioritizing Federal lands. Utilization of new scientific information and advanced modeling techniques accounts for many of the changes in the revised critical habitat; in particular, the location of areas essential to northern spotted owls may have shifted from previous designations based on the best information available regarding the spatial distribution of high-value habitat. These advances include improvements in remotely-sensed vegetation data, use of models that better identify spatial configurations of habitat features important to owls, and assessment of relative population performance of northern spotted owls under different critical habitat designations. In addition, negative effects of barred owls on northern spotted owl populations were incorporated into the modeling process.

Late-successional reserves (LSRs) were not prioritized in this approach based solely on their status as a reserved land allocation, but were included in the 2012 designation only where the habitat quality was high enough to meet the selection criteria. In contrast, the 2008 critical habitat identified lands in part based on status as LSRs. However, LSRs were not originally designed under the NWFP solely to meet the needs of the northern spotted owl, but may include areas designated for other late-successional forest species. Therefore, not all LSRs contain habitat of sufficient quality to be included in the critical habitat network for the northern spotted owl. Connected to the decision to designate lands in part because of their status as LSRs, we did not include NWFP matrix on Forest Service lands in 2008. In this designation we have included NWFP matrix lands where they contain high quality habitat essential to the species' conservation. As described in the section Changes from the Proposed Rule, we tested a habitat network that did not include many of these high-value matrix lands; doing so led to a significant increase in the risk of extinction for the species, therefore these lands are retained in this final designation.

Table 5 shows a comparison of areas included in the 2008 designation and those included in this revision to critical habitat. The process we used to determine occupied areas containing essential features and unoccupied areas essential to the conservation of the species is described in Criteria Used to Identify Critical Habitat.

TABLE 5—COMPARISON OF AREA INCLUDED IN 2008 CRITICAL HABITAT AND 2012 CRITICAL HABITAT BY REGION. THE 11 REGIONS ARE DESCRIBED IN DETAIL IN THE PROPOSED REVISED CRITICAL HABITAT DESIGNATION SECTION

Modeling region	2012 Critical habitat		2008 Final critical habitat	
	acres	hectares	acres	hectares
North Coast Olympics	824,500	333,663	485,039	196,289

TABLE 5—COMPARISON OF AREA INCLUDED IN 2008 CRITICAL HABITAT AND 2012 CRITICAL HABITAT BY REGION. THE 11 REGIONS ARE DESCRIBED IN DETAIL IN THE PROPOSED REVISED CRITICAL HABITAT DESIGNATION SECTION—Continued

Modeling region	2012 Critical habitat		2008 Final critical habitat	
	acres	hectares	acres	hectares
Oregon Coast	859,864	347,975	507,082	205,209
Redwood Coast	180,855	73,189	70,153	28,390
West Cascades North	542,274	219,450	390,232	157,921
West Cascades Central	909,687	368,136	546,333	221,093
West Cascades South	1,355,198	548,429	700,421	283,450
East Cascades North	1,345,523	544,514	687,702	278,303
East Cascades South	368,381	149,078	207,291	83,888
Klamath East	1,052,731	426,025	667,795	270,247
Klamath West	1,197,389	484,565	667,795	270,247
Inner California Coast Ranges	941,568	381,039	535,863	216,856
Grand total	9,577,969	3,876,064	5,312,327	2,149,823

The reduction in the number of critical habitat units from 33 in 2008 to 11 in 2012 is a reflection, in part, of our decision to aggregate habitat by regions. The 2008 designation included 33 critical habitat units; the 2012 revision includes 11 critical habitat units with 60 subunits.

Our determination of PCEs in this revised designation incorporates new information resulting from research conducted since the last revision in 2008. This new information, along with relevant older studies, allowed us to include a higher level of specificity in the PCEs in this revision. This final rule also includes two changes in overall organization. The 2008 revised designation considered nesting and roosting habitat as separate PCEs. In this designation, we have combined these habitat types, because northern spotted owls generally use the same habitat for both nesting and roosting; they are not separate habitat types, and function differs only based on whether a nest structure is present. At the scale of a rangewide designation of critical habitat, nesting and roosting habitats cannot be systematically distinguished, and, therefore, we combined them in our analysis and resulting rulemaking. For project planning and management of northern spotted owls at the local scale, the distinction between nesting and roosting habitat remains useful, especially in portions of the subspecies' range where nesting structures are conspicuous (e.g., mistletoe brooms). The second organizational change was to subdivide the range of the northern spotted owl into four separate regions, and to describe PCEs for foraging habitat separately for each of these to provide more appropriate region-specific information.

VI. Critical Habitat

Background

Critical habitat is defined in section 3 of the Act as:

(1) The specific areas within the geographical area occupied by the species, at the time it is listed in accordance with the Act, on which are found those physical or biological features;

(a) Essential to the conservation of the species; and

(b) Which may require special management considerations or protection; and

(2) Specific areas outside the geographical area occupied by the species at the time it is listed, upon a determination that such areas are essential for the conservation of the species.

Conservation, as defined under section 3 of the Act, means to use and the use of all methods and procedures that are necessary to bring an endangered or threatened species to the point at which the measures provided pursuant to the Act are no longer necessary. Such methods and procedures include, but are not limited to, all activities associated with scientific resources management such as research, census, law enforcement, habitat acquisition and maintenance, propagation, live trapping, and transplantation, and, in the extraordinary case where population pressures within a given ecosystem cannot be otherwise relieved, may include regulated taking.

Critical habitat receives protection under section 7 of the Act through the requirement that Federal agencies ensure, in consultation with the Service, that any action they authorize, fund, or carry out is not likely to result in the destruction or adverse modification of critical habitat. The designation of critical habitat does not affect land ownership or establish a refuge, wilderness, reserve, preserve, or other conservation area. Such designation does not allow the government or public to access private lands. Such designation does not require implementation of restoration, recovery, or enhancement measures by non-Federal landowners. Where a landowner requests Federal agency funding or authorization for an action that may affect a listed species or critical habitat, the consultation requirements of section 7(a)(2) of the Act would apply, but even in the event of a destruction or adverse modification finding, the obligation of the Federal action agency and the landowner is not to restore or recover the species, but to implement reasonable and prudent alternatives to avoid destruction or adverse modification of critical habitat.

Under the first prong of the Act's definition of critical habitat, areas within the geographical area occupied by the species at the time it was listed are included in a critical habitat designation if they contain physical or biological features: (1) Which are essential to the conservation of the species, and (2) which may require special management considerations or protection. For these areas, critical habitat designations identify, to the extent known using the best scientific and commercial data available, those physical or biological features that are essential to the conservation of the species (such as space, food, cover, and protected habitat). In identifying those physical or biological features within an area, we focus on the principal biological or physical constituent elements (PCEs—primary constituent elements such as roost sites, nesting grounds, rainfall, canopy cover, soil type) that are essential to the conservation of the species.

Under the second prong of the Act's definition of critical habitat, we can designate critical habitat in areas outside the geographical area occupied by the species at the time it is listed, upon a determination that such areas are essential for the conservation of the species. For example, an area that was not occupied at the time of listing but is essential to the conservation of the species may be included in the critical habitat designation. We designate critical habitat in areas outside the geographical area occupied by a species only when a designation limited to its range would be inadequate to ensure the conservation of the species (50 CFR 424.12(e)).

Section 4 of the Act requires that we designate critical habitat on the basis of the best scientific and commercial data available. Further, our Policy on Information Standards Under the Endangered Species Act (published in the **Federal Register** on July 1, 1994 (59 FR 34271)), the Information Quality Act (section 515 of the Treasury and General Government Appropriations Act for Fiscal Year 2001 (Pub. L. 106–554; H.R. 5658)), and our associated Information Quality Guidelines, provide criteria, establish procedures, and provide guidance to ensure that our decisions are based on the best scientific data available. They require our biologists, to the extent consistent with the Act and with the use of the best scientific data available, to use primary and original sources of information as the basis for recommendations to designate critical habitat.

When we are determining which areas should be designated as critical habitat, our primary source of information is generally the information developed during the listing process for the species. Additional information sources may include the recovery plan for the species, articles in peer-reviewed journals, conservation plans developed by States and counties, scientific status surveys and studies, biological assessments, other unpublished materials, or experts' opinions or personal knowledge.

Habitat is dynamic, and northern spotted owls may move from one area to another over time. We recognize that critical habitat designated at a particular point in time may not include all of the habitat areas that we may later determine are necessary for the recovery of the species. For these reasons, a critical habitat designation does not signal that habitat outside the designated area is unimportant or may not be needed for recovery of the species. Areas that are important to the conservation of the species, both inside and outside the critical habitat designation, will continue to be subject to: (1) Conservation actions implemented under section 7(a)(1) of the Act, (2) regulatory protections afforded by the requirement in section 7(a)(2) of the Act for Federal agencies to insure their actions are not likely to jeopardize the continued existence of any endangered or threatened species, and (3) the prohibitions of section 9 of the Act on taking any individual of the species, including taking caused by actions that affect habitat. Federally funded or permitted projects affecting listed species outside their designated critical habitat areas may still result in jeopardy findings in some cases. These protections and conservation tools will continue to contribute to recovery of this species. Similarly, critical habitat designations made on the basis of the best available information at the time of designation will not control the direction and substance of future recovery plans, habitat conservation plans (HCPs), or other species conservation planning efforts if new information available at the time of these planning efforts calls for a different outcome.

Physical or Biological Features

In accordance with section 3(5)(A)(i) and 4(b)(1)(A) of the Act and regulations at 50 CFR 424.12, in determining which areas within the geographical area occupied by the species at the time of listing to designate as critical habitat, we consider the physical or biological features essential to the conservation of the species and which may require special management considerations or protection. These include, but are not limited to:

(1) Space for individual and population growth and for normal behavior;

(2) Food, water, air, light, minerals, or other nutritional or physiological requirements;

(3) Cover or shelter;

(4) Sites for breeding, reproduction, or rearing (or development) of offspring; and

(5) Habitats that are protected from disturbance or are representative of the historical, geographical, and ecological distributions of a species.

For the northern spotted owl, the physical or biological features essential to the conservation of the species are forested areas that are used or likely to be used for nesting, roosting, foraging, or dispersing. The specific characteristics or components that comprise these features include, for example, specific ranges of forest stand density and tree size distribution; coarse woody debris; and specific resources, such as food (prey and suitable prey habitat), nest sites, cover, and other physiological requirements of northern spotted owls and considered essential for the conservation of the species. Below, we describe the life-history needs of the species and the broader physical or biological features essential to the conservation of the northern spotted owl, which informed our identification of the primary constituent elements (PCEs). The following information is based on studies of the habitat, ecology, and life history of the species, as described in the final listing rule for the northern spotted owl, published in the **Federal Register** on June 26, 1990 (55 FR 26114); the Revised Recovery Plan for the Northern Spotted Owl released on June 30, 2011 (USFWS 2011); the Background section of this document; and the following information.

Although the northern spotted owl is typically considered a habitat and prey specialist, it uses a relatively broad array of forest types for nesting, roosting, foraging, and dispersal. The diversity of forest types used is a reflection of the large geographical range of this subspecies, and the strong gradation in annual precipitation and temperature associated with both coastal mountain ranges and the Cascade Range. While the northern spotted owl is unquestionably associated with old-growth forests, habitat selection and population performance involves many additional features (Loehle *et al.* 2011, p. 20). This description of physical or biological features summarizes both variation in habitat use and particular features or portions of the overall gradient of variation that northern spotted owls preferentially select, and that we, therefore, consider essential to their conservation. We begin by considering the broad-scale patterns of climate, elevation, topography, and forest community type that act to influence northern spotted owl distributions and space for population growth and dispersal. We then discuss the abundance and pattern of habitats used for nesting, roosting, and foraging at the landscape scale that influence the availability and occupancy of breeding sites and the survival and fecundity of northern spotted owls. Thus, we begin by considering factors that operate at broader spatial scales and proceed to factors that influence habitat quality at the forest stand scale. When we discuss the physical or biological features, we focus on features that are common range wide, but also summarize specific features or patterns of habitat selection that characterize particular regions.

Physical Influences Related to Features Essential to the Northern Spotted Owl

Climate, elevation, and topography are features of the physical environment that influence the capacity of a landscape to support habitat with high value for northern spotted owls and the type of habitat needed by the species. The distribution and amount of habitat on the landscape reflects interactions among these physical elements. Several studies have found that physical aspects of the environment, such as topographic position, aspect, and elevation, influence the northern spotted owl's selection of habitat (e.g., Clark 2007, pp. 97–111; Stalberg *et al.* 2009, p. 80). These features are also factors in determining the type of habitats essential to northern spotted owl conservation.

Climate—Population processes for northern spotted owls are affected by both large-scale fluctuations in climate conditions and by local weather variation (Glenn 2009, pp. 246–248). The influence of weather and climate on northern spotted owl populations has been documented in northern California (Franklin *et al.* 2000, pp. 559–583), Oregon (Olson *et al.* 2004, pp. 1047–1052; Dugger *et al.* 2005, pp. 871–877; Glenn *et al.* 2010, pp. 2546–2551), and Washington (Glenn *et al.* 2010, pp. 2546–2551). Climate and weather effects on northern spotted owls are mediated by vegetation conditions, and the combination of climate and vegetation variables improves models designed to predict the distribution of northern spotted owls (e.g., Carroll 2010, pp. 1434–1437).

Climate niche models for the northern spotted owl identified winter precipitation as the most important climate variable influencing ability to predict the distribution of northern spotted owl habitat (Carroll 2010, p. 1434). This finding is consistent with previous demographic studies that suggest there are negative effects of winter and spring precipitation on survival, recruitment, and dispersal (Franklin *et al.* 2000; pp. 559–583). Niche modeling suggested that precipitation variables, both in winter and in summer, were more influential than winter and summer temperatures (Carroll 2010, p. 1434–1436).

Wet, cold weather during the winter or nesting season, particularly the early nesting season, has been shown to negatively affect northern spotted owl reproduction (Olson *et al.* 2004, p. 1039; Dugger *et al.* 2005, p. 863; Glenn *et al.* 2011b, p. 1279), survival (Franklin *et al.* 2000, p. 539; Olson *et al.* 2004, p. 1039; Glenn *et al.* 2011a, p. 159), and recruitment (Franklin *et al.* 2000, p. 559; Glenn *et al.* 2010, p. 2546). Cold, wet weather may reduce reproduction or survival during the breeding season, due to declines or decreased activity in small mammal populations, so that less food is available during this period when metabolic demands are high (Glenn *et al.* 2011b, pp. 1290–1294). Wet, cold springs or intense storms during this time may increase the risk of starvation in adult birds (Franklin *et al.* 2000, pp. 559–590). Cold, wet weather may also limit abundance of prey (Lehmkuhl *et al.* 2006, pp. 589–595), and reduce the male northern spotted owl's ability to bring food to incubating females or nestlings (Franklin *et al.* 2000, pp. 559–590). Cold, wet nesting seasons have been shown to increase the mortality of nestlings due to chilling (Franklin *et al.* 2000, pp. 559–590), and reduce the number of young fledged per pair per year (Franklin *et al.* 2000, p. 559, Olson *et al.* 2004, p. 1047; Glenn *et al.* 2011b, p. 1279). Wet, cold weather may decrease survival of dispersing juveniles during their first winter, thereby reducing recruitment (Franklin *et al.* 2000, pp. 559–590).

Habitat quality may offset the negative effects of climate extremes. Franklin *et al.* (2000, pp. 582–583) argued that northern spotted owl populations are regulated or limited by both habitat quality and environmental factors, such as weather. Abundance and availability of prey may ultimately limit northern spotted owl populations, and abundance of prey is strongly associated with habitat conditions. As habitat quality decreases, other factors, such as weather, have a stronger influence on demographic performance. In essence, the presence of high-quality habitat appears to buffer the negative effects of cold, wet springs and winters on survival of northern spotted owls, as well as ameliorate the effects of heat. High-quality northern spotted owl habitat was defined in a northern California study area as a mature or old-growth core within a mosaic of old and younger forest (Franklin *et al.* 2000, p. 559). The high-quality habitat can help maintain a stable prey base, thereby reducing the cost of foraging during the early breeding season, when energetic needs are high (Carey *et al.* 1992, pp. 223–250; Franklin *et al.* 2000, p. 559). In addition, mature and old forest with high canopy cover typically remains cooler during summer months than younger stands.

Drought or hot temperatures during the previous summer have also been associated with reduced northern spotted owl recruitment and survival (Glenn *et al.* 2010, p. 2546). Drier, warmer summers and drought conditions during the growing season strongly influence primary production in forests, food availability, and the population sizes of small mammals (Glenn *et al.* 2010, p. 2546). Northern flying squirrels (one of the northern spotted owl's primary prey), for example, forage primarily on ectomycorrhizal fungi (truffles), many of which grow better under moist conditions (Lehmkuhl *et al.* 2004, pp. 58–60). Drier, warmer summers, or the high-intensity fires, which such conditions support, may change the range or availability of these fungi, affecting northern flying squirrels and the northern spotted owls that prey on them. Periods of drought are associated with declines in annual survival rates for other raptors, due to a presumed decrease in prey availability (Glenn *et al.* 2010, pp. 2546–2551).

Mexican northern spotted owls (*Strix occidentalis lucida*) and California northern spotted owls (*S. o. occidentalis*) have a narrow temperature range in which body temperature can be maintained without additional metabolic energy expenditure (Ganey *et al.* 1993, pp. 653–654; Weathers *et al.* 2001, pp. 682–686). Others (e.g., Franklin *et al.* 2000, entire) have assumed the northern spotted owl to be similar in this regard. While winter temperatures are relatively mild across much of the northern spotted owl's range, heat stress has been identified as a potential stressor at temperatures exceeding 30 °C (86 °F; Weathers *et al.* 2001, p. 678). The northern spotted owl's selection for areas with older-forest characteristics has been hypothesized to be related, in part, to its needing cooler areas in summer to avoid heat stress (Barrows and Barrows 1978, entire).

Elevation and Topography—Elevation and corresponding changes in temperature or moisture regimes constrain the development of vegetation communities selected by northern spotted owls, and may exceed the bounds of physiological tolerance of northern spotted owls or their prey as well. Several studies have noted the avoidance or absence of northern spotted owls above location-specific elevational limits (Blakesley *et al.* 1992, pp. 390–391; Hershey *et al.* 1998, p. 1406; LaHaye and Gutiérrez 1999, pp. 326, 328). In some locations, elevational limits occur despite the presence of forests that appear to have the structural characteristics typically associated with northern spotted owl habitat. Where forest structure is not the apparent cause of elevational limits, the mechanistic bases of these limits are unknown, but they could be related to prey availability, presence of competitors, or extremes of temperature or precipitation. Habitat for northern spotted owls can occur from sea level to the lower elevation limit of subalpine vegetation types. This upper elevation limit varies with latitude from about 3,000 feet (ft) (900 meters (m)) above sea level in coastal Washington and Oregon (Davis and Lint 2005, p. 32) to about 6,000 ft (1,800 m) above sea level near the southern edge of the range (derived from Davis and Lint 2005, p. 32).

Topography also influences the distribution of northern spotted owl habitat and patterns of habitat selection. The effects of topography are strongest in drier forests, where aspect and insolation (amount of solar radiation received in an area) contribute to moisture stress that can limit forest density and tree growth. In drier forests east of the Cascades and in the Klamath region, suitable habitat can be concentrated at intermediate topographic positions, on north-facing aspects, and in concave landforms that retain moisture. This leads to a distribution of suitable habitat characterized by ribbon-like bands and discrete patches. Ribbons occur along drainages and valley bottoms, along the north faces of ridges that trend from east to west, and at intermediate topographic positions between drier pine-dominated forests at lower elevations, and subalpine forest types at higher elevations. Discrete patches also occur on top of higher plateaus. Northern spotted owl populations inhabiting drier forests have higher fecundity and lower survival rates than owls in other regions (Hicks *et al.* 2003, pp. 61–62; Anthony *et al.* 2006, pp. 28, 30). The naturally fragmented distribution of suitable habitat in drier forests, and increased predation risk associated with traversing this landscape, may be one of many features that contributed to the evolution of these life-history characteristics.

Slope may also influence the distribution of suitable habitat. Intermediate slopes have been associated with northern spotted owl sites in some studies (e.g., Gremel 2005, p. 37; Gaines *et al.* 2010, pp. 2048–2050; USFWS 2011, Appendix C), but the mechanisms underlying this association are unclear, potentially including a variety of features from soil depth to competition with barred owls.

Disturbance Regimes—Natural disturbances and anthropogenic (human-caused) activities continuously shape the amount and distribution of northern spotted owl habitat on the landscape. In moist forests west of the Cascades in Washington and Oregon, and in the Redwood region in California, anthropogenic activities have a dominant influence on distribution patterns of remaining habitat, with natural disturbances typically playing a secondary role. In contrast, drier forests east of the Cascades and in the Klamath region have dynamic disturbance regimes that continue to exert a strong influence on northern spotted owl habitat. Climate change may modify disturbance regimes across the range of the northern spotted owl, resulting in substantial changes to the frequency and extent of habitat disruption by natural events.

In drier forests, low- and mixed-severity fires historically contributed to a high level of spatial and temporal variability in landscape patterns of disturbed and recovering vegetation. However, anthropogenic activities have so altered these historical patterns and composition of vegetation, fuels, and associated disturbance regimes, that contemporary landscapes no longer function as they did historically (Hessburg *et al.* 2000a, pp. 77–78; Hessburg and Agee 2003, pp. 44–51; Hessburg *et al.* 2005, pp. 122–127, 134–136; Skinner *et al.* 2006, pp. 176–179; Skinner and Taylor 2006, pp. 201–203).

Fire exclusion, combined with the removal of fire-tolerant structures (e.g., large, fire-tolerant tree species such as ponderosa pine, western larch (*Larix occidentalis*), and Douglas-fir), have reduced the resiliency of the landscape to fire and other disturbances, (Agee 1993, pp. 280–319; Hessburg *et al.* 2000a, pp. 71–80; Hessburg and Agee 2003, pp. 44–46). Understory vegetation in these forests has shifted in response to fire exclusion from grasses and shrubs to shade-tolerant conifers, reducing fire tolerance of these forests, and increasing drought stress on dominant tree species.

Anthropogenic activities have also fundamentally changed the spatial distribution of fire-intolerant stands among the fire-tolerant stands, changing the pattern of fire activity across the landscape. Past management has altered the natural disturbance regime, homogenized the formerly patchy vegetative network, and reduced the complexity that was more prevalent during the presettlement era (Skinner 1995, pp. 224–226; Hessburg and Agee 2003, pp. 44–45; Hessburg *et al.* 2007, p. 21; Kennedy and Wimberly 2009, pp. 564–565). This alteration in the disturbance regime further affects forest structure and composition. Patches of fire-intolerant vegetation that had been spatially separated have become more contiguous and are more prone to conducting fire, insects, and diseases across larger swaths of the landscape (Hessburg *et al.* 2005, pp. 71–74, 77–78). This homogenized landscape may be altering the size and intensity of current disturbances and further altering landscape functionality (e.g., Everett *et al.* 2000, pp. 221–222).

The intensity and spatial extent of natural disturbances that affect the amount, distribution, and quality of northern spotted owl habitat in dry forests are also influenced by local topographic features, elevation, and climate (Swanson *et al.* 1988, entire). At local scales, these factors can be used to identify areas that are insulated from recent or existing disturbance, and consequently tend to persist without disturbance for longer periods (Camp *et al.* 1997, entire). These disturbance refugia are locations where northern spotted owl habitat has a higher likelihood of developing and persisting in drier forests. As a result of these unevenly distributed disturbance regimes, especially in the drier forests within its range, habitat for the northern spotted owl naturally occurs in a patchy mosaic in various stages of suitability in these regions. Sufficient area to provide for these habitat dynamics and to allow for the maintenance of adequate quantities of suitable habitat on the landscape at any one point in time is, therefore, essential to the conservation of the northern spotted owl in the dry forest regions.

Pattern and Distribution of Habitat—Historically, forest types occupied by the northern spotted owl were fairly continuous, particularly in the wetter parts of its range in coastal northern California and most of western Oregon and Washington. Suitable forest types in the drier parts of the range (interior northern California, Klamath region, interior southern Oregon, and east of the Cascade crest in Oregon and Washington) occur in a mosaic pattern interspersed with infrequently used vegetation types, such as open forests, shrubby areas, and grasslands. As described above, natural disturbance processes in these drier regions likely contributed to a pattern in which patches of habitat in various stages of suitability shift positions on the landscape through time. In the Klamath Mountains Provinces of Oregon and California, and to a lesser extent in the Coast and Cascade Provinces of California, large areas of serpentine soils exist that are typically not capable of supporting northern spotted owl habitat (Davis and Lint 2005, pp. 31–33).

Biological Influences Related to Features Essential to the Northern Spotted Owl

Forest Community Type (Composition)—Across their geographical range, northern spotted owl use of habitat spans several scales, with increasing levels of habitat selection specificity at each scale. We refer to these scales as the ''landscape,'' ''home range,'' and ''core area'' scales. Nest stands within core areas are even more narrowly selected (see Functional Categories of Northern Spotted Owl Habitat, in the Background section, above).

Landscapes supporting populations of northern spotted owls are the broadest scale we considered, encompassing areas sufficient to support numerous reproductive pairs (roughly 20,000 to 200,000 ac (8,100 to 81,000 ha). At the landscape scale, the northern spotted owl inhabits most of the major types of coniferous forests across its geographical range, including Sitka spruce, western hemlock, mixed conifer and mixed evergreen, grand fir, Pacific silver fir, Douglas-fir, redwood/Douglas-fir (in coastal California and southwestern Oregon), white fir, Shasta red fir, and the moist end of the ponderosa pine zone (Forsman *et al.* 1984, pp. 8–9; Franklin and Dyrness 1988, entire; Thomas *et al.* 1990, p. 145). These forest types may be in early-, mid-, or late-seral stages, and must occur in concert with at least one of the physical or biological features characteristic of breeding and nonbreeding (dispersal) habitat, described below.

Landscape-level patterns in tree species composition and topography can influence the distribution and density of northern spotted owls. These differences in northern spotted owl distribution occur even when different forest types have similar structural attributes, suggesting that northern spotted owls may prefer specific plant associations or tree species. Some forest types, such as pine-dominated and subalpine forests, are infrequently used, regardless of their structural attributes. In areas east of the Cascade Crest, northern spotted owls select forests with high proportions of Douglas-fir trees. The effects of tree species composition on habitat selection also extend to hardwoods within conifer-dominated forests (e.g., Meyer *et al.* 1998, p. 35). For example, our habitat modeling indicated that habitat value in the central Western Cascades was negatively related to proportion of hardwoods present. At the home range and core area scales, locations occupied by northern spotted owls consistently have greater amounts of mature and old-growth forest compared to random locations or unused areas. The proportion of older or structurally complex forest within the home range varies greatly by geographical region, but typically falls between 30 and 78 percent (Courtney *et al.* 2004, p. 5–6). In studies where circles of different sizes were compared, differences between northern spotted owl sites and random locations diminished as circles of increasing size were evaluated (Courtney *et al.* 2004, p. 5–7), suggesting habitat selection is stronger at the core area scale than at the home range and landscape scales.

Population Spatial Requirements—We have described a range of climatic, elevational, topographic, and compositional factors, and associated disturbance dynamics typical of different regions, that constrain the amount and distribution of northern spotted owl habitat across landscapes. Within this context, areas that contain the physical or biological features described below must provide habitat in an amount and distribution sufficient to support persistent populations, including metapopulations of reproductive pairs, and opportunities for nonbreeding and dispersing owls to move among populations to be considered essential to the conservation of the northern spotted owl.

Northern spotted owls maintain large home ranges that vary in size across nearly an order of magnitude across the species' range, from about 1,400 to 14,000 ac (570 to 5,700 ha), depending on geographic latitude and prey resources (see *Home Range Requirements,* below). Overlap occurs among adjoining territories, but the large size of territories nonetheless means that populations of northern spotted owls require landscapes with large areas of habitat suitable for nesting, roosting, and foraging. For example, in the northern parts of the subspecies' range where territories are largest, a population of 20 resident pairs would require at least 100,000 ac (about 40,500 ha) of habitat that is relatively densely distributed and of high quality.

As described in the Background section above, several studies have examined patterns of northern spotted owl habitat selection at the territory scale and the consequences on fitness of habitat configuration within a territory. We do not know if the features that contribute to enhancing northern spotted owl occupancy and reproductive success at the territory scale can be scaled up to predict what landscape-scale patterns of habitat are most conducive to stable or increasing northern spotted owl populations. Studies that use populations as units of analysis in order to investigate the effects of the landscape-scale configuration of habitat on the performance of northern spotted owl populations have only begun recently. Past models of northern spotted owl population dynamics have included predictions about the effects of habitat configuration on population performance, but these predictions have not been tested or validated by empirical studies (Franklin and Gutiérrez 2002; p. 215). Recent demographic analyses suggested that recruitment was positively related to the proportion of study areas covered by suitable habitat (see Forsman *et al.* 2011, pp. 59–62), but this covariate was not associated with other aspects of demographic performance, and few other covariates were investigated.

When the northern spotted owl was listed as threatened in 1990 (55 FR 26114; June 26, 1990), habitat loss and fragmentation of old-growth forest were identified as major factors contributing to declines in northern spotted owl populations. As older forests were reduced to smaller and more isolated patches, the ability of northern spotted owls to successfully disperse and establish territories was likely reduced (Lamberson *et al.* 1992, pp. 506, 508, 510–511). Lamberson *et al.* (1992, pp. 509–511) identified an apparent sharp threshold in the amount of habitat below which northern spotted owl population viability plummeted. Lamberson *et al.* (1994, pp. 185–186, 192–194) concluded that size, spacing, and shape of reserved areas all had strong influence on population persistence, and reserves that could support a minimum of 20 northern spotted owl territories were more likely to maintain northern spotted owl populations than smaller reserves. They also found that juvenile dispersal was facilitated in areas large enough to support at least 20 northern spotted owl territories.

In addition to area size, spacing between reserves had a strong influence on successful dispersal (Lamberson *et al.* 1992, pp. 508, 510–511). Forsman *et al.* (2002, pp. 15–16) reported dispersal distances of 1,475 northern spotted owls in Oregon and Washington for 1985 to 1996. Median maximum dispersal distance (the straight-line distance between the natal site and the farthest location) for radio-marked juvenile male northern spotted owls was 12.7 miles (mi) (20.3 kilometers (km)), and that of female northern spotted owls was 17.2 mi (27.5 km) (Forsman *et al.* 2002: Table

2). Dispersal data and other studies on the amount and configuration of habitat necessary to sustain northern spotted owls provided the foundation for developing previous northern spotted owl habitat reserve systems. Given the range-wide declining trends in northern spotted owl populations, as well as declining trends in the recruitment of new individuals into territorial populations (Forsman *et al.* 2011, pp. 59–66, Table 22), we have determined that, to be essential, physical or biological features must be positioned on the landscape to enable populations to persist and to allow individual owls to disperse among populations.

In contrast to earlier designations of critical habitat, we did not develop an *a priori* rule set to identify those areas that provide the physical or biological features essential to the conservation of the owl, using factors such as minimum size of habitat blocks, targeted numbers of owl pairs, or maximum distance between blocks of habitat. Instead, we determined the spatial extent and placement of the areas providing the physical or biological features that are essential to the conservation of the owl based on the relative demographic performance of the habitat models tested. This process is summarized in the section Criteria Used to Identify Critical Habitat, presented later in this document, and is presented in detail in our supporting documentation (Dunk *et al.* 2012b, entire). This supporting documentation, which describes in detail the modeling process we used, is available at our Web site. We refer to this document in the Summary of Comments and Recommendations section, below, as our ''Modeling Supplement'' (Dunk *et al.* 2012b).

Home Range Requirements—Most adult northern spotted owls remain on their home range throughout the year; therefore, their home range must provide all the habitat components, including prey, needed for the survival and successful reproduction of a territorial pair. The home range of a northern spotted owl is relatively large, but varies in size across the range of the subspecies (Courtney *et al.* 2004, p. 5–24; 55 FR 26117; June 26, 1990). Home range sizes are largest in Washington (Olympic Peninsula: 9,231 ac (3,736 ha) (Forsman *et al.* 2005, pp. 371–372), and generally decrease along a north-south gradient to approximately 1,430 ac (580 ha) in the Klamath region of northwestern California and southern Oregon (Zabel *et al.* 1995, p. 436). Northern spotted owl home ranges are generally larger where northern flying squirrels are the predominant prey and smaller where woodrats are the predominant prey (Zabel *et al.* 1995, p. 436). Home range size also increases with increasing forest fragmentation (Carey *et al.* 1992, p. 235; Franklin and Gutiérrez 2002, p. 212; Glenn *et al.* 2004, p. 45) and decreasing proportions of nesting habitat on the landscape (Carey *et al.* 1992, p. 235; Forsman *et al.* 2005, p. 374), suggesting that northern spotted owls increase the size of their home ranges to encompass adequate amounts of suitable forest types (Forsman *et al.* 2005, p. 374).

Meta-analysis of features associated with occupancy at the territory-scale indicated that northern spotted owls consistently occupy areas having larger patches of older forests that were more numerous and closer together than random sites (Franklin and Gutiérrez 2002; p. 212). In the Klamath and Redwood regions owls also consistently occupy sites with higher forest heterogeneity than random sites. Occupied sites in the Klamath region, in particular, show a high degree of vegetative heterogeneity, with more variable patch sizes and more perimeter edge than in other regions (Franklin and Gutiérrez 2002; p. 212). In the Klamath region, ecotones, or edges between older forests and other seral stages, may contribute to improved access to prey (Franklin and Gutiérrez 2002, p. 215). Several studies in the Klamath region and the Redwood region have found that variables describing the relationship between habitat core area and edge length improve the ability of models to predict northern spotted owl occupancy (e.g., Folliard *et al.* 2000, pp. 79–81; Zabel *et al* 2003, pp. 1936–1938). In contrast, northern spotted owl sites in the Oregon Coast Range had a more even distribution of cover types than random locations, and nest stands had a higher ratio of core to edge and more complex stand shapes than non-nest stands (Courtney *et al.* 2004, p. 5–9).

A home range provides the habitat components essential for the survival and successful reproduction of a resident breeding pair of northern spotted owls. The exact amount, quality, and configuration of these habitat types required for survival and successful reproduction varies according to local conditions and factors, such as the degree of habitat fragmentation, proportion of available nesting habitat, and primary prey species (Courtney *et al.* 2004, p. 5–2).

Core Area Requirements—Northern spotted owls often use habitat within their home ranges disproportionally, and exhibit central-place foraging behavior (Rosenberg and McKelvey 1999, p. 1028), with much activity centered within a core area surrounding the nest tree during the breeding season. During fall and winter, as well as in nonbreeding years, owls often roost and forage in areas of their home range more distant from the core. The size of core areas varies considerably across the subspecies' geographical range following a pattern similar to that of home range size (Bingham and Noon 1997, p. 133), varying from over 4,057 ac (1,642 ha) in the northernmost (flying squirrel prey) provinces (Forsman *et al.* 2005, pp. 370, 375) to less than 500 ac (202 ha) in the southernmost (dusky-footed woodrat prey) provinces (Pious 1995, pp. 9–10, Table 2; Zabel *et al.* 2003, pp. 1036–1038). Owls often switch nest trees and use multiple core areas over time, possibly in response to local prey depletion or loss of a particular nest tree.

Core areas contain greater proportions of mature or old forest than random or nonuse areas (Courtney *et al.* 2004, p. 5–13), and the amount of high-quality habitat at the core area scale shows the strongest relationships with occupancy (Meyer *et al.* 1998, p. 34; Zabel *et al.* 2003, pp. 1027, 1036), survival (Franklin *et al.* 2000, p. 567; Dugger *et al.* 2005, p. 873), and reproductive success (Ripple *et al.* 1997, pp. 155 to 156; Dugger *et al.* 2005, p. 871). In some areas, edges between forest types within northern spotted owl home ranges may provide increased prey abundance and availability (Franklin *et al.* 2000, p. 579). For successful reproduction, core areas need to contain one or more forest stands that have both the structural attributes and the location relative to other features in the home range that allow them to fulfill essential nesting, roosting, and foraging functions (Carey and Peeler 1995, pp. 233–236; Rosenberg and McKelvey 1999, pp. 1035–1037).

Areas to Support Dispersal and Nonbreeding Owls—Northern spotted owls regularly disperse through highly fragmented forested landscapes that are typical of the mountain ranges in western Washington and Oregon, and have dispersed from the Coastal Mountains to the Cascades Mountains in the broad forested regions between the Willamette, Umpqua, and Rogue Valleys of Oregon (Forsman *et al.* 2002, p. 22). Corridors of forest through fragmented landscapes serve primarily to support relatively rapid movement through such areas, rather than colonization or residency of nonbreeding owls.

During the transience (movement) phase, dispersers used mature and old-growth forest slightly more than its availability; during the colonization phase, mature and old-growth forest was used at nearly twice its availability (Miller *et al.* 1997, p. 144). Closed pole-sapling-sawtimber habitat was used roughly in proportion to availability in both phases and may represent the minimum condition for movement. Open sapling and clearcuts were used less than expected based on availability during colonization (Miller *et al.* 1997, p. 145). In comparison, nondispersing subadults or nonbreeding adults that are residents require habitats that are more similar to the nesting, roosting, and foraging habitats utilized by breeding pairs. This suggests that juveniles and transient dispersers either have a less developed ability to avoid areas where starvation or predation are more likely, or they can use a greater variety of forested habitats than nondispersing adults, or both.

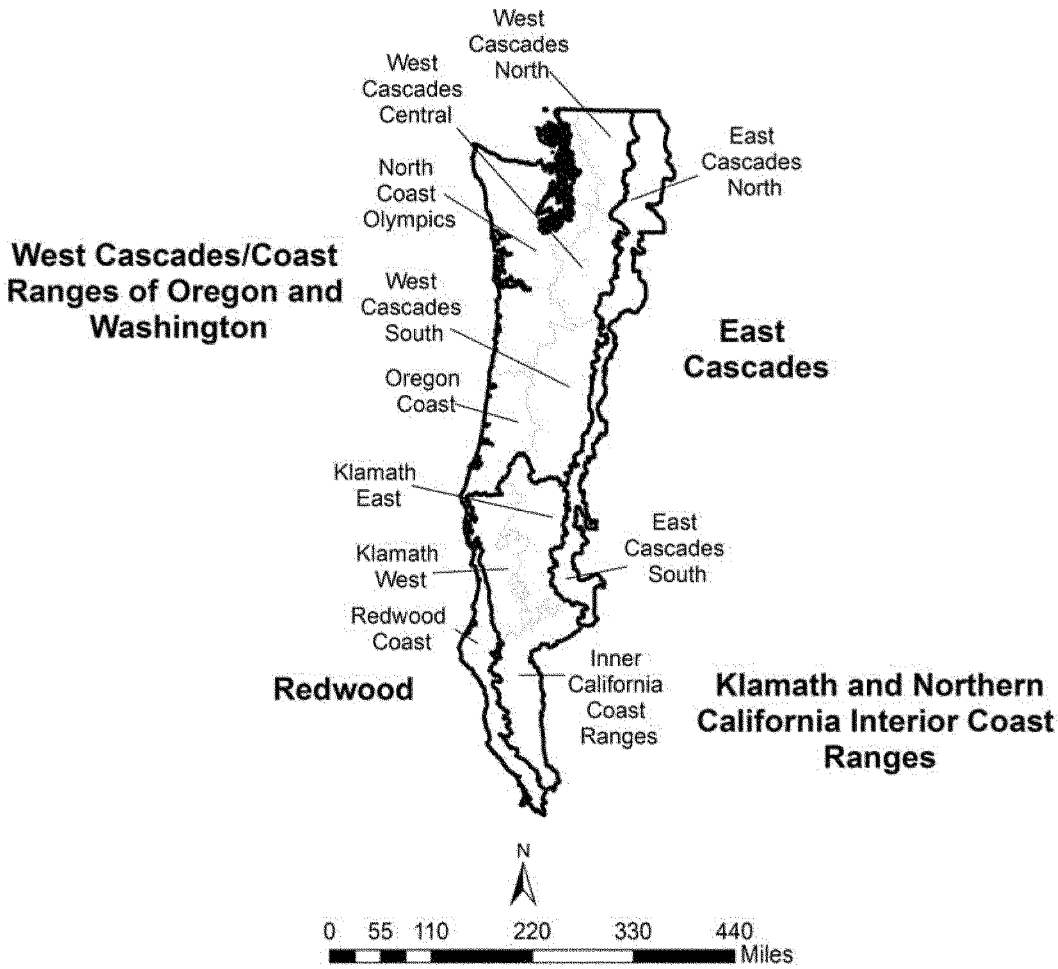
We currently do not have sufficient information to permit formal modeling of dispersal habitat and the influence of dispersal habitat condition on dispersal success (USFWS 2011, p. C–15). We expect, based on the studies discussed above, that dispersal success is highest when dispersers move through forests that have the characteristics of nesting-roosting and foraging habitats. Northern spotted owls can also disperse successfully through forests with less complex structure, but risk of starvation and predation likely increase with increasing divergence from the characteristics of suitable (nesting, roosting, foraging) habitat. The suitability of habitat to contribute to successful dispersal of northern spotted owls is likely related to the degree to which it ameliorates heat stress, provides abundant and accessible prey, limits predation risk, and resembles habitat in natal territories (Carey 1985, pp. 105–107; Buchanan 2004, pp. 1335–1341).

Dispersal habitat is habitat that both juvenile and adult northern spotted owls must use when looking to establish a new territory. Although optimal dispersal habitat would be the same as suitable nesting, roosting, or foraging habitat (mature and old-growth stands), dispersing owls will use younger forest for dispersal, and the Interagency Scientific Committee (Thomas *et al.* 1990) suggested the 50–11–40 rule for maintaining baseline forest conditions between blocks of old forest to enhance dispersal. Forests composed of at least 50 percent of trees with 11 inches (in) (28 centimeters (cm)) diameter at breast height (dbh) or greater, and with roughly a minimum 40 percent canopy cover, were considered to meet this baseline condition for northern spotted owl dispersal. Dispersal habitat can occur between larger blocks of nesting, foraging, and roosting habitat or within blocks of nesting, roosting, and foraging habitat. Dispersal habitat is essential to maintaining stable populations by promoting rapid filling of territorial vacancies when resident northern spotted owls die or leave their territories, and to providing adequate gene flow across the range of the species.

Regional Variation in Habitat Use—Differences in patterns of habitat associations across the range of the northern spotted owl suggest four different broad zones of habitat use, which we characterize as the (1) West Cascades/Coast Ranges of Oregon and Washington, (2) East Cascades, (3) Klamath and Northern California Interior Coast Ranges, and (4) Redwood Coast (Figure 1. We configured these zones based on a qualitative assessment of similarity among ecological conditions and habitat associations within the 11 different regions analyzed, as these 4 zones efficiently capture the range in variation of some of the physical or biological features essential to the conservation of the northern spotted owl. We summarize the physical or biological features for each of these four zones, emphasizing zone-specific features that are distinctive within the context of general patterns that apply across the entire range of the northern spotted owl.

BILLING CODE 4310–55–P

Figure 1. Eleven regions and four zones of habitat associations of northern spotted owls in Washington, Oregon, and California.



BILLING CODE 4310–55–C

West Cascades/Coast Ranges of Oregon and Washington

This zone includes five regions west of the Cascade crest in Washington and Oregon (Western Cascades North, Central and South; North Coast Ranges and Olympic Peninsula; and Oregon Coast Ranges; USFWS 2011, p. C–13). Climate in this zone is characterized by high rainfall and cool to moderate temperatures. Variation in elevation between valley bottoms and ridges is relatively low in the Coast Ranges, creating conditions favorable for development of contiguous forests. In contrast, the Olympic and Cascade ranges have greater topographic variation with many high-elevation areas supporting permanent snowfields and glaciers. Douglas-fir and western hemlock dominate forests used by northern spotted owls in this zone. Root diseases and wind-throw are important natural disturbance mechanisms that form gaps in forested areas. Flying squirrels are the dominant prey, with voles and mice also representing important items in the northern spotted owl's diet.

Our habitat modeling indicated that vegetation structure had a dominant influence on owl population performance, with habitat pattern and topography also contributing. High canopy cover, high density of large trees, high numbers of subcanopy vegetation layers, and low to moderate slope positions were all important features.

Nesting habitat in this zone is mostly limited to areas with large trees with defects such as mistletoe brooms, cavities, or broken tops. The subset of foraging habitat that is not nesting/roosting habitat generally had slightly lower values than nesting habitat for canopy cover, tree size and density, and canopy layering. Prey species (primarily northern flying squirrel) in this zone are associated with mature to late-successional forests, resulting in small differences between nesting, roosting, and foraging habitat.

East Cascades

This zone includes the Eastern Cascades North and Eastern Cascades South regions (USFWS 2011, p. C–13). This zone is characterized by a continental climate (cold, snowy winters and dry summers) and a high frequency of natural disturbances due to fires and outbreaks of forest insects and pathogens. Flying squirrels are the dominant prey species, but the diet of northern spotted owls in this zone also includes relatively large proportions of bushy-tailed woodrats, snowshoe hare, pika, and mice (Forsman *et al.* 2001, pp. 144–145).

Our modeling indicates that habitat associations in this zone do not show a pattern of dominant influence by one or a few variables (USFWS 2011, Appendix C). Instead, habitat association models for this zone included a large number of variables, each making a relatively modest contribution (20 percent or less) to the predictive ability of the model. The features that were most useful in predicting habitat quality were vegetation structure and composition, and topography, especially slope position in the north. Other efforts to model habitat associations in this zone have yielded similar results (e.g., Gaines *et al.* 2010, pp. 2048–2050; Loehle *et al.* 2011, pp. 25–28).

Relative to other portions of the subspecies' range, nesting and roosting habitat in this zone includes relatively younger and smaller trees, likely reflecting the common usage of dwarf mistletoe brooms (dense growths) as nesting platforms (especially in the north). Forest composition that includes high proportions of Douglas-fir is also associated with this nesting structure. Additional foraging habitat in this zone generally resembles nesting and roosting habitat, with reduced canopy cover and tree size, and reduced canopy layering. High prey diversity suggests relatively diverse foraging habitats are used. Topographic position was an important variable, particularly in the north, possibly reflecting competition from barred owls (Singleton *et al.* 2010, pp. 289, 292). Barred owls, which have been present for over 30 years in northern portions of this zone, preferentially occupy valley-bottom habitats, possibly compelling northern spotted owls to establish territories on less productive, mid-slope locations (Singleton *et al.* 2010, pp. 289, 292).

Klamath and Northern California Interior Coast Ranges

This zone includes the Klamath West, Klamath East, and Interior California Coast regions (USFWS 2011, p. C–13). This region in southwestern Oregon and northwestern California is characterized by very high climatic and vegetative diversity resulting from steep gradients of elevation, dissected topography, and large differences in moisture from west to east. Summer temperatures are high, and northern spotted owls occur at elevations up to 5,800 ft (1,768 m). Western portions of this zone support a diverse mix of mesic forest communities interspersed with drier forest types. Forests of mixed conifers and evergreen hardwoods are typical of the zone. Eastern portions of this zone have a Mediterranean climate with increased occurrence of ponderosa pine. Douglas-fir dwarf mistletoe (*Arceuthobium douglasii*) is rarely used for nesting platforms in the western part of the northern spotted owl's range, but is commonly used in the east. The prey base for northern spotted owls in this zone is correspondingly diverse, but dominated by dusky-footed woodrats, bushy-tailed woodrats, and flying squirrels. Northern spotted owls have been well studied in the western Klamath portion of this zone (Forsman *et al.* 2004, p. 217), but relatively little is known about northern spotted owl habitat use in the eastern portion and the California Interior Coast Range portion of the zone. Our habitat association models for this zone suggest that vegetation structure and topographic features are nearly equally important in influencing owl population performance, particularly in the Klamath. High canopy cover, high levels of canopy layering, and the presence of very large dominant trees were all important features of nesting and roosting habitat. Compared to other zones, additional foraging habitat for this zone showed greater divergence from nesting habitat, with much lower canopy cover and tree size. Low to intermediate slope positions were strongly favored. In the eastern Klamath, presence of Douglas-fir was an important compositional variable in our habitat model (USFWS 2011, Appendix C).

Redwood Coast

This zone is confined to the northern California coast, and is represented by the Redwood Coast region (USFWS 2011, p. C–13). It is characterized by a maritime climate with moderate temperatures and generally mesic conditions. Near the coast, frequent fog delivers consistent moisture during the summer. Terrain is typically low-lying (0 to 3,000 ft (0 to 900 m)). Forest communities are dominated by redwood, Douglas-fir–tanoak (*Lithocarpus densiflorus*) forest, coast live oak (*Quercus agrifolia*), and tanoak series. Dusky footed woodrats are the dominant prey items for northern spotted owls in this zone.

Habitat association models for this zone diverged strongly from models for other zones. Topographic variables (slope position and curvature) had a dominant influence with vegetation structure having a secondary role. Low position on slopes was strongly favored, along with concave landforms.

Several studies of northern spotted owl habitat relationships suggest that stump-sprouting and rapid growth of redwood trees, combined with high availability of woodrats in patchy, intensively managed forests, enables northern spotted owls to occupy a wide range of vegetation conditions within the redwood zone. Rapid growth rates enable young stands to develop structural characteristics typical of older stands in other regions. Thus, relatively small patches of large remnant trees can also provide nesting habitat structure in this zone.

Physical or Biological Features and Primary Constituent Elements

Under the Act and its implementing regulations, we are required to identify the physical or biological features essential to the conservation of the northern spotted owl in areas occupied at the time of listing, focusing on the features' primary constituent elements. Primary constituent elements are those specific elements of the physical or biological features that provide for a species' life-history processes and are essential to the conservation of the species. The physical or biological features essential to the conservation of the northern spotted owl are forested lands that can be used for nesting, roosting, foraging, or dispersing. We have further determined that these physical or biological features may require special management considerations or protection, as described in the section *Special Management Considerations or Protection,* below. For the northern spotted owl, the primary constituent elements are the specific characteristics that make areas suitable for nesting, roosting, foraging and dispersal habitat. To be essential to the conservation of the northern spotted owl, these features need to be distributed in a spatial configuration that is conducive to persistence of populations, survival and reproductive success of resident pairs, and survival of dispersing individuals until they can recruit into a breeding population.

Models developed for the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011, Appendix C) to assess habitat suitability for the northern spotted owl across the range of the species and applied here to help identify potential critical habitat were based on habitat conditions within 500-acre (200-ha) core areas. Because core areas support a mix of nesting, roosting, and foraging habitats, their characteristics provide a basis for identification and quantification of PCEs.

Physical or Biological Features by Life-History Function

Each of the essential features—in this case, forested lands that provide the functional categories of northern spotted owl habitat—comprises a complex interplay of structural elements, such as tree size and species, stand density, canopy diversity, and decadence.

Northern spotted owls have been shown to exhibit strong associations with specific PCEs; however, the range of combinations of PCEs that may constitute habitat (particularly foraging habitat) is broad. In addition, the relative importance of specific habitat elements (and subsequently their relevance as PCEs) is strongly influenced by physical factors, such as elevation and slope position, and the degree to which physical factors influence the role of individual PCEs varies geographically. In addition to forest type, the key elements of habitats with the physical or biological features essential for the conservation of the northern spotted owl may be organized as follows:

Nesting and Roosting Habitat

Nesting and roosting habitat provides structural features for nesting, protection from adverse weather conditions, and cover to reduce predation risks for adults and young. Because nesting habitat provides resources critical for nest site selection and breeding, its characteristics tend to be conservative; stand structures at nest sites tend to vary little across the northern spotted owl's range. Nesting stands typically include a moderate to high canopy cover (60 to over 80 percent); a multilayered, multispecies canopy with large (greater than 30 in (76 cm) dbh) overstory trees; a high incidence of large trees with various deformities (e.g., large cavities, broken tops, mistletoe infections, and other evidence of decadence); large snags; large accumulations of fallen trees and other woody debris on the ground; and sufficient open space below the canopy for northern spotted owls to fly (Thomas *et al.* 1990, p. 164; 57 FR 1798, January 15, 1992). These findings were recently reinforced in rangewide models developed by Davis and Dugger (2011, Table 3–1, p. 39), who found that stands used for nesting (moderate to high suitability) exhibited high canopy cover of conifers (65 to 89 percent), large trees (mean diameter from 20 to 36 in (51 to 91 cm)), with a forest density of 6 to 19 large trees (greater than 30 in dbh) per acre (15 to 47 large trees (greater than 76 cm dbh) per hectare), and high diameter diversity.

Recent studies have found that northern spotted owl nest stands tend to have greater tree basal area, number of canopy layers, density of broken-top trees, number or basal area of snags, and volume of logs (Courtney *et al.* 2004, pp. 5–16 to 5–19, 5–23) than non-nest stands. In some forest types, northern spotted owls nest in younger forest stands that contain structural characteristics of older forests (legacy features from previous stands before disturbance). In the portions of the northern spotted owl's range where Douglas-fir dwarf mistletoe occurs, infected trees provide an important source of nesting platforms (Buchanan *et al.* 1993, pp. 4–5). Nesting northern spotted owls consistently occupy stands having a high degree of canopy cover that may provide thermoregulatory benefits (Weathers *et al.* 2001, p. 686), allowing northern spotted owls a wider range of choices for locating thermally neutral roosts near the nest site. A high degree of canopy cover may also conceal northern spotted owls, reducing potential predation. Studies of roosting locations found that northern spotted owls tended to use stands with greater vertical canopy layering (Mills *et al.* 1993, pp. 318–319), canopy cover (King 1993, p. 45), snag diameter (Mills *et al.* 1993, pp. 318–319), diameter of large trees (Herter *et al.* 2002, pp. 437, 441), and amounts of large woody debris (Chow 2001, p. 24; reviewed in Courtney *et al.* 2004, pp. 5–14 to 5–16, 5–23). Northern spotted owls use the same habitat for both nesting and roosting; the characteristics of roosting habitat differ from those of nesting habitat only in that roosting habitat need not contain the specific structural features used for nesting (Thomas *et al.* 1990, p. 62). Aside from the presence of the nest structure, nesting and roosting habitat are generally inseparable.

Habitat modeling developed for the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011, Appendix C) and used as one means of helping us identify potential critical habitat for the northern spotted owl supports previous descriptions of nesting habitat (57 FR 1796, January 15, 1992; 73 FR 47326, August 13, 2008), and suggests a high degree of similarity among the 11 ecological regions across the range of the species. Across regions, moderate to high suitability nesting habitat was characterized as having high canopy cover (65 to over 80 percent) and high basal area (240 ft²/ac; (55 m²/ha), mean dbh of conifers at least 16.5 to 24 in (42 to 60 cm), and a significant component of larger trees (greater than 30 in (75 cm)).

Foraging Habitat

Habitats used for foraging by northern spotted owls vary widely across the northern spotted owl's range, in accordance with ecological conditions and disturbance regimes that influence vegetation structure and prey species distributions. In general, northern spotted owls select old forests for foraging in greater proportion than their availability at the landscape scale (Carey *et al.* 1992, pp. 236–237; Carey and Peeler 1995, p. 235; Forsman *et al.* 2005, pp. 372–373), but will forage in younger stands and brushy openings with high prey densities and access to prey (Carey *et al.* 1992, p. 247; Rosenberg and Anthony 1992, p. 165; Thome *et al.* 1999, pp. 56–57; Irwin *et al.* 2012, pp. 208–210). Throughout much of the owl's range, the same habitat that provides for nesting and roosting also provides for foraging, although northern spotted owls have greater flexibility in utilizing a variety of habitats for foraging than they do for nesting and roosting. That is, habitats that meet the species' needs for nesting and roosting generally also provide for foraging (and dispersal) requirements of the owl. However, in some areas owls may use other types of habitats for foraging, in addition to those used for nesting and roosting; thus, habitat that supports foraging (or dispersal) does not always support the other PCEs, and does not necessarily provide for nesting or roosting. Variation in the potential use of various foraging habitats throughout the range of the northern spotted owl is described here.

West Cascades/Coast Ranges of Oregon and Washington

In the West Cascades/Coast Ranges of Oregon and Washington, high-quality foraging habitat is also nesting/roosting habitat. Foraging activity is positively associated with tree height diversity (North *et al.* 1999, p. 524), canopy cover (Irwin *et al.* 2000, p. 180; Courtney *et al.* 2004, p. 5–15), snag volume, density of snags greater than 20 in (50 cm) dbh (North *et al.* 1999, p. 524; Irwin *et al.* 2000, pp. 179–180; Courtney *et al.* 2004, p. 5–15), density of trees greater than or equal to 31 in (80 cm) dbh (North *et al.* 1999, p. 524) density of trees 20 to 31 in (51 to 80 cm) dbh (Irwin *et al.* 2000, pp. 179–180), and volume of woody debris (Irwin *et al.* 2000, pp. 179–180).

While the majority of studies reported strong associations with old-forest characteristics, younger forests with some structural characteristics (legacy features) of old forests (Carey *et al.* 1992, pp. 245 to 247; Irwin *et al.* 2000, pp. 178 to 179), hardwood forest patches, and edges between old forest and hardwoods (Glenn *et al.* 2004, pp. 47–48) are also used by foraging northern spotted owls.

East Cascades

Foraging habitats used by northern spotted owls in the East Cascades of Oregon, Washington, and California were similar to those used in the Western Cascades, but can also encompass forest stands that exhibit somewhat lower mean tree sizes (quadratic mean diameter 16 to 22 in (40 to 55 cm) (Irwin *et al.* 2012, p. 207). However, foraging activity was still positively associated with densities of large trees (greater than 26 in (66 cm)) and increasing basal area (Irwin *et al.* 2012, p. 206). Stands dominated by Douglas-fir and white fir/Douglas-fir, or grand fir/Douglas-fir were preferred in some regions, whereas stands dominated by ponderosa pine were generally avoided (Irwin *et al.* 2012, p. 207).

Klamath and Northern California Interior Coast Ranges

Because diets of northern spotted owls in the Klamath and Northern California Interior Coast Ranges consist predominantly of both northern flying squirrels and dusky-footed woodrats, habitats used for foraging northern spotted owls are much more variable than in northern portions of the species' range. As in other regions, foraging northern spotted owls select stands with mature and old-forest characteristics such as increasing mean stand diameter and densities of trees greater than 26 in (66 cm) dbh (Irwin *et al.* 2012, p. 206) and a dominant canopy of large conifer trees greater than 21 in (52.5 cm) dbh (Solis and Gutierrez 1990, p. 747), high canopy cover (87 percent at frequently used sites; Solis and Gutierrez 1990, p. 747, Table 3), and multiple canopy layers (Solis and Gutierrez 1990, pp. 744–747; Anthony and Wagner 1999, pp. 14, 17). However, other habitat elements are disproportionately used, particularly forest patches within riparian zones of low-order streams (Solis and Gutierrez 1990, p. 747; Irwin *et al.* 2012, p. 208) and edges between conifer and hardwood forest stands (Zabel *et al.* 1995, pp. 436–437; Ward *et al.* 1998, pp. 86, 88–89). Foraging use is positively influenced by conifer species, including incense-cedar (*Calocedrus decurrens*), sugar pine (*P. lambertiana*), Douglas-fir, and hardwoods such as bigleaf maple (*Acer macrophyllum*), California black oak (*Q. kelloggii*), live oaks, and Pacific madrone (*Arbutus menziesii*) as well as shrubs (Sisco 1990, p. 20; Irwin *et al.* 2012, pp. 206–207, 209–210), presumably because they produce mast important for prey species. Within a mosaic of mature and older forest habitat, brushy openings and dense young stands or low-density forest patches also receive some use (Sisco 1990, pp. 9, 12, 14, 16; Zabel *et al.* 1993, p. 19; Irwin *et al.* 2012, pp. 209–210).

Redwood Coast

The preponderance of information regarding habitats used for foraging by northern spotted owls in the Redwood Coast zone comes from intensively managed industrial forests. In these environments, which comprise the majority of the redwood region, interspersion of foraging habitat and prey-producing habitat appears to be an important element of habitat suitability. Foraging habitat is used by owls to access prey and is characterized by a wide range of tree sizes and ages. Foraging activity by owls is positively associated with density of small to medium sized trees (10 to 22 in (25 to 56 cm)) and trees greater than 26 in (66 cm) in diameter (Irwin *et al.* 2007b, p. 19) or greater than 41 years of age (MacDonald *et al.* 2006, p. 381). Foraging was also positively associated with hardwood species, particularly tanoak (MacDonald *et al.* 2006, pp. 380–382; Irwin *et al.* 2007a, pp. 1188–1189). Prey-producing habitats occur within early-seral habitats 6 to 20 years old (Hamm and Diller 2009, p. 100, Table 2), typically resulting from clearcuts or other intensive harvest methods. Habitat elements within these openings include dense shrub and hardwood cover, and woody debris.

Nonbreeding and Dispersal Habitat

Although the term ''dispersal'' frequently refers to post-fledgling movements of juveniles, for the purposes of this rule we are using the term to include all movement during both the transience and colonization phase, and to encompass important concepts of linkage and connectivity among owl subpopulations. Population growth can only occur if there is adequate habitat in an appropriate configuration to allow for the dispersal of owls across the landscape. Although habitat that allows for dispersal may currently be marginal or unsuitable for nesting, roosting, or foraging, it provides an important linkage function among blocks of nesting habitat both locally and over the owl's range that is essential to its conservation. However, as noted above, we expect dispersal success is highest when dispersers move through forests that have the characteristics of nesting-roosting and foraging habitats. Although northern spotted owls may be able to move through forests with less complex structure, survivorship is likely decreased. Dispersal habitat, at a minimum, consists of stands with adequate tree size and canopy cover to provide protection from avian predators and at least minimal foraging opportunities; there may be variations over the owl's range (e.g., drier site in the east Cascades or northern California). This may include younger and less diverse forest stands than foraging habitat, such as even-aged, pole-sized stands, but such stands should contain some roosting structures and foraging habitat to allow for temporary resting and feeding during the transience phase.

Habitat supporting nonbreeding northern spotted owls, or the colonization phase of dispersal, is generally equivalent to nesting, roosting, and foraging habitat and is described above, although it may be in smaller amounts than that needed to support nesting pairs.

Primary Constituent Elements for the Northern Spotted Owl

Based on our current knowledge of the physical or biological features and habitat characteristics required to sustain the species' life-history processes, we determine that the primary constituent elements specific to the northern spotted owl are as follows; note that PCE 1 must occur in concert with PCE 2, 3, or 4:

(1) Forest types that may be in early-, mid-, or late-seral stages and that support the northern spotted owl across its geographical range; these forest types are primarily:

(a) Sitka spruce,
(b) Western hemlock,
(c) Mixed conifer and mixed evergreen,
(d) Grand fir,
(e) Pacific silver fir,
(f) Douglas-fir,
(g) White fir,
(h) Shasta red fir,
(i) Redwood/Douglas-fir (in coastal California and southwestern Oregon), and
(j) The moist end of the ponderosa pine coniferous forests zones at elevations up to approximately 3,000 ft (900 m) near the northern edge of the range and up to approximately 6,000 ft (1,800 m) at the southern edge.

(2) Habitat that provides for nesting and roosting. In many cases the same habitat also provides for foraging (PCE (3)). Nesting and roosting habitat provides structural features for nesting, protection from adverse weather conditions, and cover to reduce predation risks for adults and young. This PCE is found throughout the geographical range of the northern spotted owl, because stand structures at nest sites tend to vary little across the northern spotted owl's range. These habitats must provide:

(a) Sufficient foraging habitat to meet the home range needs of territorial pairs of northern spotted owls throughout the year.

(b) Stands for nesting and roosting that are generally characterized by:

(i) Moderate to high canopy cover (60 to over 80 percent);

(ii) Multilayered, multispecies canopies with large (20–30 in (51–76 cm) or greater dbh) overstory trees;

(iii) High basal area (greater than 240 ft^2/ac (55 m^2/ha));

(iv) High diversity of different diameters of trees;

(v) High incidence of large live trees with various deformities (e.g., large cavities, broken tops, mistletoe infections, and other evidence of decadence);

(vi) Large snags and large accumulations of fallen trees and other woody debris on the ground; and

(vii) Sufficient open space below the canopy for northern spotted owls to fly.

(3) Habitat that provides for foraging, which varies widely across the northern spotted owl's range, in accordance with ecological conditions and disturbance regimes that influence vegetation structure and prey species distributions. Across most of the owl's range, nesting and roosting habitat is also foraging habitat, but in some regions northern spotted owls may additionally use other habitat types for foraging as well. The foraging habitat PCEs for the four ecological zones within the geographical range of the northern spotted owl are generally the following:

(a) West Cascades/Coast Ranges of Oregon and Washington

(i) Stands of nesting and roosting habitat; additionally, owls may use younger forests with some structural characteristics (legacy features) of old forests, hardwood forest patches, and edges between old forest and hardwoods;

(ii) Moderate to high canopy cover (60 to over 80 percent);

(iii) A diversity of tree diameters and heights;

(iv) Increasing density of trees greater than or equal to 31 in (80 cm) dbh increases foraging habitat quality (especially above 12 trees per ac (30 trees per ha));

(v) Increasing density of trees 20 to 31 in (51 to 80 cm) dbh increases foraging habitat quality (especially above 24 trees per ac (60 trees per ha));

(vi) Increasing snag basal area, snag volume (the product of snag diameter, height, estimated top diameter, and including a taper function (North *et al.* 1999, p. 523)), and density of snags greater than 20 in (50 cm) dbh all contribute to increasing foraging habitat quality, especially above 4 snags per ac (10 snags per ha);

(vii) Large accumulations of fallen trees and other woody debris on the ground; and

(viii) Sufficient open space below the canopy for northern spotted owls to fly.

(b) East Cascades

(i) Stands of nesting and roosting habitat;

(ii) Stands composed of Douglas-fir and white fir/Douglas-fir mix;

(iii) Mean tree size greater than 16.5 in (42 cm) quadratic mean diameter;

(iv) Increasing density of large trees (greater than 26 in (66 cm)) and increasing basal area (the total area covered by trees measured at breast height) increases foraging habitat quality;

(v) Large accumulations of fallen trees and other woody debris on the ground; and

(vi) Sufficient open space below the canopy for northern spotted owls to fly.

(c) Klamath and Northern California Interior Coast Ranges

(i) Stands of nesting and roosting habitat; in addition, other forest types with mature and old-forest characteristics;

(ii) Presence of the conifer species, incense-cedar, sugar pine, Douglas-fir, and hardwood species such as bigleaf maple, black oak, live oaks, and madrone, as well as shrubs;

(iii) Forest patches within riparian zones of low-order streams and edges between conifer and hardwood forest stands;

(iv) Brushy openings and dense young stands or low-density forest patches within a mosaic of mature and older forest habitat;

(v) High canopy cover (87 percent at frequently used sites);

(vi) Multiple canopy layers;

(vii) Mean stand diameter greater than 21 in (52.5 cm);

(viii) Increasing mean stand diameter and densities of trees greater than 26 in (66 cm) increases foraging habitat quality;

(ix) Large accumulations of fallen trees and other woody debris on the ground; and

(x) Sufficient open space below the canopy for northern spotted owls to fly.

(d) Redwood Coast

(i) Nesting and roosting habitat; in addition, stands composed of hardwood tree species, particularly tanoak;

(ii) Early-seral habitats 6 to 20 years old with dense shrub and hardwood cover and abundant woody debris; these habitats produce prey, and must occur in conjunction with nesting, roosting, or foraging habitat;

(iii) Increasing density of small-to-medium sized trees (10 to 22 in (25 to 56 cm)) increases foraging habitat quality;

(iv) Trees greater than 26 in (66 cm) in diameter or greater than 41 years of age; and

(v) Sufficient open space below the canopy for northern spotted owls to fly.

(4) Habitat to support the transience and colonization phases of dispersal, which in all cases would optimally be composed of nesting, roosting, or foraging habitat (PCEs (2) or (3)), but which may also be composed of other forest types that occur between larger blocks of nesting, roosting, and foraging habitat. In cases where nesting, roosting, or foraging habitats are insufficient to provide for dispersing or nonbreeding owls, the specific dispersal habitat PCEs for the northern spotted owl may be provided by the following:

(a) Habitat supporting the transience phase of dispersal, which includes:

(i) Stands with adequate tree size and canopy cover to provide protection from avian predators and minimal foraging opportunities; in general this may include, but is not limited to, trees with at least 11 in (28 cm) dbh and a minimum 40 percent canopy cover; and

(ii) Younger and less diverse forest stands than foraging habitat, such as even-aged, pole-sized stands, if such stands contain some roosting structures and foraging habitat to allow for temporary resting and feeding during the transience phase.

(b) Habitat supporting the colonization phase of dispersal, which is generally equivalent to nesting, roosting, and foraging habitat as described in PCEs (2) and (3), but may be smaller in area than that needed to support nesting pairs.

This revised designation describes the physical or biological features and their primary constituent elements essential to support the life-history functions of the northern spotted owl. We have determined that all of the units and subunits designated in this rule were occupied by the northern spotted owl at the time of listing, and that (depending on the scale at which occupancy is considered) some smaller areas within the subunits may have been unoccupied at the time of listing. To address any uncertainty regarding occupancy, we have also evaluated all of the areas identified here as critical habitat under the standard of section 3(5)(a)(ii) of the Act, and determined that they are essential to the conservation of the species, as described in Criteria Used to Identify Critical Habitat, below. The criteria section also describes our evaluation of the configuration of the physical or biological features on the landscape to determine where those features are essential to the conservation of the northern spotted owl. We have further determined that the physical or biological features essential to the conservation of the northern spotted owl require special management considerations or protection, as described below.

In areas occupied at the time of listing, not all of the revised critical habitat will contain all of the PCEs, because not all life-history functions require all of the PCEs. Some subunits contain all PCEs and support multiple life processes, while some subunits may contain only those PCEs necessary to support the species' particular use of that habitat. However, all of the areas occupied at the time of listing and designated as critical habitat support at least the first PCE described (forest-type), in conjunction with at least one other PCE. Thus PCE (1) must always occur in concert with at least one additional PCE (PCE 2, 3, or 4).

Special Management Considerations or Protection

When designating critical habitat, we assess whether the specific areas within the geographical area occupied by the species at the time of listing contain features that are essential to the conservation of the species and which may require special management considerations or protection. The term critical habitat is defined in section 3(5)(A) of the Act, in part, as the specific areas within the geographical areas occupied by the species, at the time it is listed, on which are found those physical or biological features essential to the conservation of the species and ''which may require special management considerations or protection.'' Accordingly, in identifying critical habitat in areas occupied at the time of listing, we determine whether the features essential to the conservation of the species on those areas may require any special management actions or protection. Here we present a discussion of the special management considerations or protections that may be required throughout the critical habitat for the northern spotted owl. In addition, for the benefit of land managers, we provide management suggestions consistent with the recommendations of the Revised Recovery Plan for consideration.

An effective critical habitat strategy needs to conserve extant, high-quality northern spotted owl habitat in order to reverse declining population trends and address the threat from barred owls. The northern spotted owl was initially listed as a threatened species due largely to both historical and ongoing habitat loss and degradation. The recovery of the northern spotted owl therefore requires both protection of habitat and management where necessary to provide sufficient high-quality habitat to allow for population growth and to provide a buffer against threats such as competition with the barred owl. Recovery Criterion 3 in the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011) is the ''Continued Maintenance and Recruitment of Northern Spotted Owl Habitat,'' which is further described as the achievement of a stable or increasing trend in northern spotted owl nesting, roosting, and foraging habitat throughout the range of the species. Meeting this recovery criterion will require special management considerations or protection of the physical or biological features essential to the conservation of the northern spotted owl in all of the critical habitat units and subunits, as described here. Special management includes both passive and active management.

The 2011 Revised Recovery Plan for the Northern Spotted Owl describes the three main threats to the northern spotted owl as competition from barred owls, past habitat loss, and current habitat loss (USFWS 2011, p. III–42). As the barred owl is present throughout the range of the northern spotted owl, special management considerations or protections may be required in all of the critical habitat units and subunits to ensure the northern spotted owl has sufficient habitat available to withstand competitive pressure from the barred owl (Dugger *et al.* 2011, pp. 2459, 2467). In particular, studies by Dugger *et al.* (2011, p. 2459) and Wiens (2012, entire) indicated that northern spotted owl demographic performance is better when additional high-quality habitat is available in areas where barred owls are present.

Scientific peer reviewers of the 2011 Revised Recovery Plan for the Northern Spotted Owl (USFSW 2011, entire) and Forsman *et al.* (2011, p. 77) recommended that we address currently observed downward demographic trends in northern spotted owl populations by protecting currently occupied sites, as well as historically occupied sites, and by maintaining and restoring older and more structurally complex multilayered conifer forests on all lands (USFWS 2011, pp. III–42 to III–43). The types of management or protections that may be required to achieve these goals and maintain the physical or biological features essential to the conservation of the owl in occupied areas vary across the range of the species. Some areas of northern spotted owl habitat, particularly in wetter forest types, are unlikely to be enhanced by active management activities, but instead need protection of the essential features; whereas other forest areas would likely benefit from more proactive forestry management. For example, in drier, more fire-prone regions of the owl's range, habitat conditions will likely be more dynamic, and more active management may be required to reduce the risk to the essential physical or biological features from fire, insects, disease, and climate change, as well as to promote regeneration following disturbance.

While we recommend conservation of high-quality and occupied northern spotted owl habitat, long-term northern spotted owl recovery could benefit from forest management where the basic goals are to restore or maintain ecological processes and resilience, as discussed in detail in the Revised Recovery Plan (USFWS 2011, pp. III–11 to III–39). Special management considerations or protections may be required throughout the critical habitat to achieve these goals and benefit the conservation of the owl. The natural ecological processes and landscape that once provided large areas of relatively contiguous northern spotted owl habitat (especially on the west side of the Cascade Range) have been altered by a history of anthropogenic activities, such as timber harvest, road construction, development, agricultural conversion, and fire suppression. The resilience of these systems is now additionally challenged by the effects of climate change. As recommended in the Revised Recovery Plan for the Northern Spotted Owl, active forest management may be required throughout the range of the owl with the goal of maintaining or restoring forest ecosystem structure, composition, and processes so they are sustainable and resilient under current and future climate conditions, to provide for the long-term conservation of the species (USFWS 2011, p. III–13). For example, in some areas, past management practices have decreased age-class diversity and altered the structure of forest patches; in these areas, management, such as targeted vegetation treatments, could simultaneously reduce fuel loads and increase canopy and age-class diversity (Miller *et al.* 2009, p. 30; Stephens *et al.* 2009, p. 316–318; Stephens *et al.* 2012b, p. 554; Fontaine and Kennedy 2012, p. 1559; Chmura *et al.* 2011, p. 1134; USFWS 2011, p. III–18).

In moist forests that are currently providing mature and late-successional forest that functions as habitat for northern spotted owls, active management is generally unnecessary to conserve older growth forests (Johnson and Franklin 2009, p. 3). Within younger, homogeneous stands, active management that retains larger and older trees but reduces density of smaller trees may be useful to accelerate development of within-stand structural diversity. Management insights, such as those provided by Aubry *et al.* (2009, entire), Johnson and Franklin (2009, entire), Johnson and Franklin (2012 entire), Kerr 2012, entire), and Spies *et al.* (2010, entire), provide examples of how such actions could occur in a manner consistent with northern spotted owl conservation in moist forests.

In dry forest regions, where natural disturbance regimes and vegetation structure, composition, and distribution have been substantially altered since Euro-American settlement, vegetation and fuels management (through influencing fire behavior, severity, and distribution) may be required to retain and recruit northern spotted owl habitat on the landscape (Buchanan 2009, pp. 114–115; Healey *et al.* 2008, pp. 1117–1118; Roloff *et al.* 2012, pp. 8–9; Ager *et al.* 2007, pp. 53–55; Ager *et al.* 2012, pp. 279–282; Franklin *et al.* 2009, p. 46; Kennedy and Wimberly 2009, pp. 564–565), to conserve other biodiversity (Perry *et al.* 2011, p. 715), and to restore more natural vegetation and disturbance regimes and heterogeneity (e.g., Stephens *et al.* 2012b, pp. 557–558). Special management considerations may be required to maintain adequate northern spotted owl habitat in the near term, not only to allow northern spotted owls to persist in the face of threats from barred owl expansion and habitat modifications from fire and other disturbances, but also to restore landscapes to a more resilient state in the face of alterations projected to occur with ongoing climate change (USFWS 2011, p. III–32).

If land managers are actively managing forests, we recommend that these activities be focused on lower quality owl habitat (lower relative habitat sustainability (RHS)); that these activities focus on ecological restoration, or apply principles of ecological forestry; and, where possible, evaluate the effects of these treatments on northern spotted owls and other species of concern using an active adaptive forest management framework.

We recognize that the only regulatory effect of the designation of critical habitat is that section 7(a)(2) of the Act applies, and that it does not require active management or mandate any specific type of management; it only requires that Federal agencies ensure that their actions are not likely to destroy or adversely modify critical habitat, as those terms are used in section 7. However, because the Act requires us to make a determination that the physical and biological features essential to conservation of the species may also need special management considerations or protection, we are taking this opportunity to describe, for consideration by land managers, specific management approaches and types of forest where land managers should consider applying them in order to maintain sufficient suitable habitat across the range of the owl. We have determined that the physical and biological features in habitat occupied by the species at the time it was listed, as represented by the primary constituent elements, may require special management considerations or protection as required by 16 U.S.C. 1532(5)(A). However, nothing in this rule requires land managers to implement, or precludes land managers from implementing, special management or protection measures.

Because these will vary geographically, here we provide a more detailed discussion of the types of management considerations or protections that may be required to preserve or enhance the essential physical or biological features for the northern spotted owl in the West Cascades/Coast Ranges of Oregon and Washington, East Cascades, Klamath and Northern California Interior Coast Ranges, and the Redwood Coast.

West Cascades/Coast Ranges of Oregon and Washington

Special management considerations or protection may be required in areas of moist forests to conserve or protect older stands that contain the conditions to support northern spotted owl occupancy (RA10: USFWS 2011, p. 43) or contain high-value northern spotted owl habitat (RA32: USFWS 2011, p. 67). Silvicultural treatments are generally not needed to maintain existing old-growth forests and high-quality habitat on moist sites (Wimberly *et al.* 2004, p. 155; Johnson and Franklin 2009, pp. 3, 39). In contrast to dry forests, short-term fire risk is generally lower in the moist forests that not only dominate on the west side of the Cascade Range, but also occur east of the Cascades as a higher-elevation band or as peninsulas or inclusions in mesic forests. Disturbance-based management for forests and northern spotted owls in moist forest areas should be different from that applied in dry forests. Efforts to alter either fuel loading or potential fire behavior in these sites could have undesirable ecological consequences as well (Johnson and Franklin 2009, p. 39; Mitchell *et al.* 2009, pp. 653–654; USFWS 2011, p. III–17). Furthermore, commercial thinning has been shown to have negative consequences for northern spotted owls (Forsman *et al.* 1984, Meiman *et al.* 2003) and their prey (Waters *et al.* 1994, Luoma *et al.* 2003, Wilson 2010). Active management may be more appropriate in younger plantations that are not currently on a trajectory to develop old-growth structure. These stands typically do not provide high-quality northern spotted owl habitat, although they may occasionally be used for foraging and dispersal.

In general, to advance long-term northern spotted owl recovery and ecosystem restoration in moist forests in the face of climate change and past management practices, special management considerations or protections may be required that follow these principles as recommended in the 2011 Revised Recovery Plan (USFWS 2011, p. III–18):

(1) Conserve older stands that contain the conditions to support northern spotted owl occupancy or high-value northern spotted owl habitat as described in Recovery Actions 10 and 32 (USFWS 2011, pp. III–43, III–67). On Federal lands this recommendation applies to all land-use allocations (see also Thomas *et al.* 2006, pp. 284–285).

(2) Management emphasis needs to be placed on meeting northern spotted owl recovery goals and long-term ecosystem restoration and conservation. When there is a conflict between these goals, actions that would disturb or remove the essential physical or biological features of northern spotted owl critical habitat need to be minimized and reconciled with long-term ecosystem restoration goals.

(3) Continue to manage for large, continuous blocks of late-successional forest.

(4) In areas that are not currently late-seral forest or high-value habitat and where more traditional forest management might be conducted (e.g. matrix), these activities should consider applying ecological forestry prescriptions. Some examples that could be utilized include Franklin *et al.* (2002, pp. 417–421; 2007, entire), Kerr (2012), Drever *et al.* (2006, entire), Johnson and Franklin (2009, pp. 39–41), Swanson *et al.* (2010, entire), and others cited in the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011, pp. III–14, III–17 to III–19).

These special management considerations or protections apply to Units 1, 2, 4, 5 and 6 of the revised critical habitat.

East Cascades

Special management considerations or protection may be required in the East Cascades to address the effects of past activities associated with Euro-American settlement, such as timber harvest, livestock grazing, fire suppression, and fire exclusion, that have substantially altered the inland northwest, modifying the patterns of vegetation and fuels, and subsequent disturbance regimes to the degree that contemporary landscapes no longer function as they did historically (Hessburg *et al.* 2000a, pp. 74–81; Hessburg and Agee 2003, pp. 44–46; Hessburg *et al.* 2005, pp. 134–135; Skinner *et al.* 2006, pp. 178–179; Skinner and Taylor 2006, pp. 201–203; Miller *et al.* 2009, p. 30; Stephens *et al.* 2009, pp. 316–318; Stephens *et al.* 2012b, p. 554; Fontaine and Kennedy 2012, p. 1559; Chmura *et al.* 2011, p. 1134). This has affected not only the existing forest and disturbance regimes, but the quality, amount, and distribution of northern spotted owl habitat on the landscape (Buchanan 2009, pp. 114–115; Healey *et al.* 2008, pp. 1117–1118; Roloff *et al.* 2012, pp. 8–9; Ager *et al.* 2007, pp. 53–55; Ager *et al.* 2012, pp. 279–282; Franklin *et al.* 2009, p. 46; Kennedy and Wimberly 2009, pp. 564–565). In order to preserve the essential physical or biological features, these dynamic, disturbance-prone forests should be managed in a way that promotes northern spotted owl conservation, responds to climate change, and restores dry forest ecological structure, composition and processes, including wildfire and other disturbances (USFWS 2011, p. III–20). The following restoration principles apply to the management that may be required in this dry forest region (USFWS 2011, pp. III–34 to III–35):

(1) Conserve older stands that contain the conditions to support northern spotted owl occupancy or high-value northern spotted owl habitat as described in Recovery Actions 10 and 32 (USFWS 2011, pp. III–43, III–67). On Federal lands this recommendation applies to all land-use allocations (see also Thomas *et al.* 2006, pp. 284–285).

(2) Emphasize vegetation management treatments outside of northern spotted owl territories or highly suitable habitat;

(3) Design and implement restoration treatments at the landscape level;

(4) Retain and restore key structural components, including large and old trees, large snags, and downed logs;

(5) Retain and restore heterogeneity within stands;

(6) Retain and restore heterogeneity among stands;

(7) Manage roads to address fire risk; and

(8) Consider vegetation management objectives when managing wildfires, where appropriate.

The above principles will result in treatments that have a variety of effects on northern spotted owl habitat in the short and long term. For example, some restoration treatments may have an immediate neutral or beneficial effect on existing northern spotted owl habitat (e.g., roads management, some prescribed fire prescriptions). Other treatments, however, may involve reductions in stand densities, canopy cover, or ladder fuels (understory vegetation that has the potential to carry up into a crown fire)—and thus affect the physical or biological features needed by the species. At the stand scale, this can result in a level of conflict between conserving existing northern spotted owl habitat and restoring dry-forest ecosystems. Resolution of such conflicts can be enhanced by considering the range of forest conditions that comprise suitable owl habitat and tailoring management accordingly.

Land managers should change from the practice of implementing many small, uncoordinated and independent fuel-reduction and restoration treatments. Instead, coordinated and strategic efforts that link individual projects to the larger objectives of restoring landscapes while conserving and recovering northern spotted owl habitat are needed (sensu Sisk *et al.* 2005, entire; Prather *et al.* 2008, entire; Gaines *et al.* 2010, entire). Some examples of this type of planning in the east Cascades that may be emulated or referenced include the Okanagon-Wenatchee National Forest (USDA 2010, entire), The Nature Conservancy (Davis *et al.* 2012, entire), and the Deschutes National Forest (Smith *et al.* 2011, entire).

The special management considerations or protections identified here apply to Units 7 and 8 of the revised critical habitat.

Klamath and Northern California Interior Coast Ranges

The special management considerations or protections that may be required in the Klamath and Northern California Interior Coast Ranges represent a mix of the requirements needed to maintain or enhance the essential physical or biological features in mesic and dry forest types. This region in southwestern Oregon and northwestern California is characterized by very high climatic and vegetative diversity resulting from steep gradients of elevation, dissected topography, and large differences in moisture from west to east. Summer temperatures are high, and northern spotted owls occur at elevations up to 1,768 m (5,800 ft). Western portions of this zone support a diverse mix of mesic forest communities interspersed with drier forest types. Forests of mixed conifers and evergreen hardwoods are typical of the zone. Eastern portions of this zone have a Mediterranean climate with increased occurrence of ponderosa pine. Douglas-fir dwarf mistletoe is rarely used for nesting platforms in the west, but commonly used in the east. The prey base for northern spotted owls in this zone is correspondingly diverse, but is dominated by dusky-footed woodrats, bushy-tailed woodrats, and flying squirrels. Northern spotted owls have been well studied in the western portion of this zone (Forsman *et al.* 2005, p. 219), but relatively little is known about northern spotted owl habitat use in the eastern portion and the California Interior Coast Range portion of the zone.

High canopy cover, high levels of canopy layering, and the presence of very large dominant trees were all important features of nesting and roosting habitat. Compared to other zones, models of foraging habitat for this zone showed greater divergence from nesting habitat. Low to intermediate slope positions were strongly favored. In the eastern Klamath, presence of Douglas-fir was an important compositional variable. Habitat associations in the Klamath zone are diverse and unique, reflecting the climate, topography, and vegetation of this area. Nesting and roosting habitat somewhat resembles that of other zones, with a greater emphasis on topography that provides some relief from high temperatures while foraging habitat in this zone includes more open forests. Consequently, management actions consistent with maintaining and developing northern spotted owl habitat need to consider local conditions. In some areas, appropriate management will be more consistent with dry forest management strategies, while in other areas wet forest management strategies will be more appropriate.

This region contains habitat characteristics of both moist and dry forests interspersed across a highly diverse landscape (Halofsky *et al.* 2011, p. 1). The special management recommendations from the moist and dry forest sections, above, apply to the management actions or protections that may be required in the Klamath and Northern California Interior Coast Ranges. Similar to the discussion in moist forests concerning conservation of small patches of early-seral habitat, Perry *et al.* (2011, p. 715) noted that replacement of early successional shrub-hardwood communities by closed forests in the absence of fire significantly impacts landscape diversity. Restoration of appropriate fire regimes and use of targeted silvicultural intervention may be effective where the goal is to restore or maintain this diversity (Halofsky *et al.* 2011, p. 15). An example of this type of planning in this area that may be emulated or referenced is the Ashland Forest Resiliency Project (USDA 2009, entire).

The special management considerations or protections identified here apply to Units 9, 10, and 11 of the revised critical habitat.

Redwood Coast

Special management considerations or protection may be needed in the Redwood Coast Zone to maintain or enhance the essential physical or biological features for the owl. Although the Redwood Coast zone of coastal northern California is considered part of the wet/moist forest region within the range of the northern spotted owl, there are distinct differences in northern spotted owl habitat use and diet within this zone. The long growing season in this region, combined with redwood's ability to resprout from stumps, allows redwood stands to attain suitable stand structure for nesting in a relatively short period of time (40–60 years) if legacy structures are present. Late-successional forest is an important component of nesting and roosting habitat in the Redwood Zone, and demographic productivity on northern spotted owl breeding sites has been positively correlated with the density of legacy trees in proximity to owl nest sites (Thome *et al.* 1999, p. 57). Forest management in this region should conserve older stands that contain the conditions to support northern spotted owl occupancy or high-value northern spotted owl habitat as described in Recovery Actions 10 and 32 (USFWS 2011, pp. III–43, III–67). On Federal lands this recommendation applies to all land-use allocations (see also Thomas *et al.* 2006, pp. 284–285). In this region, some degree of fine-scale fragmentation in redwood forests appears to benefit northern spotted owls. Forest openings aged 5 to 20 years (e.g., harvest units or burns), with dense shrub and hardwood cover, and abundant food sources, can provide high-quality habitat for the northern spotted owl's primary prey, the dusky-footed woodrat. Woodrat populations within recent openings probably peak by about stand age 10. Food sources and understory cover decline steadily through about stand age 20, when the woodrat population-source diminishes. In northern spotted owl territories within the Redwood Zone, active management that creates small openings in proximity to nesting, roosting, or foraging habitat may enhance northern spotted owl foraging opportunities.

The special management considerations or protections identified here apply to Unit 3 of the revised critical habitat.

Summary of Special Management Considerations or Protection

We find that each of the areas occupied at the time of listing that we are designating as critical habitat contains features essential to the conservation of the species that may require special management considerations or protection to ensure the conservation of the northern spotted owl. These special management considerations or protection may be required to preserve and enhance the essential features needed to achieve the conservation of the northern spotted owl. Additional information on management activities compatible with northern spotted owl conservation can be found within the Section 7 Consultation section of this preamble.

VII. Criteria Used To Identify Critical Habitat

As required by section 4(b)(1)(A) of the Act, we use the best scientific and commercial data available to designate critical habitat. We have reviewed the available information pertaining to the habitat requirements of the species. In accordance with the Act and its implementing regulations at 50 CFR 424.12(e), based on this review, we have identified the specific areas within the geographical area occupied by the species at the time it was listed on which are found those physical or biological features essential to the conservation of the species, and which may require special management considerations or protection. In addition, we considered whether any additional areas outside those occupied at the time of listing are essential for the conservation of the species.

Occupied Areas

For the purpose of developing and evaluating this revised critical habitat designation for the northern spotted owl, we identified ''geographical area occupied by the species'' at the time it was listed consistent with the species' distribution, population ecology, and use of space. We based our identification of occupied geographical areas on: (1) The distribution of verified northern spotted owl locations at the time of listing and (2) scientific information regarding northern spotted owl population structure and habitat associations.

We determined the geographical area occupied by the species at the time of listing based in part on a habitat suitability model incorporating the distribution of approximately 4,000 known northern spotted owl territories across the geographical range of the species (USFWS 2011, Appendix C). We used this model rather than just relying on surveyed sites at that time because large areas within the species' geographical range had not been surveyed; therefore the distribution of northern spotted owl populations was incompletely known at the time the species was listed, and remains so today. For this reason, designating critical habitat based solely on the locations of territories identified through surveys would exclude a substantial proportion of the area that would have been occupied by the species at the time of listing, and that provides the physical or biological features essential to the conservation of the species. To address this, we used our descriptions of the physical and biological features to develop a habitat suitability model that enabled us to map the distribution of relative habitat suitability and reliably identify areas that would have supported northern spotted owl territories at the time of listing, based on habitat value (USFWS 2011, Appendix C). Our habitat suitability model was based on GNN (Gradient Nearest Neighbor) vegetation data from 1996, and the locations of approximately 4,000 known owl pairs documented within 3 years of the date of the GNN vegetation data (USFWS 2011, p. C–20). Because our evaluations of model performance demonstrated that the models had good predictive ability (USFWS 2011, Appendix C, p. C–38–42) we used the relative habitat suitability models to predict the distribution of areas that would have supported occupancy by spotted owls at the time of listing.

Because the best available habitat and owl location data and information corresponded to 1996, we made an explicit assumption that the 1996-based habitat suitability model would reliably predict the distribution of spotted owls at the time of listing (1990). This assumption was based on: (1) Our expectation that patterns of habitat selection by spotted owls would not change over a 6-year period; (2) the high degree of site fidelity exhibited by territorial spotted owls over many years; and (3) the fact that the amount and distribution of older forest habitat, which takes many decades to develop and is a primary component of northern spotted owl habitat, would not have increased significantly in the period between listing and 1996. Therefore, we concluded that the 1996 GNN layer is a reasonable representation of the habitat that would have been occupied by northern spotted owls at the time of listing.

We tested this assumption by analyzing the relationship between our 1996 habitat suitability map and the distribution of 3,723 spotted owl sites known to be occupied at the time of listing (1987–1996). This time period reasonably represents the time of listing because northern spotted owls are relatively long-lived and exhibit a high degree of fidelity to territory core areas; their territory locations are, therefore, relatively stable through time, unless substantial changes occur to territory habitat. For this reason, we consider it highly likely that locations occupied between 1987 and 1990, and 1990 and 1996 were also occupied at the time of listing in 1990. We found that over 85 percent of the proposed critical habitat area was within the estimated home ranges of known spotted owl sites, strongly supporting our assumption that the model reliably predicted areas were occupied at the time of listing.

However, restricting a definition of occupancy to areas known to be used by resident territorial owls overlooks a large segment of the owl population that is not generally reflected in standard survey methodologies, as described below. Northern spotted owl populations consist of the territorial, resident owls, for which we have documentation of occupancy throughout much of the owl's range, described above, but also include nonterritorial adult ''floaters'' and dispersing subadult owls. Both dispersing subadults and nonterritorial floaters are consistently present on the landscape and require suitable habitat to support dispersal and survival until they recruit into the breeding population; this habitat requirement is in addition to that already utilized by resident territorial owls. Nonterritorial owls are difficult to detect in surveys because most surveys rely on territorial defense behavior of resident owls (responding to artificial owl calls) to determine their presence. Because they are difficult to detect, the number and distribution of nonterritorial and dispersing owls is poorly known for any given northern spotted owl population. However, they constitute essential elements of northern spotted owl populations, and can reliably be assumed to occur in suitable habitat within the same landscapes occupied by territorial owls. As stated, the great majority (85 percent) of the area within the identified critical habitat is covered by the home ranges of known owl territories at the time of listing. Because it is well established that dispersing subadults and non-territorial northern spotted owls regularly occupy high-quality habitat in the vicinity of other territorial northern spotted owls, and because our relative habitat suitability models exhibited high accuracy at predicting the probability of presence by owls, we conclude that these areas of high-quality habitat were occupied by the species at the time of listing.

Therefore, based on the best available scientific information regarding population structure of northern spotted owls, ''occupied at the time of listing'' encompasses (1) home ranges of resident, territorial northern spotted owls known from surveys to be present at the time of listing, (2) home ranges of territorial owls that would have been present at the time of listing based on a model developed specifically to predict owl presence based on relative habitat suitability, and (3) areas used by nonterritorial and dispersing owls that were likely to be present within the matrix of territories in a given landscape known to be occupied by resident owl pairs.

Having determined our working definition of the term ''occupied,'' in this instance, we then characterized ''specific areas'' as used in the definition of critical habitat in section 3(5)(A) of the Act, to conform with known patterns of space-use and distribution exhibited by northern spotted owls. Northern spotted owls are wide-ranging organisms that maintain large home ranges and disperse relatively long distances. Home ranges are used regularly by territorial owls for foraging, raising young, and other activities, and are actively defended by the resident pair year-round; as such, we consider these home ranges to be continually occupied by the species. Although much activity is centered on core areas within the home ranges, northern spotted owls are dependent upon the entirety of the home range for prey resources and use it on a regular basis throughout the year. As described earlier, territorial northern spotted owls cover home ranges from roughly 1,400 ac (570 ha) at the southern end of their range (Zabel *et al.* 1995, p. 436) up to over 14,000 ac (5,700 ha) (USDI 1992, p. 23; USFWS 1994 in litt., p. 1) in the northern portion of the species' range. These large home ranges may overlap with those of neighboring northern spotted owls, such that large landscapes may be fully occupied by population clusters in areas where suitable habitat is well distributed. Some demographic study areas still exhibit this pattern over large landscapes today, although overlapping home ranges were more the case when the northern spotted owl was first listed, prior to extensive colonization of the species' range by the barred owl.

To conservatively evaluate the proportion of each subunit that was composed of areas known to be occupied by northern spotted owls at the time of listing, we calculated the area within estimated home ranges (USFWS 2011, p. C–63 Table C–24) for all verified northern spotted owl locations known at the time of listing, as described above. Overall, 85 percent of the area designated is within estimated home ranges of verified territorial northern spotted owls located through surveys at the time of listing; this area is entirely representative of verified owl locations, and does not include habitat occupied based on habitat suitability or nonresident owls. Twenty-two (37 percent) of the 60 subunits have at least 90 percent of their area within verified known home ranges; 41 (68 percent) have at least 70 percent. As explained above, given that these areas represent occupancy by verified resident owls only, and considering the suitable habitat available at the time of listing in these same landscapes, we conclude that the remainder of these areas was occupied by other resident owls that simply were not within surveyed areas, nonterritorial adult owls (floaters), or dispersing subadults.

To help us identify and map potential critical habitat for the owl, we used a three-step modeling framework developed as part of the Revised Recovery Plan that integrates a northern spotted owl habitat model, a habitat conservation planning model, and a population simulation model. The details of this modeling framework are presented in Appendix C of the Revised Recovery Plan (USFWS 2011), and a detailed technical description of the modeling and habitat network evaluation process we used in this revised designation of critical habitat is provided in Dunk *et al.* (2012b, entire). Both of these supporting documents are available at *http://www.regulations.gov* (see **ADDRESSES**), or by contacting the

Oregon Fish and Wildlife Office (see **FOR FURTHER INFORMATION CONTACT**).

The overall approach for critical habitat modeling consisted of three main steps (USFWS 2011, Appendix C, p. C–3) to help refine, select, and evaluate a series of alternative critical habitat networks for the northern spotted owl. Each of these steps helped us to identify a critical habitat network that meets the statutory definition of critical habitat, namely, the distribution of the physical or biological features needed by the species across its geographical range occupied at the time of listing, and the identification of a landscape configuration where these features, as well as any necessary unoccupied areas, are essential to the conservation of the species. These steps are summarized here, and then each is described in further detail.

Step 1: At the outset, the attributes of forest composition and structure and characteristics of the physical environment associated with nesting, roosting, and foraging habitat—physical or biological features used by the species—were identified based on published research, input from individual experts, and analysis of northern spotted owl location and habitat data from nearly 4,000 known owl pairs (USFWS 2011, pp. C–20 to C–28). We then used these physical or biological features of nesting, roosting, and foraging habitats to create a rangewide map of relative habitat suitability using the model MaxEnt (Phillips *et al.* 2006, entire; Phillips and Dudik 2008, entire), based on the habitat selection exhibited by these known owl pairs. In addition to providing a map of relative habitat suitability, this process allowed us to evaluate an area's suitability and determine whether the presence of the species was likely based on an assessment of known species-habitat relationships.

Step 2: We developed northern spotted owl habitat networks based on the relative habitat suitability map using the Zonation conservation planning model (Moilanen and Kujala 2008, entire). The Zonation model used a hierarchical prioritization of the landscape based on relative habitat suitability and other user-specified criteria (e.g., land ownership) to develop the most efficient solutions for incorporating high-value habitat. Zonation analyses were conducted separately for each region to ensure that reserves would be well-distributed across the range of the owl. Zonation also allowed for consideration of land ownership in development of reserve designs.

Step 3: In the last step, we determined where the physical or biological features, as well as unoccupied areas, are essential to the conservation of the species. To do this we used a spatially explicit northern spotted owl population model (HexSim) (Schumaker 2008, entire) to predict relative responses of northern spotted owl populations to different habitat network designs, and evaluated these responses against the recovery objectives and criteria for the northern spotted owl using a rule set based on those criteria. Simulations from these models are not meant to be estimates of what will occur in the future, but rather provide information on trends predicted to occur under different network designs; this allowed us to compare the relative performance of various critical habitat scenarios.

In Step 1 of the modeling framework, we used published research, input from individual experts, and analysis of northern spotted owl location and habitat data to develop models of relative habitat suitability for northern spotted owls. These relative habitat suitability models identify areas with habitat that provides the combination of variables (forest composition and structure, and abiotic factors such as elevation, precipitation, and temperature) with a high predictive probability of supporting northern spotted owls, based on data gathered from known owl sites. Based on the physical or biological features of nesting, roosting, and foraging habitats known to be utilized by resident owls, we used these models to identify areas containing those physical or biological features required by the owl, and to map their distribution across the range of the owl (USFWS 2011, pp. C–27 to C–42, C–62). Because the models are based in large part on data from nearly 4,000 owl sites (USFWS 2011, p. C–62), model outputs highlight surveyed and verified owl home ranges. However, they also identify areas with habitat that supported territorial and non-territorial owls at the time of listing, based on habitat suitability, and areas that may have been unoccupied at the time of listing, but that may be essential for the conservation of the species based on their relative habitat suitability as well as the habitat characteristics needed for population growth or dispersal (see below). To ensure that the variety of physical or biological features used by northern spotted owls across their range is represented in the models, we applied separate habitat models for each of 11 ecological regions, based on differences in forest environments, northern spotted owl habitat use and prey distribution, and variation in ecological conditions (USFWS 2011, C–7 to C–13).

In Step 2 of the modeling framework, we used a habitat conservation planning model (Zonation) (Moilanen *et al.* 2005, entire; Moilanen and Kujala 2008, entire) to develop a northern spotted owl conservation planning model. We used this in the critical habitat process to aggregate areas of greatest relative habitat suitability (areas occupied at the time of listing that provide the physical or biological features, or areas of habitat that may have been unoccupied at the time of listing, but have the potential to play an essential conservation role, for example, in providing connectivity between isolated populations) from Step 1 into discrete units. This process provided a series of maps representing a range of alternative critical habitat networks, each containing a different amount and distribution of northern spotted owl habitat quality (representing differing amounts and configurations of the primary constituent elements). The Zonation model seeks to provide the most efficient design (most habitat value on smallest land area) and allowed us to maximize reliance on public lands to provide what is essential to northern spotted owl conservation.

In Step 3 of the modeling framework, we developed a northern spotted owl population simulation model that allowed us to simulate the relative population responses of northern spotted owls to various habitat conservation network scenarios (HexSim) (Schumaker 2011, entire). In developing this rule, we used this northern spotted owl population simulation model to compare alternative critical habitat networks and evaluate each design's ability to meet the recovery goals and criteria for the northern spotted owl (described further below, and in detail in Dunk *et al.* 2012b). This step of the process enabled us to determine the amount and configuration of physical or biological features on the landscape that are essential to the conservation of the owl, as well as to determine those unoccupied areas essential for the conservation of the species. By evaluating northern spotted owl population metrics, such as relative population size, population trend, and extinction risk that resulted from each scenario evaluated, we are designating the most efficient habitat network necessary to conserve the northern spotted owl (efficient, as noted above, in terms of balancing greatest conservation value for the owl in proportion to acres designated). This network has the potential to support an increasing or stable population trend of northern spotted owls, exhibits relatively low extinction risk, both rangewide and at the recovery unit scale (recovery units, as identified in the Revised Recovery Plan for the Northern Spotted Owl, are defined by physiographic provinces (USFWS 2011, pp. III–1 to III–2)), and achieves adequate connectivity among recovery units, while prioritizing reliance on public lands.

We determined what is essential to recovery of the northern spotted owl by evaluating the performance of each potential critical habitat scenario considered against the recovery needs of the owl. In contrast with earlier conservation modeling efforts for the northern spotted owl, the modeling framework we utilized does not rely on *a priori* (predefined) rule sets for features such as size of habitat blocks, number of owl pairs per block, or distance between blocks (USFWS 2011, p. C–4) to determine what is essential for the conservation of the species. Instead, we evaluated northern spotted owl population metrics such as relative population size and trend to determine what is essential to owl conservation, both in terms of where and how much of the physical or biological features are essential and how much unoccupied habitat is essential to meet the recovery objectives for the owl, as defined in the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011, p. ix) and detailed in our supporting documentation (Dunk *et al.* 2012b, entire).

To accomplish this, we developed a rule set for the identification of critical habitat based on the ability of that habitat to meet the recovery objectives and criteria set forth in the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011, p. ix). The recovery objectives for the northern spotted owl are:

(1) Northern spotted owl populations are sufficiently large and distributed such that the species no longer requires listing under the Act;

(2) Adequate habitat is available for northern spotted owls and will continue to exist to allow the species to persist without the protection of the Act; and

(3) The effects of threats have been reduced or eliminated such that northern spotted owl populations are stable or increasing and northern spotted owls are unlikely to become threatened again in the foreseeable future.

The recovery criteria for the northern spotted owl (aside from the requirement for post-delisting monitoring) are:

Recovery Criterion 1—Stable Population Trend: The overall population trend of northern spotted owls throughout the range is stable or increasing over 10 years, as measured by a statistically reliable monitoring effort.

Recovery Criterion 2—Adequate Population Distribution: Northern spotted owl subpopulations within each province (i.e., recovery unit), excluding the Willamette Valley Province, achieve viability, as informed by the HexSim population model or some other appropriate quantitative measure.

Recovery Criterion 3—Continued Maintenance and Recruitment of Northern Spotted Owl Habitat: The future range-wide trend in northern spotted owl nesting/roosting and foraging habitat is stable or increasing throughout the range, from the date of Revised Recovery Plan approval, as measured by effectiveness monitoring efforts or other reliable habitat monitoring programs.

We used the following rule set to compare and evaluate the potential of various habitat scenarios to meet these recovery objectives and criteria, and thus determine what is essential to the conservation of the northern spotted owl:

(1) Ensure sufficient habitat to support population viability across the range of the species.

(a) Habitat can support an increasing or stable population trend, as measured by a population growth rate of 1.0 or greater.

(b) Habitat will be sufficient to insure a low risk of extinction.

(2) Support demographically stable populations in each recovery unit.

(a) Habitat can support an increasing or stable population trend in each recovery unit.

(b) Habitat will be sufficient to insure a low risk of extinction in each recovery unit.

(c) Conserve or enhance connectivity within and among recovery units.

(d) Conserve genetic diversity.

(e) Ensure sufficient spatial redundancy in critical habitat within each recovery unit.

(i) Accommodate habitat disturbance due to fire, insects, disease, and catastrophic events.

(3) Ensure distribution of northern spotted owl populations across representative habitats.

(a) Maintain distribution across the full ecological gradient of the historical range.

(4) Acknowledge uncertainty associated with both future habitat conditions and northern spotted owl population performance—including influence of barred owls, climate change, fire/disturbance risk, and demographic stochasticity—in assessment of critical habitat design.

These critical habitat objectives of supporting population viability and demographically stable populations are intended to be met in concert with the implementation of recovery actions to address other nonhabitat-based threats to the owl.

We applied this rule set to the outcome of HexSim modeling simulations on the various habitat scenarios considered (see Appendix C of the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011) and Dunk *et al.* 2012b, entire, for all details). Each HexSim simulation began with a population of 10,000 females (all population metrics are in numbers of females), consisted of 100 replicates and 350 time steps for each habitat scenario considered, and included the introduction of environmental stochasticity. We then evaluated the relative performance of each habitat scenario using numerous metrics to assess the ability of that scenario to meet the specified recovery goals for the northern spotted owl, as laid out in our rule set for identifying critical habitat; these metrics were evaluated at the scale of each region, as well as collectively rangewide. Our metrics of population performance resulting from each habitat scenario considered included:

- The percentage of simulations during which the rangewide population fell below 1,250 individuals.
- The percentage of simulations during which the rangewide population fell below 1,000 individuals.
- The percentage of simulations during which the rangewide population fell below 750 individuals.
- The percentage of simulations during which the population fell below 250 in each region (using 250 as a quasi-extinction threshold).
- The percentage of simulations during which the population fell below 100 in each region (using 100 as a quasi-extinction threshold).
- The percentage of simulations that went to extinction (population = 0) in each region.
- The mean population size from time step 150 to time step 350 in each region.
- The mean population size at the last time step in each region.
- The mean population size at the last time step rangewide.

Measures of extinction risk are used as an indirect measure of sufficient population abundance, as well as viability.

These metrics were used to comparatively evaluate the ability of each scenario under consideration to determine what is essential for the conservation of the species as informed by our rule set. We selected habitat scenarios for further evaluation if they outperformed the other scenarios under consideration in terms of being better able to meet the population abundance, viability, and trend criteria both across regions and rangewide. In all cases, we attempted to identify the most efficient (smallest) total area that would meet the population goals essential to recovery. Our final critical habitat designation is based on the habitat network that best met all of these criteria, and then was further refined, as described below.

We also focused on public lands to the maximum extent possible (see Dunk *et al.* 2012b, entire, for specific details). In this step, we compared scenarios that did not discriminate between various land ownerships, and those that prioritized publicly owned lands. As Federal agencies have a mandate under section 7(a)(1) of the Act to utilize their authorities in furtherance of the purposes of the Act by carrying out programs for the conservation of listed species, we looked first to Federal lands for critical habitat. However, in some areas of limited Federal ownership, State and private lands may provide areas determined to be essential to the northern spotted owl by contributing to demographic support and connectivity to facilitate dispersal and colonization. In all cases, if the scenarios under consideration provided equal contribution to recovery, as measured by the population metrics described above, we chose the scenario that prioritized inclusion of federally owned lands. State and private lands were included only if they were necessary to achieve conservation of the species, and were determined to provide either occupied areas that support the PCEs or unoccupied areas essential for the conservation of the owl. We also considered Indian lands in our evaluations; if habitat scenarios performed equally well with or without Indian lands, we did not include them (see Indian Lands, below).

To determine which of the numerous potential arrays of habitat we considered contained only those areas that are essential to the conservation of the northern spotted owl, we evaluated each of them according to the rule set and criteria detailed above. Briefly summarizing, all of the habitat networks we assessed contained varying amounts of the physical or biological features needed by the northern spotted owl in varying amounts and spatial arrangements across the range of the species. Our first consideration in determining which of these scenarios contained the physical or biological features in the quantity and configuration essential to the conservation of the species (i.e., the physical and biological features essential to the conservation of the species) was our evaluation of how well the network performed in terms of contributing toward the recovery criteria for the northern spotted owl; we used the recovery criteria as our standard for the conservation of the species.

To ensure that we designated only what is essential to the species' conservation, our secondary consideration was efficiency. For our purposes, we evaluated efficiency both in terms of number of acres and landownership. Some of the networks we evaluated were smaller than this final designation, or did not include any State or private lands; however, such networks failed to meet the recovery criteria required to achieve the conservation of the species, and therefore could not be considered to provide the quantity and configuration of the physical or biological features essential to the conservation of the species. Other potential designations were significantly larger than this final designation and while they were also capable of meeting the recovery criteria, they did not provide proportionately greater conservation value relative to the additional area (as measured, for example, in relative projected numbers of owls). We concluded that such networks therefore included large areas of habitat that may contribute to recovery, but that are not necessary to achieve the recovery criteria for the northern spotted owl, therefore these superfluous areas could not be considered essential to the conservation of the species.

Finally, our assessment of potential habitat networks, based not only on the population models but additionally refined by expert opinion, as described below, indicated that critical habitat limited to areas presently occupied by the northern spotted owl would not be sufficient to achieve the recovery criteria for the species, as such a designation would lead to inadequate population distribution and inadequate population connectivity (50 CFR 424.12(e)). Modeling led us to a similar conclusion regarding areas that were occupied at the time of listing; networks limited to such areas were not capable of meeting the recovery criteria for the species, and the models assisted us in identifying those additional specific areas of habitat unoccupied at the time of listing that are essential in terms of achieving the conservation of the species. Another element of an essential network was therefore the identification of sufficient areas of suitable habitat or potentially suitable habitat not presently occupied by the northern spotted owl, or that was not occupied at the time of listing, to achieve the conservation of the species, in conjunction with occupied habitat.

Our final designation is the critical habitat network that includes the quantity and spatial configuration of habitat that meets the requirement that it contain occupied areas with the essential physical and biological features or unoccupied areas that are themselves essential for conservation of the species by achieving the recovery criteria for the northern spotted owl while avoiding the designation of areas of habitat that do not make an essential contribution to the conservation of the species. This essential habitat network is composed predominantly of areas occupied at the time of listing and that contain the essential physical or biological features, in conjunction with some areas that may have been unoccupied at the time of listing, to collectively comprise the habitat configuration and quantity that most efficiently meets the recovery criteria for the species. All areas in this final critical habitat designation, whether considered occupied at the time of listing or unoccupied at the time of listing, are therefore considered essential to the conservation of the species. The specific modeling outcomes and our evaluation of each potential critical habitat network are presented in detail in Dunk *et al.* 2012b.

It is important to recognize that although the application of this modeling framework provided the foundation for identifying those areas that meet the definition of critical habitat for the northern spotted owl, the models do not simply produce a map of critical habitat. Working from the model results, we then further refined the model-based map units, after considering land ownership patterns, interagency coordination, and best professional judgment, with the objective of increasing the efficiency and effectiveness of the critical habitat designation, as well as making corrections based on ground truthing and local knowledge. The process generally consisted of modifying boundaries to better conform to existing administrative and landscape features, removing small areas of relatively lower-suitability habitat, and incorporating additional areas that may have been unoccupied at the time of listing, but were determined to be essential for population connectivity, for population growth, or to accommodate maintenance of suitable habitat on the landscape for owls in the face of natural disturbance regimes (e.g., fire) or competition with the barred owl, while retaining the overall configuration of the model-based maps. In addition, as part of this refinement process, expert knowledge helped us to identify essential areas such as the unique oak woodland ecotype used by northern spotted owls at the southernmost extent of the species' range in Napa, Sonoma, and Marin Counties, California. We used the population simulation model to evaluate whether this revised critical habitat network continued to provide what is essential to the conservation of the northern spotted owl, and used this same process to evaluate changes made between the proposed and final rule (see Changes from Proposed Rule for details).

Summary of How We Determined Where Physical and Biological Features and Unoccupied Areas Are Essential to Conservation of the Species

The decision of where the requisite physical and biological features and unoccupied areas are essential to the northern spotted owl was made by identifying those areas in the range of the owl that are necessary to achieving a relatively high likelihood of meeting the recovery objectives described in the Revised Recovery Plan (USFWS 2011, p. ix), while at the same time minimizing the inclusion of areas that are relatively less important or not necessary to spotted owl recovery. Striking this balance required by the Act—designating only those areas that contain the essential features or are themselves essential for conservation of the species and not unnecessarily designating the entire geographical area that is or can be occupied by the species—was accomplished using the best available information: a combination of scientific modeling, expert scientific opinion of agency biologists and peer reviewers, and careful consideration of public comment.

We made sure that this final critical habitat designation includes only what is essential to the species' conservation by evaluating a variety of potential critical habitat networks and assessing their relative probability of meeting recovery objectives and, secondarily, their relative ''efficiency'' in meeting these objectives. The various scenarios were designed to bracket a variety of conditions and included different aggregations of total habitat area, landscape juxtaposition, and forest conditions. Some were smaller or larger in total size than this final designation, and some did or did not include Federal matrix lands, State lands, or private lands. The process of comparing alternative networks and population results is described in detail in the Modeling Supplement (Dunk *et al.* 2012b). When compared to other possible network scenarios, we conclude the final identification of critical habitat either contains essential physical and biological features or is otherwise essential because it has the highest likelihood of meeting recovery objectives in the most efficient manner for the following reasons.

(1) It ensures that northern spotted owl populations are sufficiently large to exhibit low extinction risk at the rangewide scale. Under the final designation, modeled rangewide populations have less than a 10 percent probability of declining to fewer than 1,000 females, and a 3 percent probability of declining to fewer than 750 females. Modeled population size and extinction risk results for the designation are within the top 10 percent of all alternative networks, yet the designation is much smaller than other top-ranking alternatives.

(2) It ensures that northern spotted owl populations are well-distributed across the geographic range of the species by selecting a habitat network that supports population sizes with low extinction risk within each of 11 modeling regions. Modeling region-specific population sizes in the final designation are in the top 10 percent of all alternative networks.

(3) It ensures that adequate amounts of current and future habitat is available for spotted owls to persist and recover by designating a habitat network consisting of approximately 50 percent of the available high-suitability spotted owl habitat rangewide. An additional 21 percent of high-quality habitat is encompassed within Congressionally Reserved lands that are not designated, but will retain their value for spotted owls. This high-quality habitat, in addition to areas required for population connectivity, is necessary to support rangewide populations with low extinction risk at both rangewide and regional scales.

(4) Compared to previous spotted owl conservation strategies, it provides increased redundancy in habitat to help buffer potential adverse impacts due to climate change and other stochastic (i.e., unpredictable) events by enlarging the total area of the final designation within the fire-prone portions of the northern spotted owl's range. This means that the final designation supports larger populations in some modeling regions than would be minimally required to achieve low extinction risk. Although it is impossible to predict with precision how much redundancy may be required to deal with future changes in forest conditions, this is essential to ameliorating the potential impacts of fire, insects, and forest disease on spotted owls.

(5) The balancing of population objectives and parsimony resulted in a final designation that encompasses 50 percent of the total available high-suitability habitat rangewide and less than nine percent of low-quality habitat, and supported population size and extinction risk within the top 10 percent of all alternatives. Other larger alternatives had similar or slightly better population characteristics, but contained much larger proportions of lower-suitability habitat. The small amount of low-quality habitat contained in the final designation is essential because it provides for population growth and connectivity both within regional populations and between populations; however, we determined that additional lower-suitability habitat was not necessary to the conservation of the species.

We considered but rejected potential critical habitat networks that provided less total area, that did not include Federal matrix lands, or that did not include some State or private lands where Federal lands were lacking, because these networks had a significantly lower likelihood of meeting recovery objectives as measured by demographic modeling results and expert scientific opinion. For example, modeled rangewide population sizes in this final designation were 1.7 times larger than under the proposed rule's Possible Outcome 4, which did not include any State or private lands, and nearly twice the size of populations under 2008 critical habitat. This larger population size is essential because it results in low extinction risk. Likewise, we considered but rejected several potential networks that included significantly more total area than the final designation. These potential networks had a high probability of meeting recovery objectives as measured by model results and expert opinion, but they did not confer much of a net increase in the likelihood of meeting recovery objectives beyond what is provided by the final designation. This lack of parsimony, combined with a lack of a proportional increase in measurable demographic performance, justified the rejection of these larger potential networks when compared to the final designation.

This methodological approach was generally supported by the scientific peer reviewers. One peer reviewer felt the proposed critical habitat identified too much total area, and another peer reviewer felt that more land area should be included, but most peer reviewers felt the total area and the juxtaposition of land areas seemed reasonable and scientifically justified given the current status of the owl and the recovery objectives. Most of these experts also concluded that the use of the modeling process was justified for informing the final decision.

In sum, we believe this final designation of critical habitat for the northern spotted owl meets the intent of the Act by identifying those areas containing essential features or are otherwise essential in a way that has a very high probability of providing for the conservation of the species, while minimizing the potential for unnecessarily including areas of low conservation value to the species.

Unoccupied Areas

Based on the northern spotted owl's wide-ranging use of the landscape, and the distribution of known owl sites at the time of listing across the units and subunits designated as critical habitat in this rule, we find that all units and all subunits meet the Act's definition of being within the geographical area occupied by the species at the time of listing.

As noted above in *Occupied Areas,* within the units and subunits designated as critical habitat, each consists predominantly of habitat occupied by the species at the time of listing. However, parts of most units and subunits contain a forested mosaic that includes younger forests that may not have been occupied at the time of listing; we evaluated such areas of younger forest as unoccupied at the time of listing. Unoccupied areas must meet the standard of section 3(5)(a)(ii) of the Act: They must be determined to be essential for the conservation of the species. In addition, there are some areas we have concluded were highly likely occupied at the time of listing, based on the presence of suitable habitat and our predictive models, but acknowledge there is some element of uncertainty to recognizing these areas as occupied under the statutory definition due to the lack of survey information. Therefore, we also evaluated all areas that we concluded were likely occupied but which lack survey information applying the standard of section 3(5)(A)(ii) of the Act, and have determined that all such areas included in this designation are essential for the conservation of the species. Finally, as noted earlier, as a result of our application of the modeling framework and refinement process described above, in which we evaluated various habitat scenarios to identify the network that is essential to the conservation of the species by providing the quantity and configuration of habitat essential for the conservation of the species, we have additionally determined that all areas identified here as critical habitat, whether occupied at the time of listing or unoccupied at the time of listing, are essential for the conservation of the species and therefore meet the definition of critical habitat under section 3(5)(A)(ii) of the Act.

Thus, even if not occupied at the time of listing, all units and subunits designated as critical habitat are essential for the conservation of the species because, in addition to nesting, roosting, foraging, and dispersal habitat, they provide connectivity between occupied areas, room for population growth, and the ability to provide sufficient suitable habitat on the landscape for owls in the face of natural disturbance regimes (e.g., fire).

In general, northern spotted owls require large areas of habitat due to their expansive home range requirements and the need for connectivity between subpopulations to maintain genetic diversity and support stable, viable populations over the long term. The northern spotted owl was initially listed in large part due to past habitat loss and degradation. In addition, recent work has confirmed that northern spotted owls require additional areas of habitat to persist in the face of competition with barred owls (Dugger *et al.* 2011, p. 2467). Given the effects of past habitat loss and the increased habitat area needed to offset competition from the barred owl, our assessment indicates that large areas of contiguous areas of nesting, roosting, and foraging habitat are essential to sustaining viable northern spotted owl populations and meeting recovery goals.

In addition, because past habitat loss and degradation was identified as a major threat to the northern spotted owl at the time of listing and because this threat currently continues, conservation and recovery of the species is dependent in part on development of additional habitat to allow for population growth and recovery. Therefore, portions of the habitat mosaic in some subunits designated as critical habitat within the geographical area occupied by the species at the time of listing consist of younger or partially harvested forest. These are essential for the conservation of the species because they are capable of developing the PCEs that support nesting, roosting, or foraging by northern spotted owls that will be necessary for population growth. Typically the result of past timber harvest or wildfire, these areas of younger forest contain the elements conducive to fully developing the physical or biological features essential to the conservation of the owl (they are of suitable elevation, climate, and forest community type). They may, however, be lacking some element of the physical or biological features, such as large trees or dense canopies that are associated with nesting habitat. In particular, of 60 subunits designated, 4 (NCO–4, NCO–5, and ORC–1) contain proportionally greater areas of younger forests that are essential for the conservation of the species, because they can develop additional habitat necessary to support viable northern spotted owl populations in the future. These subunits are located within Southwestern Washington and Oregon Coast Ranges Areas of Special Concern (Thomas *et al.* 1990, pp. 66–69), areas described as exhibiting a scarcity of suitable habitat due to extensive timber harvest. The recovery goal of achieving viable populations distributed across the range of the owl cannot be achieved without these areas; therefore, we have determined them to be essential for the conservation of the species.

Finally, there are portions of two subunits that function primarily for connectivity between populations. Although portions of these subunits may not have been occupied at the time of listing, these areas contain the dispersal and foraging habitat to support movement between adjacent subunits and are therefore essential to provide population connectivity. Many of these areas are also anticipated to develop into habitat capable of supporting nesting pairs in the future. In 1990, the Interagency Scientific Committee (ISC) (Thomas *et al.* 1990, entire) identified ''Areas of Special Concern'' in the Draft Strategy for the Conservation of the Northern Spotted Owl. The ISC defined Areas of Special Concern as lands where past natural occurrences and human actions had adversely affected habitat more than in the remainder of the physiographic province under consideration (Thomas *et al.* 1990, p. 66). Within the Areas of Special Concern described by the ISC (Thomas *et al.* 1990, pp. 66–69), we identified areas that were strategically located between subunits that would otherwise be demographically isolated. Of 60 subunits designated, two (ORC–4 and ECS–3) are identified as functioning primarily for population connectivity with less than 70 percent of the subunit covered by survey-located owl sites.

Our evaluation of the various habitat scenarios considered in the modeling process described above enabled us to determine the amount and configuration of habitat essential for the conservation of the owl, based on the relative ability of that habitat network to meet the recovery criteria of stable or increasing populations and adequate distribution of viable populations. Although this evaluation was primarily based on areas we know to have been occupied at the time of listing, our evaluation of the distribution and configuration of the physical and biological features essential to the conservation of the owl additionally identified areas that may not have been occupied at the time of listing, if those areas were essential to meeting the recovery goals for the species. We have determined these areas to be essential for the conservation of the species, to provide for dispersal and connectivity between currently occupied areas, allow space for population growth, and provide habitat replacement in the event of disturbances, such as wildfires and competition with barred owls. Our evaluation of alternative habitat networks, described above, indicates that the specific areas identified in this designation are necessary to achieve the amount and configuration of habitat that meets the recovery criteria for the species. Because these areas do so efficiently (without designating more areas than are needed, or designating areas that would not make a significant contribution to conservation value), we have determined that these areas are essential for the conservation of the species. As described above, we have determined that a critical habitat designation that does not include these areas, even if they may not be occupied, would be inadequate to ensure the conservation of the species. The resulting revised critical habitat represents the amount and spatial distribution of habitats that we have determined to be essential for the conservation of the northern spotted owl.

This designation is an improvement over the previous designation in that it anticipates that in geographical regions with drier forests and more dynamic natural disturbance regimes, land managers will consider taking a landscape approach to managing critical habitat. This landscape approach would recognize that large areas are essential in these regions to accommodate disturbance-driven shifts in the physical or biological features essential for the conservation of the northern spotted owl, and that restorative management actions may be needed across these landscapes to help manage for resilience in such a dynamic ecosystem. These large landscapes, although essential to provide for the conservation of the northern spotted owl, do include within their boundaries several particular types of areas that are not included in critical habitat, because they cannot support northern spotted owl habitat. The following types of areas are not critical habitat for the northern spotted owl, and are not included in the revised designation:

- Meadows and grasslands. These include dry, upland prairies and savannas found in the valleys and foothills of western Washington, Oregon, and northwest California; subalpine meadows; and grass and forb dominated cliffs, bluffs and grass balds found throughout these same areas. Dominated by native grasses and diverse forbs, they may include a minor savanna component of Oregon white oak, Douglas-fir, or Ponderosa pine.
- Oak and aspen (*Populus* spp.) woodlands. Oak woodlands are characterized by an open canopy dominated by Oregon white oak but may also include ponderosa pine, California black oak, Douglas-fir, or canyon live oak. The understory is relatively open with shrubs, grasses and wildflowers. Oak woodlands are typically found in drier landscapes and on south-facing slopes. Note this exception for oak woodlands does not include tanoak (*Notholithocarpus densiflorus*) stands, closed-canopy live oak (*Quercus agrifolia*) woodlands and open-canopied valley oak (*Quercus lobata*) and mixed-oak woodlands in subunits ICC–6 and RDC–5 in Napa, Sonoma, and Marin Counties, California. Aspen woodlands are dominated by aspen trees with a forb, grass or shrub understory and are typically found on mountain slopes, rock outcrops and talus slopes, canyon walls, and some seeps and stream corridors. This forest type also can occur in riparian areas or in moist microsites within drier landscapes.
- Manmade structures (such as buildings, aqueducts, runways, roads, and other paved areas) and the land on which they are located.

When determining critical habitat boundaries, we made every effort to avoid including these areas because they lack physical or biological features for the northern spotted owl. Due to the limitations of mapping at such fine scales, however, we were often not able to segregate these areas from areas shown as critical habitat on critical habitat maps suitable in scale for publication within the Code of Federal Regulations. Thus, we have included regulatory text clarifying that these areas are not included in the designation even if within the mapped boundaries of critical habitat, as a Federal action involving these lands would not trigger section 7 consultation with respect to effects to critical habitat unless the specific action would affect the physical or biological features in the adjacent critical habitat.

VIII. Final Critical Habitat Designation

Consistent with the standards of the Act and our regulations we have identified 9,577,969 ac (3,876,064ha) in 11 units and 60 subunits as meeting the definition of critical habitat for the northern spotted owl. The 11 units we have identified as critical habitat are: (1) North Coast Olympics, (2) Oregon Coast Ranges, (3) Redwood Coast, (4) West Cascades North, (5) West Cascades Central, (6) West Cascades South, (7) East Cascades North, (8) East Cascades South, (9) Klamath West, (10) Klamath East, and (11) Interior California Coast Ranges. All of the critical habitat units and subunits identified were occupied at the time of listing; however, some units may include some smaller areas that were not known to be occupied at the time of listing but have been determined to be essential to the conservation of the species. In addition, as described above, we have determined that all areas being designated are essential to the conservation of the species. Land ownership of the designated critical habitat includes Federal and State lands. No tribal lands are included in the critical habitat designation. The approximate area of each critical habitat unit is shown in Table 6. Table 7 gives totals by land ownership.

TABLE 6—REVISED CRITICAL HABITAT UNITS FOR THE NORTHERN SPOTTED OWL

[Area estimates reflect all land within critical habitat unit boundaries.]

Critical habitat unit	Land ownership	Acres	Hectares
Unit 1—North Coast Olympics	Federal	696,230	281,754
	State	128,270	51,909
	Total	824,500	333,663
Unit 2—Oregon Coast Ranges	Federal	788,919	319,264
	State	70,945	28,711
	Total	859,864	347,975
Unit 3—Redwood Coast	Federal	111,258	45,025
	State	48,912	19,794
	Local government	20,684	8,371
	Total	180,855	73,189
Unit 4—West Cascades North	Federal	541,476	219,127
	State	798	323
	Total	542,274	219,450
Unit 5—West Cascades Central	Federal	908,861	367,802
	State	825	334
	Total	909,687	368,136
Unit 6—West Cascades South	Federal	1,354,989	548,345
	State	209	85
	Total	1,355,198	548,429
Unit 7—East Cascades North	Federal	1,338,988	541,869
	State	6,534	2,644
	Total	1,345,523	544,514
Unit 8—East Cascades South	Federal	368,380	149,078
Unit 9—Klamath West	Federal	1,186,750	480,260
	State	10,639	4,305
	Total	1,197,389	484,565

Local Government	20,684	8,371
Private	0	0
Other Federal (DOD)	0	0
Tribal	0	0
Total	9,577,969	3,876,064

We present brief descriptions of all units and their subunits below. For each subunit, we describe the proportion of the area that is covered by verified northern spotted owl home ranges at the time of listing. As described above in the section Criteria Used to Identify Critical Habitat, all areas being designated that were occupied at the time of listing contain the physical or biological features essential to the conservation of the northern spotted owl, and which may require special management considerations or protection. In addition, there are smaller areas of suitable habitat within subunits that we considered likely occupied by nonterritorial owls and dispersing subadults, at the time of listing, as well as some smaller areas of younger forest within the larger habitat mosaic that may have been unoccupied at the time of listing. Due to some potential for uncertainty in these latter two categories of areas in terms of occupancy at the time of listing, we evaluated all such areas applying the standard under section 3(5)(A)(ii) of the Act, and have determined that all such areas included in this designation are essential to the conservation of the species. In addition, as a result of our application of the modeling framework described earlier, we have determined that all areas identified here as critical habitat, whether occupied at the time of listing or unoccupied at the time of listing, are essential to the conservation of the species and therefore meet the definition of critical habitat under section 3(5)(A)(ii) of the Act. This applies to all units and subunits described below.

Unit 1: North Coast Ranges and Olympic Peninsula (NCO)

Unit 1 consists of 824,500 ac (333,623 ha) and contains five subunits. This unit consists of the Oregon and Washington Coast Ranges Section M242A, based on section descriptions of forest types from Ecological Subregions of the United States (McNab and Avers 1994a, Section M242A). This region is characterized by high rainfall, cool to moderate temperatures, and generally low topography (1,470 to 2,460 ft (448 to 750 m)). High elevations and cold temperatures occur in the interior portions of the Olympic Peninsula, but northern spotted owls in this area are limited to the lower elevations (less than 2,950 ft (900 m)). Forests in the NCO are dominated by western hemlock, Sitka spruce, Douglas-fir, and western red cedar (*Thuja plicata*). Hardwoods are limited in species diversity (consist mostly of bigleaf maple and red alder (*Alnus rubra*)) and distribution within this region, and typically occur in riparian zones. Root pathogens like laminated root rot (*Phellinus weirii*) are important gap formers, and vine maple (*Acer circinatum*), among others, fills these gaps. Because Douglas-fir dwarf mistletoe is unusual in this region, northern spotted owl nesting habitat consists of stands providing very large trees with cavities or deformities. A few nests are associated with western hemlock dwarf mistletoe (*Arceuthobium tsugense* subsp. *tsugense*). Northern spotted owl diets are dominated by species associated with mature to late-successional forests (flying squirrels, red tree voles), resulting in similar definitions of habitats used for nesting/roosting and foraging by northern spotted owls.

Subunit Descriptions: Unit 1

NCO–1. The NCO–1 subunit consists of approximately 293,539 ac (118,791 ha) in Clallam, Jefferson, Grays Harbor, and Mason Counties, Washington, and comprises lands managed by U.S. Forest Service (USFS) and State of Washington. The USFS manages 230,966 ac (93,309 ha) as Late-successional Reserves to maintain functional, interactive, late-successional and old-growth forest ecosystems and 62,966 ac (25,481 ha) under the adaptive management area land use allocation. Threats in this subunit include current and past timber harvest, competition with barred owls, and isolation on a peninsula (along with subunit NCO–2). This subunit is expected to function primarily for demographic support of the overall population. NCO–1 is located primarily in the watersheds of Lyre, Hoko, Soleduck, Hoh, Quinault, Queets, and Clearwater Rivers, and includes the northern part of the Lower Chehalis River watershed.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 94 percent of the area of NCO–1 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

NCO–2. The NCO–2 subunit consists of approximately 213,633 ac (86,454 ha) in Kitsap, Clallam, Jefferson, Grays Harbor, and Mason Counties, Washington, and comprises lands managed by the USFS. The USFS manages 173,682 ac (70,287 ha) as Late-successional Reserves to maintain functional, interactive, late-successional and old-growth forest ecosystems and 39,083 ac (15,816 ha) under the adaptive management area land use allocation. Threats in this subunit include current and past timber harvest, competition with barred owls, and isolation on a peninsula (along with subunit NCO–1). This subunit is expected to function primarily for demographic support of the overall population. NCO–2 is located primarily in the watersheds of the Elwha, Dungeness, Quilcene, Snow, Skokomish, and Dosewallips rivers.

Our evaluation of sites known to be occupied at the time of listing indicate that approximately 95 percent of the area of this subunit was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

NCO–3. We exempted subunit NCO–3 from the final designation of critical habitat under Section 4(a)(3) of the Act (See Exemptions section below). This subunit is comprised approximately 14,313 ac (5,792 ha) of lands managed by the Department of Defense as part of Joint Base Lewis-McChord under their integrated natural resource management plan (INRMP).

NCO–4. The NCO–4 subunit consists of approximately 179,745 ac (72,740 ha) in Clatsop, Columbia, Tillamook, and Washington Counties, Oregon, and comprises Federal lands and lands managed by the State of Oregon. Of this subunit, 117,033 ac (47,361 ha) are managed as part of the Tillamook and Clatsop State Forests for multiple uses including timber revenue production, recreation, and wildlife habitat according to the Northwest Oregon State Forest Management Plan (ODF 2010a, entire). Federal lands encompass 62,712 ac (25,379 ha) of this subunit and are managed as directed by the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest and competition with barred owls. This subunit is expected to function primarily for demographic support to the overall population. This subunit is isolated from the nearest subunit to the north but is adjacent to subunit NCO–5 to the south.

Our evaluation of sites known to be occupied at the time of listing indicate that approximately 63 percent of the area of NCO–4 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider a large part of this subunit to have been occupied at the time of listing. There are some areas of younger forest in this subunit that may have been unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat in this subunit is especially important for providing for population growth and additional demographic support in this region. The development of additional suitable habitat in this subunit is needed to support viable northern spotted owl populations over the long term. The recruitment of additional suitable habitat will also contribute to the successful dispersal of northern spotted owls, and serve to buffer northern spotted owls from competition with the barred owl.

NCO–5. The NCO–5 subunit consists of approximately 142,937 ac (57,845 ha) in Yamhill, Lincoln, Tillamook, and Polk Counties, Oregon, and comprises lands managed by the State of Oregon, the BLM, and the USFS. Of this subunit 11,067 ac (4,479 ha) are managed by the State of Oregon for multiple uses including timber revenue production, recreation, and wildlife habitat according to the Northwest Oregon State Forest Management Plan (ODF 2010a, entire), and may be considered for exclusion from the final critical habitat designation. Federal lands comprise 131,870 ac (53,666 ha) and are managed as directed by the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest and competition with barred owls. This subunit is expected to function primarily for demographic support to the overall population and north-south connectivity between subunits and critical habitat units.

Our evaluation of sites known to be occupied at the time of listing indicate that approximately 63 percent of the area of NCO–5 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider a large part of this subunit to have been occupied at the time of listing. There are some areas of younger forest in this subunit that may have been unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat in this subunit is especially important for providing for population growth and additional demographic support in this region. The development of additional suitable habitat in this subunit is needed to support viable northern spotted owl populations over the long term. The recruitment of additional suitable habitat will also contribute to the successful dispersal of northern spotted owls, and serve to buffer northern spotted owls from competition with the barred owl.

Unit 2: Oregon Coast Ranges (OCR)

Unit 2 consists of 859,864 ac (347,975 ha) and contains six subunits. This unit consists of the southern third of the Oregon and Washington Coast Ranges Section M242A, based on section descriptions of forest types from Ecological Subregions of the United States (McNab and Avers 1994a, Section M242A). We split the section in the vicinity of Otter Rock, OR, based on gradients of increased temperature and decreased moisture that result in different patterns of vegetation to the south. Generally this region is characterized by high rainfall, cool to moderate temperatures, and generally low topography (980 to 2,460 ft (300 to 750 m)). Forests in this region are dominated by western hemlock, Sitka spruce, and Douglas-fir; hardwoods are limited in species diversity (largely bigleaf maple and red alder) and distribution, and are typically limited to riparian zones. Douglas-fir and hardwood species associated with the California Floristic Province (tanoak, Pacific madrone, black oak, giant chinquapin (*Castanopsis chrysophylla*)) increase toward the southern end of the OCR. On the eastern side of the Coast Ranges crest, habitats tend to be drier and dominated by Douglas-fir. Root pathogens like laminated root rot are important gap formers, and vine maple among others fills these gaps. Because Douglas-fir dwarf mistletoe is unusual in this region, northern spotted owl nesting habitat tends to be limited to stands providing very large trees with cavities or deformities. A few nests are associated with western hemlock dwarf mistletoe. Northern spotted owl diets are dominated by species associated with mature to late-successional forests (flying squirrels, red tree voles), resulting in similar definitions of habitats used for nesting/roosting and foraging by northern spotted owls. One significant difference between OCR and NCO is that woodrats comprise an increasing proportion of the diet in the southern portion of the modeling region.

Subunit Descriptions—Unit 2

OCR–1. The OCR–1 subunit consists of approximately 110,657 ac (44,781 ha) in Polk, Benton and Lincoln Counties, Oregon, and comprises lands managed by the State of Oregon, the BLM, and the USFS. Of this subunit 6,612 ac (2,676 ha) are managed by the State of Oregon for multiple uses including timber revenue production, recreation, and wildlife habitat according to the Northwest Oregon State Forest Management Plan (ODF 2010a, entire). Federal lands comprise 104,045 ac (42,105 ha) and are managed as directed by the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest and competition with barred owls. This subunit is expected to function primarily for demographic support to the overall population and north-south connectivity between subunits and critical habitat units.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 55 percent of the area of OCR–1 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider a large part of this subunit to have been occupied at the time of listing. There are some areas of younger forest in this subunit that may have been unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat in this subunit is especially important for providing for population growth and additional demographic support in this region. The development of additional suitable habitat in this subunit is needed to support viable northern spotted owl populations over the long term. The recruitment of additional suitable habitat will also contribute to the successful dispersal of northern spotted owls, and serve to buffer northern spotted owls from competition with the barred owl.

OCR–2. The OCR–2 subunit consists of approximately 261,405 ac (105,787 ha) in Lane, Benton, and Lincoln Counties, Oregon, and comprises lands managed by the State of Oregon, the BLM, and the USFS. Of this subunit 18,504 ac (7,448 ha) are managed by the State of Oregon for multiple uses including timber revenue production, recreation, and wildlife habitat according to the Northwest Oregon State Forest Management Plan (ODF 2010a, entire). Federal lands comprise 242,901 ac (98,298 ha) and are managed as directed by the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest and competition with barred owls. This subunit is expected to function primarily for demographic support to the overall population and north-south connectivity between subunits.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 77 percent of the area of OCR–2 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

OCR–3. The OCR–3 subunit consists of approximately 203,681 ac (82,427 ha) in Lane and Douglas Counties, Oregon, and comprises lands managed by the State of Oregon, the BLM, and the USFS. Of this subunit 5,082 ac (2,07 ha) are managed by the State of Oregon for multiple uses including timber revenue production, recreation, and wildlife habitat according to the Northwest Oregon State Forest Management Plan (ODF 2010a, entire). Federal lands comprise 198,599 ac (80,369 ha) and are managed as directed by the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest and competition with barred owls. This subunit is expected to function primarily for demographic support to the overall population and for both north-south and east-west connectivity between subunits.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 97 percent of the area of OCR–3 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

OCR–4. The OCR–4 subunit consists of approximately 8,263 ac (3,344 ha) in Lane and Douglas Counties, Oregon, and comprises lands managed by the BLM as directed by the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest and competition with barred owls. This subunit is expected to function primarily for east-west connectivity between subunits and critical habitat units, and between the Oregon coast and the western Cascades.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 43 percent of the area of OCR–4 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider a large part of this subunit to have been occupied at the time of listing. There are some areas of younger forest in this subunit that may have been unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat in this subunit is especially important for providing essential connectivity between currently occupied areas to support the successful dispersal of northern spotted owls, and may also help to buffer northern spotted owls from competition with the barred owl.

OCR–5. The OCR–5 subunit consists of approximately 176,905 ac (71,591ha) in Coos and Douglas Counties, Oregon, and comprises lands managed by the State of Oregon, the BLM, and the USFS. Of this subunit 40,747 ac (16,490 ha) are managed by the State of Oregon for multiple uses including sustained economic benefit through timber harvest and management, recreation, and wildlife habitat according to the Elliot State Forest Management Plan (ODF 2011, entire). Federal lands comprise 136,158 ac (55,101 ha) and are managed as directed by the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest and competition with barred owls. This subunit is expected to function primarily for demographic support to the overall population and for north-south, and potentially east-west, connectivity between subunits.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 94 percent of the area of OCR–5 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

OCR–6. The OCR–6 subunit consists of approximately 81,900 ac (33,144 ha) in Coos and Douglas Counties, Oregon, and comprises lands managed by the BLM as directed by the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest and competition with barred owls. This subunit is expected to function primarily for demographic support to the overall population and for north-south connectivity between subunits and critical habitat units.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 97 percent of the area of OCR–6 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

Unit 3: Redwood Coast (RWC)

Unit 3 contains 180,855ac (73,189ha) and three subunits. This unit consists of the Northern California Coast Ecological Section 263, based on section descriptions of forest types from Ecological Subregions of the United States (McNab and Avers 1994b, entire). This region is characterized by low-lying terrain (0 to 2,950 ft (0 to 900 m)) with a maritime climate, generally mesic conditions, and moderate temperatures. Climatic conditions are rarely limiting to northern spotted owls at all elevations. Forest communities are dominated by redwood, Douglas-fir-tanoak forest, coast live oak, and tanoak series. The vast majority of the region is in private ownership, dominated by a few large industrial timberland holdings. The results of numerous studies of northern spotted owl habitat relationships suggest stump-sprouting and rapid growth rates of redwoods, combined with high availability of woodrats in patchy, intensively managed forests, enables northern spotted owls to maintain high densities in a wide range of habitat conditions within the Redwood zone.

Subunit Descriptions—Unit 3

RDC–1. This subunit contains 63,127 ac (25,547 ha) of lands managed by the USFS and BLM in Curry County, Oregon and in Del Norte, Humboldt, and Trinity Counties, California. Special management considerations or protection are required in this subunit to address threats from the barred owl. Suitable habitat within the subunit is relatively contiguous north-to-south, and is capable of supporting a sustainable subpopulation of owls. We expect that this subunit will provide strong connectivity among the adjacent critical habitat units to the north (OCR) and east (KLW, ICC). The subunit is weakly connected to the adjacent subunit to the south (RDC–2).

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 78 percent of the area of RDC–1 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

RDC–2. This subunit contains 65,391 ac (26,463 ha) in Mendocino and southwestern Humboldt Counties, California. There are 16,479 ac (6,669 ha) of Federal lands in the subunit, managed by the Bureau of Land Management. The California Department of Forestry and Fire Protection operates the Jackson Demonstration State Forest (48,912 ac (19,794 ha)) for multiple uses including timber production, water quality, wildlife habitat, and research.

Special management considerations or protection are required in this subunit to address threats from the barred owl. Suitable habitat within the subunit is relatively contiguous north-to-south, and is capable of supporting a sustainable subpopulation of owls. The subunit is weakly connected to the adjacent CHU to the east (ICC) and to the coastal subunit to the north (RDC–1); it is relatively well connected to the coastal subunit to the south (RDC–3).

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 85 percent of the area of RDC–2 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

RDC–3. This subunit was comprised entirely of private lands, which have been excluded from the final rule.

RDC–4. This subunit was comprised entirely of private lands, which have been excluded from the final rule.

RDC–5. This subunit contains 20,684 ac (8,371 ha) in southern Marin County, California and represents the southern range limit of the subspecies. No private lands are contained in this subunit. The Mount Tamalpais Watershed (18,900 ac (7,649 ha)) of the Marin Municipal Water District is included in the final critical habitat designation. Six Open Space Preserves (OSPs) in the Marin County Parks and Open Space System, totaling 3,627 ac (1,468 ha), are included in the final critical habitat designation, including Gary Giacomini, White Hill, Cascade Canyon, Baltimore Canyon, Camino Alto, and Blithedale Summit OSPs. Special management considerations or protection are required in this subunit to address incipient threats from the barred owl. Suitable habitat within the subunit is continuous from east to west. It is unknown whether this subunit is capable of supporting a self-sustaining subpopulation of owls without support from the subunit to the north (RDC–4). The lands between this subunit and the nearest subunit to the east (ICC–6) are dominated by agricultural and urban land use, and are very weakly connected.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 82 percent of the area of RDC–5 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

Unit 4: West Cascades North (WCN)

This unit contains 542,274 ac (219,450 ha) and two subunits. This unit coincides with the northern Western Cascades Section M242B, based on section descriptions of forest types from Ecological Subregions of the United States (McNab and Avers 1994a, Section M242B), combined with the western portion of M242D (Northern Cascades Section), extending from the U.S.-Canadian border south to Snoqualmie Pass in central Washington. It is similar to the Northern Cascades Province of Franklin and Dyrness (1988, pp. 17–20). This region is characterized by high mountainous terrain with extensive areas of glaciers and snowfields at higher elevation. The marine climate brings high precipitation (both annual and summer) but is modified by high elevations and low temperatures over much of this modeling region. The resulting distribution of forest vegetation is dominated by subalpine species, mountain hemlock and silver fir; the western hemlock and Douglas-fir forests typically used by northern spotted owls are more limited to lower elevations and river valleys (northern spotted owls are rarely found at elevations greater than 4,200 ft (1,280 m) in this region) grading into the mesic Puget lowland to the west.

Subunit Descriptions—Unit 4

WCN–1. The WCN–1 subunit consists of approximately 438,255 ac (177,355 ha) in Whatcom, Skagit, and Snohomish Counties, Washington, and comprises lands managed by the USFS and the State of Washington. The USFS manages 320,146 ac (129,559 ha) as Late-successional Reserves to maintain functional, interactive, late-successional, and old-growth forest ecosystems and 6,147 ac (2,487 ha) under the matrix land use allocation where multiple uses occur, including most timber harvest and other silvicultural activities. Threats in this subunit include current and past timber harvest, competition with barred owls, steep topography with high-elevation ridges that separate relatively small, linear strips of suitable habitat in valley bottoms, and location at the northern limit of the subspecies range. This subunit is expected to function primarily for demographic support of the overall population and to maintain the subspecies distribution in the northernmost portion of its range. WCN–1 is located in the watersheds of the Stillaguamish, Skagit, and Nooksack rivers, and is bounded on the north by the international boundary with British Columbia, Canada. In this subunit, we have excluded lands covered under the Washington Department of Natural Resources State Lands HCP.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 92 percent of the area of WCN–1 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

WCN–2. The WCN–2 subunit consists of approximately 103,988 ac (42,083 ha) in King and Snohomish Counties, Washington, and comprises lands managed by the USFS, State of Washington, and private landowners. The USFS manages 82,316 ac (33,312 ha) as Late-successional Reserves to maintain functional, interactive, late-successional, and old-growth forest ecosystems and 834 ac (338 ha) under the matrix land use allocation where multiple uses occur, including most timber harvest and other silvicultural activities. Threats in this subunit include current and past timber harvest, competition with barred owls, and steep topography with high-elevation ridges that separate relatively small, linear strips of suitable habitat in valley bottoms. This subunit has a key role in maintaining connectivity between northern spotted owl populations, both north to south in the West Cascades and west to east between the West and East Cascades units. This role is shared with the WCC–1 subunit to the south and the ECN–4 subunit to the east. This subunit is also expected to provide demographic support of the overall population. WCN–2 is located in the watersheds of the Snohomish and Cedar/Sammamish Rivers. In this subunit, we have excluded lands covered under the Washington Department of Natural Resources State Lands HCP in the final designation.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 79 percent of the area of WCN–2 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

Unit 5: West Cascades Central (WCC)

This unit contains 909,687 ac (368,136 ha) and three subunits. This region consists of the midsection of the Western Cascades Section M242B, based on section descriptions of forest types from Ecological Subregions of the United States (McNab and Avers 1994a, Section M242B), extending from Snoqualmie Pass in central Washington south to the Columbia River. It is similar to the Southern Washington Cascades Province of Franklin and Dyrness (1988, pp. 21–23). We separated this region from the northern section based on differences in northern spotted owl habitat due to relatively milder temperatures, lower elevations, and greater proportion of western hemlock/Douglas-fir forest and occurrence of noble fir (*A. procera*) to the south of Snoqualmie Pass. Because Douglas-fir dwarf mistletoe occurs rarely in this region, northern spotted owl nest sites are largely limited to defects in large trees, and occasionally nests of other raptors.

Subunit Descriptions—Unit 5

WCC–1. The WCC–1 subunit consists of approximately 225,847 ac (91,397 ha) in King, Pierce, Thurston, Lewis, Kittitas, and Yakima Counties, Washington, and comprises lands managed by USFS and State of Washington. The USFS manages 183,884 ac (76,843 ha) as Late-successional Reserves to maintain functional, interactive, late-successional, and old-growth forest ecosystems and 35,145 ac (14,222 ha) under the matrix land use allocation where multiple uses occur, including most timber harvest and other silvicultural activities. Threats in this subunit include current and past timber harvest, competition with barred owls, and stand conversion. This subunit is expected to provide demographic support of the overall population and to maintain demographic connectivity between the Cascade Range and the Olympic Peninsula in conjunction with subunit NCO–3. WCC–1 is located primarily in the watersheds of the Nisqually, Puyallup, White, Duwamish, and Green Rivers. In this subunit, we have excluded lands from our final critical habitat designation that are covered under the Washington Department of Natural Resources State Lands HCP, the Cedar River Watershed HCP, the Plum Creek Timber Central Cascades HCP, the West Fork Timber HCP, the Tacoma Water Green River Water Supply Operations and Watershed Protection HCP as well as other private lands from the final designation.

Our evaluation of sites known to be occupied at the time of listing indicate that approximately 96 percent of the area of WCC–1 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

WCC–2. The WCC–2 subunit consists of approximately 279,445 ac (113,087 ha) in Pierce, Lewis, Cowlitz, Skamania, and Yakima Counties, Washington, and comprises lands managed by USFS, State of Washington, and private landowners. The USFS manages 92,835 ac (37,569 ha) as Late-successional Reserves to maintain functional, interactive, late-successional, and old-growth forest ecosystems and 88,655 ac (35,878 ha) under the matrix land use allocation where multiple uses occur, including most timber harvest and other silvicultural activities. Threats in this subunit include current and past timber harvest and competition with barred owls. This subunit is expected to provide demographic support of the overall population. WCC–2 is located primarily in the Cowlitz River watersheds west of the Cascade Crest and the headwaters of the Naches River watershed east of the Crest. In this subunit, we have excluded lands covered under the Washington Department of Natural Resources State Lands HCP, the West Fork Timber HCP, and the Port Blakely Tree Farms L.P. (Morton Block) SHA, Landowner Option Plan, and Cooperative Habitat Enhancement Agreement in the final critical habitat designation.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 96 percent of the area of WCC–2 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

WCC–3. The WCC–3 subunit consists of approximately 394,501 ac (159,649 ha) in Clark, Skamania, and Yakima Counties, Washington, and comprises lands managed by the USFS, the State of Washington, and private landowners. The USFS manages 242,929 ac (98,310 ha) as Late-successional Reserves to maintain functional, interactive, late-successional, and old-growth forest ecosystems and 122,641 ac (49,631 ha) under the matrix land use allocation where multiple uses occur, including most timber harvest and other silvicultural activities. Threats in this subunit include current and past timber harvest, competition with barred owls, and the Columbia River as an impediment to northern spotted owl dispersal. This subunit is expected to provide demographic support of the overall population and an opportunity for demographic exchange between the WCC Unit and the WCS Unit. WCC–3 is located primarily in the watersheds of the Lewis, Wind, and White Salmon Rivers, and is bounded on the south by the Columbia River. In this subunit, we have excluded lands covered under the Washington Department of Natural Resources State Lands HCP from critical habitat designation.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 96 percent of the area of WCC–3 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

Unit 6: West Cascades South (WCS)

Unit 6 contains 1,355,198ac (548,429 ha) and contains six subunits. This unit consists of the southern portion of the Western Cascades Section M242B, based on section descriptions of forest types from Ecological Subregions of the United States (McNab and Avers 1994a, Section M242B), and extends from the Columbia River south to the North Umpqua River. We separated this region from the northern section due to its relatively milder temperatures, reduced summer precipitation due to the influence of the Willamette Valley to the west, lower elevations, and greater proportion of western hemlock/Douglas-fir forest. The southern portion of this region exhibits a gradient between Douglas-fir/western hemlock and increasing Klamath-like vegetation (mixed conifer/evergreen hardwoods), which continues across the Umpqua divide area. The southern boundary of this region is novel and reflects a transition to mixed-conifer forest (Franklin and Dyrness 1988, pp. 23–24, 137–143). The importance of Douglas-fir dwarf mistletoe increases to the south in this region, but most northern spotted owl nest sites are found in defective large trees, and occasionally nests of other raptors.

Subunit Descriptions—Unit 6

WCS–1. The WCS–1 subunit consists of approximately 92,586 ac (37,468 ha) in Multnomah, Hood River, and Clackamas Counties, Oregon, and comprises only Federal lands managed by the BLM and the USFS under the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest and competition with barred owls. This subunit is expected to function primarily for demographic support to the overall population, as well as north-south and east-west connectivity between subunits and critical habitat units.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 88 percent of the area of WCS–1 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

WCS–2. The WCS–2 subunit consists of approximately 150,105 ac (60,745 ha) in Clackamas, Marion, and Wasco Counties, Oregon, and comprises only Federal lands managed by the BLM and the USFS under the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest and competition with barred owls. This subunit is expected to function primarily for demographic support to the overall population, as well as north-south connectivity between subunits.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 82 percent of the area of WCS–2 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011 p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

WCS–3. The WCS–3 subunit consists of approximately 319,736 ac (129,393 ha) in Clackamas, Marion, Linn, and Lane Counties, Oregon, and comprises lands managed by the State of Oregon, the BLM, and the USFS. Of this subunit, 184 ac (75 ha) are managed by the State of Oregon primarily for recreation (Oregon Administrative Rules, Chapter 736, entire). The remaining 319,552 ac (129,318 ha) are Federal lands managed as directed by the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest and competition with barred owls. This subunit is expected to function primarily for demographic support to the overall population, as well as north-south connectivity between subunits.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 85 percent of the area of WCS–3 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

WCS–4. The WCS–4 subunit consists of approximately 379,130 ac (153,429 ha) in Lane and Douglas Counties, Oregon, and comprises only Federal lands managed by the BLM and the USFS under the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest and competition with barred owls. This subunit is expected to function primarily for demographic support to the overall population, as well as north-south connectivity between subunits.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 86 percent of the area of WCS–4 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

WCS–5. The WCS–5 subunit consists of approximately 356,415 ac (144,236 ha) in Lane and Douglas Counties, Oregon, and comprises only Federal lands managed by the USFS under the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest and competition with barred owls. This subunit is expected to function primarily for demographic support to the overall population, as well as north-south and east-west connectivity between subunits and critical habitat units.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 83 percent of the area of WCS–5 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

WCS–6. The WCS–6 subunit consists of approximately 99,558 ac (40,290 ha) in Lane, Klamath, and Douglas Counties, Oregon, and is managed by the BLM and the USFS as directed by the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest and competition with barred owls. This subunit is expected to function primarily for east-west connectivity between subunits and critical habitat units, and between the Oregon coast and the western Cascades.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 97 percent of the area of WCS–6 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

Unit 7: East Cascades North (ECN)

Unit 7 contains 1,345,523ac (557,002 ha) and nine subunits. This unit consists of the eastern slopes of the Cascade range, extending from the Canadian border south to the Deschutes National Forest near Bend, OR. Terrain in portions of this region is glaciated and steeply dissected. This region is characterized by a continental climate (cold, snowy winters and dry summers). High-frequency, low-intensity fire regimes occur at lower elevations, mid elevations have mixed-severity regimes, and high elevations have high-severity regimes. Increased precipitation from marine air passing east through Snoqualmie Pass and the Columbia River has resulted in an increase of moist forest conditions in this region (Hessburg *et al.* 2000b, p. 165). In Washington, ponderosa pine and Douglas-fir forest are dominant at low elevations, Douglas-fir/grand fir mixed-conifer forest are characteristic of mid-elevations, and higher elevations support forests of silver fir, hemlock, and subalpine fir. The terrain is highly dissected and mountainous. The terrain and ecology are different on the southern portion of the unit, where ponderosa pine predominates on flat terrain at low elevations, and owl habitat is restricted to buttes and the slopes of the Cascade Range in forests of Douglas-fir, grand/white fir, and true firs. There is substantially less habitat in the Deschutes area of Oregon compared to the area north of Sisters, Oregon, and into Washington. The bulk of owls in this Unit are in Washington.

Forest composition, particularly the presence of grand fir and western larch, distinguishes this modeling region from the southern section of the eastern Cascades. While ponderosa pine forest dominates lower and middle elevations in both this and the southern section, the northern section supports grand fir and Douglas-fir habitat at middle elevations. Dwarf mistletoe provides an important component of nesting habitat, enabling northern spotted owls to nest within stands of relatively younger and smaller trees.

Subunit Descriptions—Unit 7

ECN–1. The ECN–1 subunit consists of approximately 101,661 ac (41,141 ha) in Whatcom, Skagit, and Okanogan Counties, Washington, and comprises lands managed by USFS. The USFS manages 60,173 ac (24,351 ha) as Late-successional Reserves to maintain functional, interactive, late-successional and old-growth forest ecosystems and 22,802 ac (9,228 ha) under the matrix land use allocation where multiple uses occur, including most timber harvest and other silvicultural activities. Threats in this subunit include current and past timber harvest; competition with barred owls; removal or modification of habitat by forest fires, insects, and diseases; steep topography with high-elevation ridges that separate relatively small, linear strips of suitable habitat in valley bottoms; and location at the northeastern limit of the range of the subspecies. This subunit is expected to provide demographic support of the overall population and maintain the subspecies distribution in the northeastern portion of its range. ECN–1 is located primarily in the watershed of the Methow River and includes a small portion of the upper Skagit River watershed. It is bounded on the north by the international boundary with British Columbia, Canada.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 41 percent of the area of ECN–1 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

ECN–2. The ECN–2 subunit consists of approximately 60,128 ac (24,333 ha) in Chelan County, Washington, and comprises lands managed by USFS. The USFS manages 35,835 ac (14,502 ha) as Late-successional Reserves to maintain functional, interactive, late-successional and old-growth forest ecosystems and 17,545 ac (7,100 ha) under the matrix land use allocation where multiple uses occur, including most timber harvest and other silvicultural activities. Threats in this subunit include current and past timber harvest; competition with barred owls; steep topography with high-elevation ridges that separate relatively small, linear strips of suitable habitat in valley bottoms; the combination of Lake Chelan and the Sawtooth Mountains acting as a barrier to dispersal; and removal or modification of habitat by forest fires, insects, and diseases. This subunit is expected to provide demographic support of the overall population. ECN–2 is located primarily in the watersheds of the Chelan and Entiat Rivers.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 34 percent of the area of ECN–2 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

ECN–3. The ECN–3 subunit consists of approximately 301,219 ac (121,899 ha) in Chelan County, Washington, and comprises lands managed by the USFS and private landowners. The USFS manages 187,103 ac (75,718 ha) as Late-successional Reserves to maintain functional, interactive, late-successional and old-growth forest ecosystems and 114,117 ac (46,181 ha) under the matrix land use allocation where multiple uses occur, including most timber harvest and other silvicultural activities. Threats in this subunit include current and past timber harvest, competition with barred owls, and removal or modification of habitat by forest fires, insects, and diseases. This subunit is expected to provide demographic support of the overall population. ECN–3 is located primarily in the watershed of the Wenatchee River. In this subunit, we have excluded private lands and lands covered under the Washington Department of Natural Resources State Lands HCP.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 71 percent of the area of ECN–3 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

ECN–4. The ECN–4 subunit consists of approximately 222,818 ac (90,171 ha) in Kittitas County, Washington, and comprises lands managed by the USFS and the State of Washington. The USFS manages 99,641 ac (40,323 ha) as Late-successional Reserves to maintain functional, interactive, late-successional, and old-growth forest ecosystems and 118,676 ac (48,027 ha) under the matrix land use allocation where multiple uses occur, including most timber harvest and other silvicultural activities. The Washington Department of Fish and Wildlife manages 4,498 ac (1,820 ha). Threats in this subunit include current and past timber harvest, competition with barred owls, and removal or modification of habitat by forest fires, insects, and diseases. This subunit is expected to provide demographic support of the overall population. This subunit also has a key role in maintaining connectivity between northern spotted owl populations, both north to south in the East Cascades North Unit and west to east between the West and East Cascades units. This role is shared with the WCN–2 subunit and the WCC–1 subunit to the west. ECN–4 is located primarily in the Upper Yakima River watershed. In this subunit, we have excluded private lands and lands covered under the Washington Department of Natural Resources State Lands HCP and the Plum Creek Timber Central Cascades HCP.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 78 percent of the area of ECN–4 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

ECN–5. The ECN–5 subunit consists of approximately 201,108 ac (81,415 ha) in Kittitas and Yakima Counties, Washington, and comprises lands managed by the USFS and the State of Washington. The USFS manages 115,289 ac (46,656 ha) as Late-successional Reserves to maintain functional, interactive, late-successional, and old-growth forest ecosystems and 83,849 ac (33,933 ha) under the matrix land use allocation where multiple uses occur, including most timber harvest and other silvicultural activities. Threats in this subunit include current and past timber harvest, competition with barred owls, and removal or modification of habitat by forest fires, insects, and diseases. This subunit is expected to provide demographic support of the overall population. ECN–5 is located primarily in the watershed of the Naches River. In this subunit, we have excluded from final critical habitat designation lands covered under the Washington Department of Natural Resources State Lands HCP, the Plum Creek Timber Central Cascades HCP, and private lands.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 85 percent of the area of ECN–5 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

ECN–6. The ECN–6 subunit consists of approximately 81,852 ac (33,124 ha) in Skamania, Yakima, and Klickitat Counties, Washington, and comprises lands managed by the USFS and the State of Washington. The USFS manages 32,400 ac (13,112 ha) as Late-successional Reserves to maintain functional, interactive, late-successional, and old-growth forest ecosystems; and 49,452 ac (20,012 ha) under the matrix land use allocation where multiple uses occur, including most timber harvest and other silvicultural activities. Threats in this subunit include current and past timber harvest, competition with barred owls, and the Columbia River as an impediment to northern spotted owl dispersal. This subunit is expected to provide demographic support of the overall population. ECN–6 is located primarily in the watersheds of the Klickitat and White Salmon Rivers, and is bounded on the south by the Columbia River. In this subunit, we have excluded lands covered under the Washington Department of Natural Resources State Lands HCP as well as private lands from the final designation.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 88 percent of the area of ECN–6 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

ECN–7. The ECN–7 subunit consists of approximately 139,983 ac (56,649 ha) in Hood River and Wasco Counties, Oregon, and comprises only Federal lands managed by the USFS under the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest, removal or modification of habitat by forest fires and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function primarily for demographic support to the overall population, as well as north-south and east-west connectivity between subunits and critical habitat units.

Our evaluation of sites known to be occupied at the time of listing indicates that nearly 100 percent of the area of ECN–7 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

ECN–8. The ECN–8 subunit consists of approximately 94,622 ac (38,292 ha) in Jefferson and Deschutes Counties, Oregon, of Federal lands managed by the USFS under the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function primarily for demographic support to the overall population, as well as north-south connectivity between subunits.

Our evaluation of sites known to be occupied at the time of listing indicate that approximately 61 percent of the area of ECN–8 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

ECN–9. The ECN–9 subunit consists of approximately 155,434 ac (62,902 ha) in Deschutes and Klamath Counties, Oregon, and comprises only Federal lands managed by the USFS under the NWFP (USDA and USDI 1994). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function primarily for demographic support to the overall population, as well as north-south connectivity between subunits and critical habitat units.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 45 percent of the area of ECN–9 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

Unit 8: East Cascades South (ECS)

Unit 8 contains 368,381 ac (149,078 ha) and three subunits. This unit incorporates the Southern Cascades Ecological Section M261D, based on section descriptions of forest types from Ecological Subregions of the United States (McNab and Avers 1994c, Section M261D) and the eastern slopes of the Cascades from the Crescent Ranger District of the Deschutes National Forest south to the Shasta area. Topography is gentler and less dissected than the glaciated northern section of the eastern Cascades. A large expanse of recent volcanic soils (pumice region) (Franklin and Dyrness 1988, pp. 25–26), large areas of lodgepole pine, and increasing presence of red fir (*Abies magnifica*) and white fir (and decreasing grand fir) along a south-trending gradient further supported separation of this region from the northern portion of the eastern Cascades. This region is characterized by a continental climate (cold, snowy winters and dry summers) and a high-frequency/low-mixed severity fire regime. Ponderosa pine is a dominant forest type at mid-to-lower elevations, with a narrow band of Douglas-fir and white fir at middle elevations providing the majority of northern spotted owl habitat. Dwarf mistletoe provides an important component of nesting habitat, enabling northern spotted owls to nest within stands of relatively younger, smaller trees.

Subunit Descriptions—Unit 8

ECS–1. The ECS–1 subunit consists of approximately 127,801 ac (51,719 ha) in Klamath, Jackson, and Douglas Counties, Oregon, and comprises lands managed by the BLM and the USFS. Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function primarily for demographic support to the overall population, as well as north-south and east-west connectivity between subunits and critical habitat units. This subunit is adjacent to ECS–2 to the south.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 78 percent of the area of ECS–1 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

ECS–2. The ECS–2 subunit consists of approximately 66,086 ac (26,744 ha) in Klamath and Jackson Counties, Oregon, and Siskiyou County, California, all of which are Federal lands managed by the BLM and USFS per the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function primarily for north-south connectivity between subunits, but also for demographic support in this area of sparse Federal land and sparse high-quality nesting habitat.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 77 percent of the area of ECS–2 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

ECS–3. The ECS–3 subunit consists of approximately 112,179 ac (45,397 ha) in Siskiyou County, California, all of which are Federal lands managed by the USFS per the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. The function of this subunit is to provide demographic support in this area of sparsely distributed high-quality habitat and Federal land, and to provide for population connectivity between subunits to the north and south.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 69 percent of the area of ECS–3 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider a large part of this subunit to have been occupied at the time of listing. There are some areas of younger forest in this subunit that may have been unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat in this subunit is especially important for providing essential connectivity between currently occupied areas to support the successful dispersal of northern spotted owls, and may also help to buffer northern spotted owls from competition with the barred owl.

Unit 9: Klamath West (KLW)

Unit 9 contains 1,197,389 ac (484,565 ha) and nine subunits. This unit consists of the western portion of the Klamath Mountains Ecological Section M261A, based on section descriptions of forest types from Ecological Subregions of the United States (McNab and Avers 1994c, Section M261A). A long north-south trending system of mountains (particularly South Fork Mountain) creates a rainshadow effect that separates this region from more mesic conditions to the west. This region is characterized by very high climatic and vegetative diversity resulting from steep gradients of elevation, dissected topography, and the influence of marine air (relatively high potential precipitation). These conditions support a highly diverse mix of mesic forest communities such as Pacific Douglas-fir, Douglas-fir tanoak, and mixed evergreen forest interspersed with more xeric forest types. Overall, the distribution of tanoak is a dominant factor distinguishing the Western Klamath Region. Douglas-fir dwarf mistletoe is uncommon and seldom used for nesting platforms by northern spotted owls. The prey base of northern spotted owls within the Western Klamath is diverse, but dominated by woodrats and flying squirrels.

Subunit Descriptions—Unit 9

KLW–1. The KLW–1 subunit consists of approximately 147,326 ac (59,621 ha) in Douglas, Josephine, Curry, and Coos Counties, Oregon, and comprises lands managed by the State of Oregon and the BLM. Of this subunit 7,682 ac (3,109 ha) are managed by the State of Oregon for multiple uses including timber revenue production, recreation, and wildlife habitat according to the Southwest Oregon State Forests Management Plan (ODF 2010b, entire). Federal lands comprise 139,644 ac (56,512 ha) and are managed as directed by the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function for demographic support to the overall population and for north-south and east-west connectivity between subunits and critical habitat units. This subunit sits at the western edge of an important connectivity corridor between coastal Oregon and the western Cascades.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 96 percent of the area of KLW–1was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

KLW–2. The KLW–2 subunit consists of approximately 148,929 ac (60,674 ha) in Josephine, Curry, and Coos Counties, Oregon, and comprises lands managed by the USFS and the BLM as directed by the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function for demographic support to the overall population and for north-south and east-west connectivity between subunits and critical habitat units.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 71 percent of the area of KLW–2 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

KLW–3. The KLW–3 subunit consists of approximately 143,862 ac (58,219 ha) in Josephine, Curry, and Coos Counties, Oregon, and comprises lands managed by the USFS, the BLM and the State of Oregon. There are 142,982 ac (57,863 ha) of Federal lands managed as directed by the NWFP (USDA and USDI 1994, entire). The 880 ac (356 ha) of State of Oregon lands are managed according to the Southwest Oregon State Forests Management Plan (ODF 2010b, entire). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function for demographic support to the overall population and for north-south connectivity between subunits and critical habitat units.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 88 percent of the area of KLW–3 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

KLW–4. The KLW–4 subunit consists of approximately 158,299 ac (64,061 ha) in Josephine and Jackson Counties, Oregon, and Del Norte and Siskiyou Counties, California, and comprises lands managed by the USFS and the BLM that are managed as directed by the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function for demographic support to the overall population and for north-south and east-west connectivity between subunits and critical habitat units.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 95 percent of the area of KLW–4 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

KLW–5. The KLW–5 subunit consists of approximately 31,085 ac (12,580 ha) in Josephine County, Oregon, and Del Norte and Siskiyou Counties, California, all of which are Federal lands managed by the BLM and USFS per the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function for demographic support.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 98 percent of the area of KLW–5 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

KLW–6. The KLW–6 subunit consists of approximately 117,545 ac (47,569 ha) in Del Norte, Humboldt, and Siskiyou Counties, California, all of which are Federal lands managed by the USFS as directed by the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function for demographic support.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 91 percent of the area of KLW–6 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

KLW–7. The KLW–7 subunit consists of approximately 255,779 ac (103,510 ha) in Del Norte, Humboldt, and Siskiyou Counties, California, all of which are Federal lands managed by the BLM and USFS as directed by the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential or physical features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function for demographic support.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 91 percent of the area of KLW–7 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

KLW–8. The KLW–8 subunit consists of approximately 114,287 ac (46,250 ha) in Siskiyou and Trinity Counties, California, all of which are Federal lands managed by the BLM and USFS as directed by the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function for demographic support.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 85 percent of the area of KLW–8 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

KLW–9. The KLW–9 subunit consists of approximately 149,656 ac (60,564 ha) in Humboldt and Trinity Counties, California, all of which are Federal lands managed by the USFS as directed by the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function for demographic support.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 89 percent of the area of KLW–9 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

Unit 10: Klamath East (KLE)

Unit 10 contains 1,052,731ac (426,025ha) and seven subunits. This unit consists of the eastern portion of the Klamath Mountains Ecological Section M261A, based on section descriptions of forest types from Ecological Subregions of the United States (McNab and Avers 1994c, Section M261A), and portions of the Southern Cascades Ecological Section M261D in Oregon. This region is characterized by a Mediterranean climate, greatly reduced influence of marine air, and steep, dissected terrain. Franklin and Dyrness (1988, pp. 137–149) differentiate the mixed-conifer forest occurring on the ‘‘Cascade side of the Klamath from the more mesic mixed evergreen forests on the western portion (Siskiyou Mountains),’’ and Kuchler (1977) separates out the eastern Klamath based on increased occurrence of ponderosa pine. The mixed-conifer/evergreen hardwood forest types typical of the Klamath region extend into the southern Cascades in the vicinity of Roseburg and the North Umpqua River, where they grade into the western hemlock forest typical of the Cascades. High summer temperatures and a mosaic of open forest conditions and Oregon white oak (*Quercus garryana*) woodlands act to influence northern spotted owl distribution in this region. Northern spotted owls occur at elevations up to 1,768 m. Dwarf mistletoe provides an important component of nesting habitat, providing additional structure and enabling northern spotted owls to occasionally nest within stands of relatively younger, small trees.

Subunit Descriptions—Unit 10

KLE–1. The KLE–1 subunit consists of approximately 242,338 ac (98,071 ha) in Jackson and Douglas Counties, Oregon, and comprises Federal lands managed by the USFS and the BLM under the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function primarily for demographic support to the overall population, as well as north-south and east-west connectivity between subunits and critical habitat units.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 84 percent of the area of KLE–1 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

KLE–2. The KLE–2 subunit consists of approximately 101,942 ac (41,255 ha) in Josephine and Douglas Counties, Oregon, and comprises Federal lands managed by the USFS and the BLM under the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function primarily for east-west connectivity between subunits and critical habitat units, but also for demographic support. This subunit facilitates northern spotted owl movements between the western Cascades and coastal Oregon and the Klamath Mountains.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 92 percent of the area of KLE–2 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

KLE–3. The KLE–3 subunit consists of approximately 111,410 ac (45,086 ha) in Jackson, Josephine, and Douglas Counties, Oregon, and comprises Federal lands managed by the USFS and the BLM under the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function primarily for east-west connectivity between subunits and critical habitat units, but also for demographic support. This subunit facilitates northern spotted owl movements between the western Cascades and coastal Oregon and the Klamath Mountains.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 97 percent of the area of KLE–3 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

KLE–4. The KLE–4 subunit consists of approximately 254,442 ac (102,969 ha) in Jackson, Klamath, and Douglas Counties, Oregon, and comprises Federal lands managed by the USFS and the BLM under the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function primarily for east-west connectivity between subunits and critical habitat units, but also for demographic support.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 81 percent of the area of KLE–4 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

KLE–5. The KLE–5 subunit consists of approximately 38,283 ac (15,493 ha) in Jackson County, Oregon, and comprises lands managed by the BLM and USFS. The BLM and USFS lands are managed per the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function primarily for north-south connectivity between subunits, but also for demographic support.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 86 percent of the area of KLE–5 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

KLE–6. The KLE–6 subunit consists of approximately 167,849 ac (67,926 ha) in Jackson County, Oregon, and Siskiyou County, California, all of which are Federal lands managed by the BLM and USFS per the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function primarily for north-south connectivity between subunits, but also for demographic support.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 97 percent of the area of KLE–6 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

KLE–7. The KLE–7 subunit consists of approximately 66,078 ac (26,741 ha) in Siskiyou County, California, all of which are Federal lands managed by the BLM and USFS per the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function for demographic support and also for connectivity across the landscape.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 96 percent of the area of KLE–7 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

Unit 11: Interior California Coast (ICC)

Unit 11 contains 941,568 ac (381,039 ha) and eight subunits. This unit consists of the Northern California Coast Ranges ecological Section M261B, based on section descriptions of forest types from Ecological Subregions of the United States (McNab and Avers 1994c, Section M261B), and differs markedly from the adjacent redwood coast region. Marine air moderates winter climate, but precipitation is limited by rainshadow effects from steep elevational gradients (328 to 7,847 ft (100 to 2,400 m)) along a series of north-south trending mountain ridges. Due to the influence of the adjacent Central Valley, summer temperatures in the interior portions of this region are among the highest within the northern spotted owl's range. Forest communities tend to be relatively dry mixed-conifer, blue and Oregon white oak, and the Douglas-fir tanoak series. Northern spotted owl habitat within this region is poorly known; there are no Demographic Study Areas (DSAs—areas within forested habitats specifically surveyed to determine northern spotted owl occupation and density), and few studies have been conducted here. Northern spotted owl habitat and occupancy data obtained during this project suggests that some northern spotted owls occupy steep canyons dominated by live oak and Douglas-fir. The distribution of dense conifer habitats most suitable for the northern spotted owl is limited to higher elevations on the Mendocino National Forest.

Subunit Descriptions—Unit 11

ICC–1. The ICC–1 subunit consists of approximately 332,042 ac (134,372 ha) in Humboldt, Trinity, Shasta, and Tehama Counties, California, all of which are Federal lands managed by the BLM and the USFS per the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function primarily for demographic support, but also for connectivity between subunits and critical habitat units.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 97 percent of the area of ICC–1 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

ICC–2. The ICC–2 subunit consists of approximately 204,400 ac (82,718 ha) in Humboldt and Trinity Counties, California, all of which are Federal lands managed by the BLM and the USFS per the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function primarily for demographic support, but also for connectivity between subunits and critical habitat units.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 98 percent of the area of ICC–2 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

ICC–3. The ICC–3 subunit consists of approximately 103,971 ac (42,035 ha) in Trinity, Tehama, and Mendocino Counties, California, all of which are Federal lands managed by the BLM and the USFS per the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function primarily for demographic support, but also for north-south connectivity between subunits.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 89 percent of the area of ICC–3 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

ICC–4. The ICC–4 subunit consists of approximately 120,997 ac (48,966 ha) in Mendocino, Glenn, and Colusa Counties, California, all of which are Federal lands managed by the BLM and USFS per the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function primarily for demographic support.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 93 percent of the area of ICC–4 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

ICC–5. The ICC–5 subunit consists of approximately 34,957 ac (14,147 ha) in Lake and Mendocino Counties, California, all of which are Federal lands managed by the USFS and BLM per the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function primarily for demographic support, but also for connectivity between subunits and critical habitat units.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 78 percent of the area of ICC–5 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

ICC–6. The ICC–6 subunit consists of approximately 2,072 ac (839 ha) of State and Federal lands in Napa and Sonoma Counties, California.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 90 percent of the area of ICC–6 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

ICC–7. The ICC–7 subunit consists of approximately 119,742 ac (48,458 ha) in Trinity and Shasta Counties, California, all of which are Federal lands managed by the BLM and USFS per the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats to the essential physical or biological features from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function both for demographic support and for east-west connectivity between subunits in an area of sparse Federal ownership.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 73 percent of the area of ICC–7 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

ICC–8. The ICC–8 subunit consists of approximately 83,376 ac (33,742 ha) in Siskiyou and Shasta Counties, California, all of which are Federal lands managed by the BLM and the USFS per the NWFP (USDA and USDI 1994, entire). Special management considerations or protection are required in this subunit to address threats from current and past timber harvest, losses due to wildfire and the effects on vegetation from fire exclusion, and competition with barred owls. This subunit is expected to function both for demographic support and for connectivity between subunits in an area of sparse Federal ownership.

Our evaluation of sites known to be occupied at the time of listing indicates that approximately 84 percent of the area of ICC–8 was covered by verified northern spotted owl home ranges at the time of listing. When combined with likely occupancy of suitable habitat and occupancy by nonterritorial owls and dispersing subadults, we consider this subunit to have been largely occupied at the time of listing. In addition, there may be some smaller areas of younger forest within the habitat mosaic of this subunit that were unoccupied at the time of listing. We have determined that all of the unoccupied and likely occupied areas in this subunit are essential for the conservation of the species to meet the recovery criterion that calls for the continued maintenance and recruitment of northern spotted owl habitat (USFWS 2011, p. ix). The increase and enhancement of northern spotted owl habitat is necessary to provide for viable populations of northern spotted owls over the long term by providing for population growth, successful dispersal, and buffering from competition with the barred owl.

IX. Effects of Critical Habitat Designation

Section 7 Consultation

Section 7(a)(2) of the Act requires Federal agencies, including the Service, to ensure that any action they fund, authorize, or carry out is not likely to jeopardize the continued existence of any endangered species or threatened species or result in the destruction or determinations of designated critical habitat of such species. Decisions by the Fifth and Ninth Circuit Courts of Appeals have invalidated our regulatory definition of ''destruction or adverse modification'' (50 CFR 402.02) (*Gifford Pinchot Task Force* v. *U.S. Fish and Wildlife Service,* 378 F. 3d 1059 (9th Cir. 2004); *Sierra Club* v. *U.S. Fish and Wildlife Service.,* 245 F.3d 434, 442 (5th Cir. 2001)), and we do not rely on this regulatory definition when analyzing whether an action is likely to destroy or adversely modify critical habitat. Under the statutory provisions of the Act, we determine destruction or adverse modification on the basis of whether, with implementation of the proposed Federal action, the affected critical habitat would continue to serve its intended conservation function or purpose for the species.

If a Federal action may affect a listed species or its critical habitat, the responsible Federal agency (action agency) must enter into consultation with the Service. Examples of actions that are subject to the section 7 consultation process are actions on State, Indian, local, or private lands that require a Federal permit (such as a permit from the U.S. Army Corps of Engineers under section 404 of the Clean Water Act (33 U.S.C. 1251 *et seq.*) or a permit from the Service under section 10 of the Act) or that involve some other Federal action (such as funding from the Federal Highway Administration, Federal Aviation Administration, or the Federal Emergency Management Agency). Federal actions not affecting listed species or critical habitat, and actions on State, Indian, local, or private lands that are not federally funded or federally authorized do not require section 7 consultation.

Section 7 consultation results in issuance of:

(1) A concurrence letter for Federal actions that may affect, but are not likely to adversely affect, listed species or critical habitat; or

(2) A biological opinion for Federal actions that may affect, and are likely to adversely affect, listed species or critical habitat.

When we issue a biological opinion concluding that a project is likely to jeopardize the continued existence of a listed species and/or destroy or adversely modify critical habitat, we provide reasonable and prudent alternatives to the project, if any are identifiable, that would avoid the likelihood of jeopardy and/or destruction or adverse modification of critical habitat. We define ''reasonable and prudent alternatives'' (at 50 CFR 402.02) as alternative actions identified during consultation that:

(1) Can be implemented in a manner consistent with the intended purpose of the action,

(2) Can be implemented consistent with the scope of the Federal agency's legal authority and jurisdiction,

(3) Are economically and technologically feasible, and

(4) Would, in the Director's opinion, avoid the likelihood of jeopardizing the continued existence of the listed species and/or avoid the likelihood of destroying or adversely modifying critical habitat.

Reasonable and prudent alternatives can vary from slight project modifications to extensive redesign or relocation of the project. Costs associated with implementing a reasonable and prudent alternative are similarly variable.

Regulations at 50 CFR 402.16 require Federal agencies to reinitiate consultation on previously reviewed actions in instances where we have listed a new species or subsequently designated critical habitat that may be affected, and the Federal agency has retained discretionary involvement or control over the action, or the agency's discretionary involvement or control is authorized by law. Consequently, Federal agencies sometimes may need to request reinitiation of consultation with us on actions for which formal consultation has been completed, if those actions with discretionary involvement or control may affect subsequently listed species or designated critical habitat.

Determinations of Adverse Effects and Application of the ''Adverse Modification'' Standard

The key factor involved in the destruction/adverse modification determination for a proposed Federal agency action is whether the affected critical habitat would continue to serve its intended conservation function or purpose for the species with implementation of the proposed action after taking into account any anticipated cumulative effects (USFWS 2004, *in litt.* entire). Activities that may destroy or adversely modify critical habitat are those that alter the physical or biological features to an extent that appreciably reduces the conservation value of critical habitat for the northern spotted owl. As discussed above, the role of critical habitat is to support life-history needs of the species and provide for the conservation of the species.

Section 4(b)(8) of the Act requires us to briefly evaluate and describe, in any proposed or final regulation that designates critical habitat, activities involving a Federal action that may destroy or adversely modify such habitat, or that may be affected by such designation.

Activities that may affect critical habitat, when carried out, funded, or authorized by a Federal agency, should result in consultation for the northern spotted owl under section 7(a)(2) of the Act. In general, there are five possible outcomes in terms of how proposed Federal actions may affect the PCEs or physical or biological features of northern spotted owl critical habitat or essential habitat qualities associated with that critical habitat area: (1) No effect; (2) wholly beneficial effects (e.g., improve habitat condition); (3) both short-term adverse effects and long-term beneficial effects; (4) insignificant or discountable adverse effects; or (5) wholly adverse effects. Actions with no effect on the PCEs and physical or biological features of occupied areas or the essential habitat qualities in unoccupied areas do not require section 7 consultation, although such actions may still require consultation if they have effects on the species itself as a result of its status as a threatened species under the Act. Actions with effects to the PCEs, physical or biological features, or other essential habitat qualities of northern spotted owl critical habitat that are discountable, insignificant, or wholly beneficial would be considered not likely to adversely affect critical habitat, and do not require formal consultation if the Service concurs in writing with that Federal action agency determination. Actions that are likely to adversely affect the physical or biological features or other essential habitat qualities of northern spotted owl critical habitat require formal consultation and the preparation of a Biological Opinion by the Service. The Biological Opinion sets forth the basis for our section 7(a)(2) determination as to whether the proposed Federal action is likely to destroy or adversely modify northern spotted owl critical habitat.

Activities that may destroy or adversely modify critical habitat are those that alter the essential physical or biological features or other essential habitat qualities of the critical habitat to an extent that appreciably reduces the conservation value of the critical habitat for the listed species. As discussed above, the conservation role or value of northern spotted owl critical habitat is to adequately support the life-history needs of the species to the extent that well-distributed and interconnected northern spotted owl nesting populations are likely to persist within properly functioning ecosystems at the critical habitat unit and range-wide scales.

Proposed Federal actions that may affect northern spotted owl critical habitat will trigger the consultation requirements under section 7 of the Act and compliance with the section 7(a)(2) standard described above. The consultation process evaluates the effects of a proposed action to designated critical habitat regardless of the species' presence or absence. For an action that may affect critical habitat, the next step is to determine whether it is likely to adversely affect critical habitat. For example, where a project is designed to reduce fuels such that the effect of wildfires will be reduced, but will also reduce foraging opportunities within treatment areas, established interagency consultation teams should determine whether the proposed project has more than an insignificant impact on the foraging PCEs for northern spotted owls. A localized reduction in foraging habitat within a stand may have such an insignificant impact on foraging PCEs within the stand that a not likely to adversely affect determination is appropriate. Similarly, a hazard tree removal project in a stand with many suitable nest trees may have such a minimal reduction in nesting PCEs of that stand that the effect to nesting habitat is insignificant. In such a case, a ''not likely to adversely affect'' determination would be appropriate.

For actions that are likely to adversely affect critical habitat, the agencies will enter into formal consultation. At this stage of consultation, scale and context are especially important in evaluating the potential effects of forest management on northern spotted owl habitat. The degree to which various forest management activities are likely to affect the capability of the critical habitat to support northern spotted owl nesting, roosting, foraging, or dispersal will vary depending on factors such as the scope and location of the action, and the quantity of the critical habitat affected. In addition, in analyzing whether an action will likely destroy or adversely modify critical habitat, the effects of the action on the factors that were the basis for determining the area to meet the definition of critical habitat should be considered.

In general, we would anticipate that management actions that are consistent with the overall purpose for which a critical habitat unit was designated would not likely destroy or adversely modify critical habitat as those terms are used in the context of section 7(a)(2) of the Act. Such actions include activities whose intent is to restore ecological processes or long-term forest health to forested landscapes that contain northern spotted owl habitat, such as those actions described in the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011) and elsewhere in this document. However, each proposed action will be considered on a case-by-case basis.

Section 7 Process Under This Critical Habitat Rule

The Presidential Memo, dated February 28, 2012 (77 FR 12985; March 5, 2012), directed the Service to address six action items in the final revised critical habitat rule for the northern spotted owl. One item in the Memo called for the Service to develop clear direction ''for evaluating logging activity in areas of critical habitat, in accordance with the scientific principles of active forestry management and to the extent permitted by law.'' The following summarizes the evaluation process for logging activities in areas of northern spotted owl critical habitat under section 7 of the Act and its implementing regulations, and our plans for close coordination with the land management agencies to best meet the dual goals of recovering the northern spotted owl and managing our public forest lands for multiple use.

Coordination With Land Management Agencies

The Service is committed to working closely with the U.S. Forest Service and BLM to implement the active management and ecological forestry concepts discussed in the Revised Recovery Plan and this critical habitat rule. Both recommend that land managers use the best science to maintain and restore forest health and resilience in the face of climate change and other challenges.

To meet this goal, we have prioritized the timely review of forestry projects that will be proposed in critical habitat. We have already completed section 7 conference opinions on the proposed rule with the agencies, and have recently held interagency coordination meetings with the section 7 Level 1 staff in Oregon, Washington, and California. In these meetings, we identified ways to streamline the section 7 process to ensure that potential projects can be implemented in a timely manner consistent with northern spotted owl conservation. We are also closely involved in and supportive of the respective Forest Service and BLM landscape-level planning efforts currently underway, and will work with the agencies to incorporate the conservation planning recommended in the Revised Recovery Plan and discussed in this final critical habitat designation.

Finally, appropriate Service staff have been directed that all levels of management and field teams stay fully engaged in this process to ensure these commitments are met.

Determining Whether an Action Is Likely to Adversely Affect Critical Habitat

The 1992 northern spotted owl critical habitat rule (57 FR 1796; January 15, 1992) identified the primary constituent element (PCE) as the fundamental scale of analysis at which the ''evaluation of actions that may affect critical habitat for the northern spotted owl'' should occur. Those elements included nesting, roosting, foraging and dispersal habitats. In the 2008 northern spotted owl critical habitat rule (73 FR 47326; August 13, 2008), the forested stand is identified as the appropriate scale for determining whether an action was likely to adversely affect northern spotted owl critical habitat. The 2012 proposed revised critical habitat rule identified a 500-ac (200-ha) circle as a logical scale for determining the effects of a timber sale to critical habitat because research shows northern spotted owls respond more favorably to an area larger than a single tree when choosing where to live.

However, there are many variables to be considered when determining whether the effects to critical habitat are adverse or not. When making a determination as to whether an action is likely to adversely affect critical habitat, and thus require formal consultation, it is not possible to design a ''one size fits all'' set of rules due to differences in project types, habitat types, and habitat needs across the range of the species (Fontaine and Kennedy 2012, p. 1559). This determination should be conducted at a scale that is relevant to the northern spotted owl life-history functions supplied by the PCEs and affected by the project. We note that this more localized scale differs from that used in determining whether an action will destroy or adversely modify critical habitat, which is made at the scale of the designated critical habitat, as described further below.

Northern spotted owl critical habitat PCE 4 (habitat to support the transience and colonization phases of dispersal) provides a life-history need that functions at a landscape-level scale and should be assessed at a larger scale than the other PCEs. Potential scales of analysis include the local watershed (e.g., fifth-field watershed) or subwatershed (e.g., sixth-field watershed), a dispersal corridor, or a relevant landform. Both PCE 2 (habitat that provides for nesting and roosting) and PCE 3 (habitat that provides for foraging) provide life-history needs that function at a more localized landscape, which should help inform the scale at which the determination of whether an action will likely adversely affect critical habitat should be conducted. We encourage the level one consultation teams to tailor this scale of the effects determination to the localized biology of the life-history needs of the northern spotted owl (such as the stand scale, a 500-ac (200-ha) circle, or other appropriate, localized scale).

If a project produces an effect on critical habitat that is wholly beneficial, insignificant, or discountable, then the project is not likely to adversely affect critical habitat, and consultation would be concluded with a letter of concurrence. Wholly beneficial effects include those that actively promote the development or improve the functionality of critical habitat for the northern spotted owl without causing adverse effects to the PCEs. Such actions might involve variable-density thinning in forest stands that do not currently support nesting, roosting, or foraging habitat for the northern spotted owl, which would speed the development of these types of habitats, while maintaining dispersal habitat function. Thinning or other treatments in young plantations that are specifically designed to accelerate the development of owl habitat, and either are in areas that do not provide dispersal habitat or where the effects to dispersal capability would be insignificant or discountable, would also fall into the ''not likely to adversely affect'' category. While these wholly beneficial actions may affect critical habitat and would, therefore, require consultation under section 7 of the Act, they most likely would be completed via an informal consultation with a determination that they are not likely to adversely affect critical habitat.

Likewise, if the adverse effects of a proposed Federal action on the life-history needs supported by physical or biological features of northern spotted owl critical habitat are expected to be discountable or insignificant, that action would also be considered not likely to adversely affect northern spotted owl critical habitat. In such cases, the section 7 consultation requirements can also be satisfied through the informal concurrence process. Examples of such actions may include: Pre-commercial or commercial thinning that does not delay the development of essential physical or biological features; fuel-reduction treatments that have a negligible effect on northern spotted owl foraging habitat within the stand; and the removal of hazard trees, where the removal has an insignificant effect on the capability of the stand to provide northern spotted owl nesting opportunities.

Some proposed Federal forest management activities may have short-term adverse effects and long-term beneficial effects on the physical or biological features of northern spotted owl critical habitat. The Revised Recovery Plan for the Northern Spotted Owl recommends that land managers actively manage portions of both moist and dry forests to improve stand conditions and forest resiliency, which should benefit the long-term recovery of the northern spotted owl (USFWS 2011, p. III–11). For example, variable thinning in single-story, uniform forest stands to promote the development of multistory structure and nest trees may result in short-term adverse impacts to the habitat's current capability to support owl dispersal and foraging, but have long-term benefits by creating higher quality habitat that will better support territorial pairs of northern spotted owls. Such activities would have less impact in areas where foraging and dispersal habitat is not limiting, and ideally can be conducted in a manner that minimizes short-term negative impacts. Even though they may have long-term beneficial effects, if they have short-term adverse effects, such actions may adversely affect critical habitat, and would require formal consultation under section 7 of the Act. For efficiency, such actions may be evaluated under section 7 programmatically at the landscape scale (e.g., USFS or BLM District).

Habitat conditions in moist/wet and dry/fire-prone forests within the range of the northern spotted owl vary widely, as do the types of management activities designed to accelerate or enhance the development of northern spotted owl habitat. ''Wet'' and ''dry'' are ends of a spectrum, not distinct categories that adequately describe the full range of forest types within the range of the northern spotted owl. Because these categories are broad, and conditions on the ground are more variable, land managers and cooperators should have the expectation that multiple forest types may be involved, and similar projects in different forest types may not always lead to the same effect determination for purposes of compliance with section 7 of the Act.

To make effects determinations, we recommend generating area-specific maps showing the current habitat condition (such as types of habitat, known nest trees, or other feature) and, using information on the proposed action (such as location, type and intensity of harvest, location of new roads and landings, or other proposed activity effects), produce a post-project habitat map such that the pre- and post-project comparison of the PCEs can be assessed. We also recommend the cooperative development of a spatial and temporal framework for evaluating the impact of both the short- and long-term effects of the proposed activities on the northern spotted owl. Framework examples include a landscape assessment or a checklist of key questions the answers to which will illustrate how the project will impact the northern spotted owl (see Spies *et al.* 2012, p. 11, for an example).

Determining Whether an Action Will Destroy or Adversely Modify Critical Habitat

If the effects of the project have more than an insignificant or discountable impact on the ability of the PCEs to provide life-history functions for the northern spotted owl, then the project is likely to adversely affect northern spotted owl critical habitat, and formal consultation is warranted. For projects that will adversely affect critical habitat, it is the Service's responsibility to conduct an analysis of whether the action is likely to ''destroy or adversely modify critical habitat'' during the formal consultation process. As discussed below, the determination of whether an action is likely to destroy or adversely modify critical habitat is made at the scale of the entire critical habitat network. However, a proposed action that compromises the capability of a subunit or unit to fulfill its intended conservation function or purpose could represent an appreciable reduction in the conservation value of the entire designated critical habitat. Therefore, the biological opinion should describe the relationship between the conservation role of the action area, affected subunits, units, and the entire designated critical habitat. This analysis must incorporate all direct and indirect effects and any cumulative effects from the project within the action area. If, after the formal consultation analysis, it is determined that the proposed project will not destroy or adversely modify critical habitat, then the action can be conducted.

Factors to consider in evaluating whether activities, including timber harvest, are likely to destroy or adversely modify critical habitat pursuant to section 7 include:

- The extent of the proposed action, both its temporal and spatial scale, relative to the critical habitat subunit and unit within which it occurs, and the entire critical habitat network.
- The specific purpose for which the affected subunit was identified and designated as critical habitat.
- The cumulative effects of all completed activities in the critical habitat unit.
- The impact of the proposed action on the ability of the affected critical habitat to continue to support the life-history functions supplied by the PCEs.
- The impact of the proposed action on the subunit's likelihood of serving its intended conservation function or purpose.
- The impact of the proposed action on the unit's likelihood of continuing to contribute to the conservation of the species.
- The overall consistency of the proposed action with the intent of the recovery plan or other landscape-level conservation plans.
- The special importance of project scale and context in evaluating the potential effects of timber harvest to northern spotted owl critical habitat.

The first step is to describe the impacts to critical habitat in the action area with respect to the subunit's intended functions as identified in this rule. For example, if a particular subunit was designated to support northern spotted owl connectivity between subunits, then the loss or impact to connectivity must be assessed. Subunits that are expected to provide demographic support should be assessed for their ability to continue to support northern spotted owl nesting territories in conditions suitable for occupancy by pairs of owls (e.g., amount and location of nesting habitat, proximity of foraging habitat, etc.). The analysis should describe the extent to which the project is expected to prevent, preclude, or significantly impair the ability of that subunit to meet its intended function. The analysis should not incorporate the effect of the proposed action on individual northern spotted owls but, instead, on the life-history functions supplied by the PCEs and the physical biological features. Effects to northern spotted owls should be included in the effects to the species section of a biological opinion, as appropriate.

The analysis in a biological assessment or a biological opinion should include an evaluation of the type, frequency, magnitude, and duration of impacts likely to be caused by the action on the PCEs of the action area, affected subunits and critical habitat units, and an assessment of how those impacts are likely to influence the capability of the affected critical habitat units to provide for a well-distributed and self-sustaining northern spotted owl population. The analysis in a biological assessment or a biological opinion of cumulative effects on critical habitat should include a similar assessment for any future, non-Federal actions reasonably certain to occur in the action area, and at the level of the affected subunits and critical habitat units.

Consideration of the effects of the action, together with any cumulative effects, will form the basis for the biological opinion's determination as to whether the action will destroy or adversely modify critical habitat. In accordance with Service policy, the adverse modification determination is made at the scale of the entire designated critical habitat, unless the critical habitat rule identifies another basis for the analysis (FWS and NMFS 1998). The adverse modification determination for the northern spotted owl will occur at the scale of the entire designated critical habitat, as described below, with consideration given to the need to conserve viable populations within each of the recovery units identified in the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011, Recovery Criterion 2).

It is important to note that although the adverse modification determination is made at the scale of the entire designated critical habitat, a proposed action that compromises the capability of a subunit or unit to fulfill its intended conservation function or purpose could represent an appreciable reduction in the conservation value of the entire designated critical habitat. Therefore, the biological opinion should describe the relationship between the conservation role of the action area, affected subunits, units, and the entire designated critical habitat. In this way, the biological opinion establishes a sensitive analytical framework for informing the determination of whether a proposed action is likely to appreciably reduce the conservation role of critical habitat overall.

The Service has assured the BLM and FS that it is committed to working closely with them to evaluate and implement active management and ecological forestry concepts of the recovery plan and critical habitat rule into potential timber management projects. Both documents recommend that land managers use the best science to maintain and restore forest health and resilience in the face of climate change and other challenges.

To meet this goal we have prioritized the timely review of forestry projects that will be proposed in critical habitat. We have already completed section 7 conference opinions on the proposed rule with several of your units, and we have recently held interagency coordination meetings with the section 7 Level 1 staff in Oregon, Washington, and California. In these meetings, we identified ways to streamline the section 7 process to ensure that potential projects can be implemented in a timely manner consistent with northern spotted owl conservation. We are also closely involved in and supportive of the respective FS and BLM landscape-level planning efforts currently underway and will work with you to incorporate the conservation planning reflected in the revised recovery plan and the final critical habitat designation.

Finally, appropriate Service staff have been directed that all levels of management and field teams—from Level 1 biologists up to the Assistant Regional Director—stay fully engaged in this process to ensure these commitments are met. Any problems or disagreement should be promptly elevated and resolved.

Within dry forests, the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011) emphasizes active forest management that could meet overlapping goals of northern spotted owl conservation, climate change response, and restoration of dry forest ecological structure, composition, and process, including wildfire and other disturbances (USFWS 2011, pp. III–20). For the rest of the northern spotted owl's range that is not fire-prone, the Revised Recovery Plan emphasizes habitat management that accelerates the development of future habitat, restores larger habitat blocks, and reduces habitat fragmentation. The following discussion describes the type of management approaches that would be consistent with the Revised Recovery Plan in the West Cascades/Coast Ranges of Oregon and Washington, East Cascades, and the Redwood Coast zones, and in some cases includes consideration of possible corresponding effect determinations for activities implementing these approaches, for the purpose of analyzing effects to critical habitat under section 7 of the Act. The Klamath and Northern California Interior Coast Ranges regions contain conditions similar to the three regions discussed below, and similar management approaches would be consistent with the recovery needs of the owl.

West Cascades/Coast Ranges of Oregon and Washington

The primary goal of the Revised Recovery Plan for this portion of the northern spotted owl's range is to conserve stands that support northern spotted owl occupancy or contain high-value northern spotted owl habitat (USFWS 2011, p. III–17). Silvicultural treatments are generally not needed to accomplish this goal. However, there is a significant amount of younger forest that occurs between and around the older stands, where silvicultural treatments may accelerate the development of these stands into future northern spotted owl nesting habitat, even if doing so temporarily degrades existing dispersal habitat, as is recommended in Recovery Action 6 (USFWS 2011, p. III–19). The Revised Recovery Plan encourages silviculture designed to develop late-successional structural complexity and to promote resilience (USFWS 2011, pp. III–17 to III–19). Restoration or ecological prescriptions can help uniform stands of poor quality develop more quickly into more diverse, higher quality northern spotted owl habitat, and provide resiliency in the face of potential climate change impacts in the future. Targeted vegetation treatments could simultaneously increase canopy and age-class diversity, putting those stands on a more efficient trajectory towards nesting and roosting habitat, while reducing fuel loads. Introducing varying levels of spatial heterogeneity, both vertically and horizontally, into forest ecosystems can contribute to both of the goals stated above.

On matrix lands under the NWFP where land managers have a range of management goals, the Service anticipates that not all forest management projects in critical habitat will be focused on the development or conservation of northern spotted owl habitat. Ideally, proposed actions within critical habitat should occur on relatively small patches of younger, mid-seral forest stands that do not cause reductions in higher quality northern spotted owl habitat. They should also be planned in such a way that their net occurrence on the regional landscape is consistent with broader ecosystem-based planning targets (e.g., Spies *et al.* 2007a, entire) to provide the physical or biological features that are essential to the conservation of the northern spotted owl. Within that context, thinning and targeted variable-retention harvest in moist forests could be considered where the conservation of complex early-seral forest habitat is a management goal. This approach provides a contrast to traditional clearcutting that does not mimic natural disturbance or create viable early-seral communities that grow into high-quality habitat (Dodson *et al.* 2012, p. 353; Franklin *et al.* 2002,

p. 419; Swanson *et al.* 2011, p. 123; Kane *et al.* 2011, pp. 2289–2290; Betts *et al.* 2010, p. 2127, Hagar 2007, pp. 117–118). Swanson (2012, entire) provides a good overview and some management considerations.

In cases where these moist forest treatments in matrix are intended to meet management goals other than northern spotted owl conservation, they can be designed to enable the development of northern spotted owl habitat over time at the landscape scale. If planned well at this scale, these projects may have short-term adverse effects, but are not expected to adversely modify the role and function of critical habitat units. In other words, such treatments can be dispersed across the landscape and over time to both accommodate northern spotted owl habitat needs and conservation of diverse and complex early-seral habitat. Additional information about ecological forestry activities in moist forests can be found in the Revised Recovery Plan under *Northern Spotted Owls and Ecological Forestry* (USFWS 2011, p. III–11) and *Habitat Management in Moist Forests* (USFWS 2011, p. III–17).

East Cascades

The Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011) recommends that the dynamic, fire-prone portion of the northern spotted owl's range be actively managed to conserve northern spotted owls, but also address climate change and restore dry forest ecological structure, composition, and processes (*e.g.,* wildfire) to provide for the long-term conservation of the species and its habitat in a dynamic ecosystem (USFWS 2011, pp. III–13, III–20). To do this, management actions should be considered to balance short-term adverse effects with long-term beneficial effects. In some cases, formal consultation on the effects of dry forest management activities on northern spotted owl critical habitat is likely to occur; in other cases, there may be no adverse effects and consultation can be concluded informally.

Management in dry forests should increase the likelihood that northern spotted owl habitat will remain on the landscape longer and develop as part of the dynamic fire- and disturbance-adapted community. Several management approaches can be described for these systems. The first is to maintain adequate northern spotted owl habitat in the near term to allow owls to persist on the landscape in the face of threats from barred owl expansion and habitat alterations from fire and other disturbances. The next is to restore landscapes that are resilient to fire and other disturbances, including those projected to occur with climate change. This will require more than reducing fuels and thinning trees to promote low-severity fires; management will need to develop ''more natural patterns and patch size distributions of forest structure, composition, fuels, and fire regime area'' (Hessburg *et al.* 2007, p. 21).

Our prime objective for vegetation management activities within northern spotted owl critical habitat is to maintain adequate amounts of nesting, roosting, foraging, or dispersal habitat where it currently exists, and to restore degraded habitat where it is essential to the owl and can be best sustained on the landscape, as recommended in the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011, Section III). Successfully accomplishing these objectives can be facilitated by spatially and temporally explicit landscape assessments that identify areas valuable for northern spotted owl conservation and recovery, as well as areas important for process restoration (*e.g.,* Prather *et al.* 2008, p. 149; Franklin *et al.* 2008, p. 46; Spies *et al.* 2012, entire). Such assessments could answer questions that are frequently asked about proposed forest management activities, namely ''why here?'' and ''why now?'' Providing well-reasoned responses to these questions becomes especially important when restoration activities degrade or remove existing northern spotted owl habitat. By scaling up conservation and restoration planning from the stand to the landscape level, many apparent conflicts may disappear because management actions can be prioritized and spatially partitioned (Prather *et al.* 2008, p. 149; Rieman *et al.* 2010, p. 464). For example, portions of the landscape can be identified where there may be no conflict between objectives, and where relatively aggressive approaches to ecosystem restoration can occur without placing listed species at substantial risk (Prather *et al.* 2008, pp. 147–149; Gaines *et al.* 2010, pp. 2049–2050). Conflicts between objectives will remain in some locations, such as in places where removing younger, shade-intolerant conifers to reduce competition with larger, legacy conifers may result in a substantial decrease in canopy cover that translates into a reduction in northern spotted owl habitat quality. However, when this sort of treatment is well designed, strategically located, and justified within a landscape approach to treatments, it is easier to assess its effectiveness in meeting both owl conservation and forest restoration needs.

Landscape assessments developed at the scale of entire National Forests, Ranger Districts, or BLM Districts have the broad perspective that can improve ability to estimate effects of management activities on the function of critical habitat and better identify and prioritize treatment areas and the actions that will restore landscapes while conserving northern spotted owl habitat. The Okanogan-Wenatchee National Forest has developed a landscape evaluation process as part of their forest restoration strategy (USDA 2010, pp. 36–52) that can serve as an example for other administrative units when developing their own assessment approaches. We suggest that the value of such assessments in guiding vegetation management within critical habitat can be enhanced by spatially identifying locations where restoration objectives and northern spotted owl habitat objectives converge, are in conflict, or simply are not an issue (see, *e.g.,* Davis *et al.* 2012, entire). We suggest the following approach for the East Cascades:

1. Spatially identify and map:

a. Existing northern spotted owl habitat and northern spotted owl nesting sites.

b. Places on the landscape where northern spotted owl habitat is expected to be retained longer on the landscape in the face of disturbance activities such as fire and insect outbreaks.

c. Places on the landscape where key ecosystem structures and processes are at risk and would benefit from restoration (e.g. legacy trees, unique habitats).

2. Overlay what is known about landscape patterns of vegetation and disturbance processes with items from step 1 above to determine:

a. Stands of high restoration value but low value as existing northern spotted owl habitat.

b. Stands of low restoration value but high value as existing northern spotted owl habitat.

c. Stands of low restoration value and low value as existing northern spotted owl habitat.

d. Stands of high restoration value and high value as existing northern spotted owl habitat.

In locations where there is high restoration value and high value as existing northern spotted owl habitat, a landscape assessment can help to build a strong rationale for impacting owl habitat functionality to achieve broader landscape goals. Conditions that may support management activities in these stands may include, but are not limited to the following:

1. The patch of habitat is located in an area where it is likely unsustainable and has the potential for conveying natural disturbances across the landscape in ways that jeopardize large patches of suitable northern spotted owl habitat.

2. There are nearby areas that are more likely to sustain suitable northern spotted owl habitat and are either currently habitat or will likely develop suitable conditions within the next 30 years.

3. The patch of habitat does not appear to be associated with a northern spotted owl home range or to promote successful dispersal between existing home ranges.

4. The area will still retain some habitat function after treatment, while still meeting the intended restoration objective. For example, stands that are suitable as foraging habitat may be degraded post treatment but remain foraging habitat after treatment. Or, stands may be downgraded to dispersal habitat as a result of treatment.

We do not expect the desired landscape conditions will be achieved within the next decade or two; a longer time will be required as younger forests develop into northern spotted owl nesting, roosting, and foraging habitat. In the interim, we recommend that land managers consider management actions to protect current habitat, especially where it occurs in larger blocks on areas of the landscape, where it is more likely to be resistant or resilient to fires and other disturbance agents. We also encourage land managers to consider actions to accelerate the restoration of habitat, especially where it is consistent with overall forest restoration and occurs in those portions of the landscape that are less fire prone or are resilient in the face of these disturbances. The careful application of these types of activities is expected to achieve a landscape that is more resilient to future disturbances. As such, we anticipate that projects designed to achieve this goal will need to be of a larger spatial scale as to have a meaningful effect on wildfire behavior, regimes, and extent. The effects of these projects will vary depending on existing condition, prescriptions, proximity of habitat, and other factors. It is likely that such projects may affect northern spotted owl critical habitat and require section 7 consultation.

Some situations also exist in the final critical habitat area where northern spotted owl habitat has been created through fire suppression activities (e.g., meadow conversion, white fir intrusion), but retention of those forested habitat elements is contrary to the overall goals of ecosystem restoration and long-term security for the owl. Restoration projects that modify these elements, while sometimes prudent and recommended (Franklin *et al.* 2008, p. 46), may adversely affect northern spotted owls or their critical habitat, and may need to be evaluated through the section 7 consultation process. Additional information about restoration activities in dry forests can be found in the Revised Recovery Plan for the Northern Spotted Owl under *Restoring Dry Forest Ecosystems* (USFWS 2011, p. III–32).

Redwood Coast

While the Redwood Coast region of coastal northern California is similar to the West Cascades/Coast region in many respects, there are some distinct differences in northern spotted owl habitat use and diet within this zone. The long growing season, combined with the redwood's ability to resprout from stumps, allows redwood stands to attain suitable stand structure for nesting in a relatively short period of time (40 to 60 years) if legacy structures are present. In contrast to the large, contiguous, older stands desired in other wet provinces, some degree of fine-scale fragmentation in redwood forests appears to benefit northern spotted owls. These openings provide habitat for the northern spotted owl's primary prey, the dusky-footed woodrat. High woodrat abundance is associated with dense shrub and hardwood cover that persists for up to 20 years in recent forest openings created by harvesting or burns. Under dense shrub and hardwood cover, woodrats can forage, build nests, and reproduce, relatively secure from owl predation. These sites quickly become overpopulated, and surplus individuals are displaced into adjacent older stands where they become available as owl prey. When developing stands reach an age of around 20 years, understory vegetation is increasingly shaded-out, cover and food sources become scarce, and woodrat abundance declines rapidly. By this time, the stand that once supported a dense woodrat population makes a structural transition into a stand where woodrats are subject to intense owl predation. In northern spotted owl territories within the Redwood Forest zone, active management that creates small openings within foraging habitat can enhance northern spotted owl foraging opportunities and produce or retain habitat suitability in the short term. Actions consistent with this type of land management are not expected to adversely modify critical habitat.

Summary of Section 7 Process

This discussion has covered projects that may or may not require formal section 7 consultation. It is important to distinguish between a finding that a project is likely to adversely affect critical habitat and a finding at the conclusion of formal consultation that a project is likely to destroy or adversely modify critical habitat; these are two very different outcomes. It is not uncommon for a proposed project to be considered likely to adversely affect critical habitat, and thus require formal consultation, but still warrant a conclusion that it will not destroy or adversely modify critical habitat. An action may destroy or adversely modify critical habitat if it adversely affects the essential physical or biological features to an extent that the intended conservation function or purpose of critical habitat for the northern spotted owl is appreciably reduced.

The adverse modification determination is made at the scale of the entire designated critical habitat, unless the final critical habitat rule identifies another basis for that determination, such as at the scale of discrete units and/or groups of units necessary for different life cycle phases, units representing distinctive habitat characteristics or gene pools, or units fulfilling essential geographical distribution requirements of the species (USFWS and NMFS 1998, p. 4–39). In the case of northern spotted owl critical habitat, the adverse modification determination will be made at the scale of the entire designated critical habitat. However, by describing the relationship between the conservation role of affected subunits, units, and the entire designated critical habitat in the biological opinion, a sensitive analytical framework is established for informing the determination of whether a proposed action is likely to appreciably reduce the conservation role of the critical habitat overall. In this way, a proposed action that compromises the capability of a subunit or unit to fulfill its intended conservation function or purpose (e.g., demographic, genetic, or distributional support for northern spotted owl recovery) could represent an appreciable reduction in the conservation value of the entire designated critical habitat. This approach should avoid false no-adverse-modification determinations, when the functionality of a unit or subunit would actually be impaired by a proposed action.

As described above, in general, we do not anticipate that activities consistent with the stated management goals or recommended recovery actions of the Revised Recovery Plan for the Northern Spotted Owl (USFWS 2011, Chapters II and III) would constitute adverse modification of critical habitat, even if those activities may have adverse effects in the short term, if the intended result over the long term is an improvement in the function of the habitat to provide for the essential life-history needs of the northern spotted owl. However, such activities will be evaluated under section 7, taking into account the specific proposed action, location, and other site-specific factors.

X. Exemptions

Application of Section 4(a)(3) of the Act

The Sikes Act Improvement Act of 1997 (Sikes Act) (16 U.S.C. 670a) required each military installation that includes land and water suitable for the conservation and management of natural resources to complete an integrated natural resources management plan (INRMP) by November 17, 2001. An INRMP integrates implementation of the military mission of the installation with stewardship of the natural resources found on the base. Each INRMP includes:

(1) An assessment of the ecological needs on the installation, including the need to provide for the conservation of listed species;

(2) A statement of goals and priorities;

(3) A detailed description of management actions to be implemented to provide for these ecological needs; and

(4) A monitoring and adaptive management plan.

Among other things, each INRMP must, to the extent appropriate and applicable, provide for fish and wildlife management; fish and wildlife habitat enhancement or modification; wetland protection, enhancement, and restoration where necessary to support fish and wildlife; and enforcement of applicable natural resource laws.

The National Defense Authorization Act for Fiscal Year 2004 (Pub. L. 108–136) amended the Act to limit areas eligible for designation as critical habitat. Specifically, section 4(a)(3)(B)(i) of the Act (16 U.S.C. 1533(a)(3)(B)(i)) now provides: ''The Secretary shall not designate as critical habitat any lands or other geographical areas owned or controlled by the Department of Defense, or designated for its use, that are subject to an integrated natural resources management plan prepared under section 101 of the Sikes Act (16 U.S.C. 670a), if the Secretary determines, in writing, that such plan provides a benefit to the species for which critical habitat is proposed for designation.''

We consult with the military on the development and implementation of INRMPs for installations with listed species. We analyzed INRMPs developed by military installations located within the range of the designated critical habitat designation for the northern spotted owl to determine if they are exempt under section 4(a)(3) of the Act. The following areas are Department of Defense lands with completed, Service-approved INRMPs that fell within the area we proposed as revised critical habitat (77 FR 14062; March 8, 2012).

Approved INRMPs

U.S. Army Joint Base Lewis-McChord

Joint Base Lewis-McChord (JBLM), formerly known as Fort Lewis, is an 86,500-ac (35,000-ha) U.S. Army military reservation in western Washington, south of Tacoma and the Puget Sound. JBLM contains one of the largest remaining intact forest areas in the Puget Sound basin, with approximately 54,400 ac (22,000 ha) of forests and woodlands, predominantly of the dry Douglas-fir forest type and including some moist forest types (Douglas-fir, red cedar, hemlock). The forested area of JBLM is managed by the Base's Forestry Program, and the primary mission for the JBLM Forest is to provide a variety of forested environments for military training. JBLM has a history of applying an ecosystem management strategy to their forests to provide for multiple conservation goals, which have included promoting native biological diversity, maintaining and restoring unique plant communities, and developing late-successional (older) forest structure. There are 14,997 ac (6,069 ha) of lands within the boundary of JBLM that were identified in the proposed critical habitat designation; these lands comprised subunit NCO–3 in the proposed rule (77 FR 14062; March 8, 2012).

JBLM has an INRMP in place that was approved in 2008; JBLM is in the process of updating that INRMP. To date, JBLM has managed their forest lands according to their Forest Management Strategy, first prepared for then-Fort Lewis in 1995 by the Public Forestry Foundation based in Eugene, Oregon, in collaboration with The Nature Conservancy. The Forest Management Strategy was last revised in May 2005, and is also in the process of being updated (Forest Management Strategy 2005, entire). However, in 2012, JBLM amended their existing INRMP with specific regard to the northern spotted owl by completing an Endangered Species Management Plan (ESMP) that includes guidelines for protecting, maintaining, and enhancing habitat essential to support the northern spotted owl on JBLM. The Service has found, in writing, that the amended INRMP provides a net conservation benefit to the species.

The ESMP identifies management objectives for the conservation of the northern spotted owl. Specifically, the ESMP includes three focus areas for management of northern spotted owl. The long-term objective for the first is development of all four types of owl habitat (nesting, roosting, foraging, and dispersal). The long-term objectives for Focus Areas 2 and 3 are development of owl foraging and dispersal habitat. The primary conservation goals for northern spotted owl habitat on JBLM are to protect and maintain existing northern spotted owl suitable habitat; manipulate unsuitable habitat to suitable habitat; and ensure long-term suitable habitat and monitor northern spotted owl habitat to assure that goals are met and actions are successful. Although northern spotted owls are not currently known to occupy JBLM, it is the only significant Federal ownership in this region of Washington, and it provides the largest contiguous block of forest in this area as well. The potential development of suitable owl habitat at JBLM provides one of the only feasible opportunities for establishing connectivity between owl populations in the Olympic Peninsula and the western Cascades Range. Connectivity allows gene flow between populations, and further maintains northern spotted owl distribution and metapopulation dynamics, which are important components of the recovery strategy for the northern spotted owl (USFWS 2011, p. III–1, III–44). The Forest Management Strategy (2005, p. 82) notes that the mosaic of dry forest, woodland, and prairie at JBLM is very different from typical forest landscapes that support northern spotted owls, and that while suitable habitat for dispersal of northern spotted owls can be achieved in the short term, at least 40 to 50 years may be needed to meet the desired condition for foraging, nesting, and roosting habitat.

Based on the above considerations and in accordance with section 4(a)(3)(B)(i) of the Act, we have determined that the identified lands are subject to the JBLM INRMP and that conservation efforts identified in the INRMP through its ESMP for the northern spotted owl will provide a benefit to the species occurring in habitats within or adjacent to JBLM, including the northern spotted owl. Therefore, lands within this installation are exempt from critical habitat designation under section 4(a)(3) of the Act. We are not including approximately 14,997 ac (6,069 ha) of habitat in this final critical habitat designation as a result of this exemption.

XI. Exclusions

Application of Section 4(b)(2) of the Act

Section 4(b)(2) of the Act states that the Secretary must designate or make revisions to critical habitat on the basis of the best available scientific data after taking into consideration the economic impact, national security impact, and any other relevant impacts of specifying any particular area as critical habitat. The Secretary may exclude an area from critical habitat if he determines that the benefits of such exclusion outweigh the benefits of specifying such area as part of the critical habitat, unless he determines, based on the best scientific data available, that the failure to designate such area as critical habitat will result in the extinction of the species. In making that determination, the statute on its face, as well as the legislative history, are clear that the Secretary has broad discretion regarding which factor(s) to use and how much weight to give to any factor.

When considering the benefits of inclusion for an area, we consider the additional regulatory benefits that area would receive from the protection from adverse modification or destruction as a result of actions with a Federal nexus; the educational benefits of mapping essential habitat for recovery of the listed species; and any benefits that may result from a designation due to State or Federal laws that may apply to critical habitat.

When considering the benefits of exclusion, we consider, among other things, whether exclusion of a specific area is likely to result in the overall conservation of the northern spotted owl through the continuation, strengthening, or encouragement of partnerships and the implementation of management plans or programs that provide equal or more conservation for the northern spotted owl than could be achieved through a designation of critical habitat. The Secretary can consider the existence of conservation agreements and other land management plans with Federal, State, private, and tribal entities when making decisions under section 4(b)(2) of the Act. The Secretary may also consider relationships with landowners, voluntary partnerships, and conservation plans, and weigh the implementation and effectiveness of these against that of designation to determine which provides the greatest conservation value to the listed species.

Consideration of relevant impacts of designation or exclusion under section 4(b)(2) may include, but is not limited to, any of the following factors: (1) Whether the plan provides specific information on how it protects the species and the physical or biological features, and whether the plan is at a geographical scope commensurate with the species; (2) whether the plan is complete and will be effective at conserving and protecting the physical or biological features; (3) whether a reasonable expectation exists that conservation management strategies and actions will be implemented, that those responsible for implementing the plan are capable of achieving the objectives, that an implementation schedule exists, and that adequate funding exists; (4) whether the plan provides assurances that the conservation strategies and measures will be effective (i.e., identifies biological goals, has provisions for reporting progress, and is of a duration sufficient to implement the plan); (5) whether the plan has a monitoring program or adaptive management to ensure that the conservation measures are effective; (6) the degree to which the record supports a conclusion that a critical habitat designation would impair the benefits of the plan; (7) the extent of public participation; (8) a demonstrated track record of implementation success; (9) the level of public benefits derived from encouraging collaborative efforts and encouraging private and local conservation efforts; and (10) the effect designation would have on partnerships.

After evaluating the benefits of inclusion and the benefits of exclusion, we carefully weigh the two sides to determine whether the benefits of excluding a particular area outweigh the benefits of its inclusion in critical habitat. If we determine that the benefits of excluding a particular area outweigh the benefits of its inclusion, then the Secretary can exercise his discretion to exclude the area, provided that the exclusion will not result in the extinction of the species.

Under section 4(b)(2) of the Act, we must consider all relevant impacts of the designation of critical habitat, including economic impacts. In addition to economic impacts (discussed in the Economics Analysis section, below), we considered a number of factors in a section 4(b)(2) analysis. We considered whether Federal or private landowners or other public agencies have developed management plans, habitat conservation plans (HCPs) or Safe Harbor Agreements (SHAs) for the area or whether there are conservation partnerships or other conservation benefits that would be encouraged or discouraged by designation of, or exclusion from, critical habitat in an area. We also considered other relevant impacts that might occur because of the designation. To ensure that our final determination is based on the best available information, we also considered comments received on foreseeable economic, national security, or other potential impacts resulting from this designation of critical habitat from governmental, business, or private interests and, in particular, any potential impacts on small businesses.

Based on the information provided by entities seeking exclusion, as well as any additional public comments received, we evaluated whether certain lands in the proposed revised critical habitat were appropriate for exclusion from this final designation pursuant to section 4(b)(2) of the Act. Based on our evaluation, we are excluding approximately 3,879,506 ac (1,567,875 ha) of lands that meet the definition of critical habitat under section 4(b)(2) of the Act from final critical habitat.

Final Economic Analysis

Under section 4(b)(2) of the Act, we consider the economic impacts of specifying any particular area as critical habitat. In order to consider economic impacts, we prepared a draft economic analysis (DEA) of the proposed critical habitat designation and related factors (IEC 2012a). The draft analysis was made available for public review from June 1, 2012, through July 6, 2012 (77 FR 32483). Following the close of the comment period, we developed a final economic analysis (FEA) (IEC 2012b) of the potential economic effects of the designation taking into consideration the public comments and any new information.

The intent of the FEA is to quantify economic impacts that may be directly attributable to the designation of critical habitat—that is, costs above and beyond what are considered ''baseline'' costs, as described below. The economic impact of the final critical habitat designation is analyzed by comparing scenarios both ''with critical habitat'' and ''without critical habitat.'' The ''without critical habitat'' scenario represents the baseline for the analysis, and considers the costs incurred as a result of protections already in place for the species (e.g., under the Federal listing and other Federal, State, and local regulations); these are costs that are incurred regardless of whether critical habitat is designated. The ''with critical habitat'' scenario describes the ''incremental'' economic impacts associated specifically with the designation of critical habitat for the species—these costs are those not expected to occur but for the designation of critical habitat for the species. In other words, the incremental costs are those attributable solely to the designation of critical habitat above and beyond the baseline costs; these are the costs we consider in the final designation of critical habitat.

The FEA also addresses how potential economic impacts are likely to be distributed, including an assessment of any local or regional impacts of habitat conservation and the potential effects of conservation activities on government agencies, private businesses, and individuals. Decisionmakers can use this information to assess whether the effects of the designation might unduly burden a particular group or economic sector. Finally, the FEA considers those costs that may occur in the 20 years following the revised designation of critical habitat, which was determined to be the appropriate period for analysis because limited planning information was available for most activities to forecast activity levels for projects beyond a 20-year timeframe. The FEA quantifies economic impacts of northern spotted owl conservation efforts associated with timber harvests, wildfire management, barred owl management, road construction, and linear projects (road and bridge construction and maintenance, installation of power transmission lines and utility pipelines), as these are the types of activities we determined were most likely to occur within northern spotted owl habitat.

The results of the FEA concludes that only a portion of the overall proposed revised designation will result in more than incremental, minor administrative costs. Specifically, of the 13,962,449 ac proposed for designation, potential incremental changes in timber harvest practices were anticipated on only 1,449,534 ac (585,612 ha) of USFS and BLM lands, or approximately 10 percent of the proposed designation. In addition, there was potential for the owners of 307,308 ac (123,364 ha) of private land to experience incremental changes in harvests (approximately 2 percent of the proposed designation). No incremental changes in harvests are expected on State lands.

In addition, to address the uncertainty in the types of management and activities that may or may not occur within the proposed critical habitat, the FEA evaluated three scenarios to capture the full range of potential economic impacts of the designation. The first scenario contemplates that minimal or no changes to current timber management practices will occur, thus the incremental costs of the designation would be predominantly administrative. The potential additional administrative costs due to critical habitat designation on Federal lands range from $185,000 to $316,000 on an annualized basis for timber harvest.

The second scenario posits that action agencies may choose to implement management practices that yield an increase in timber harvest relative to the baseline (current realized levels of timber harvest). For this scenario, baseline harvest projections were scaled upward by 10 percent, resulting in a positive impact on Federal lands ranging from $893,000 to $2,870,000 on an annualized basis for timber harvest.

The third scenario considers that actions agencies may choose to be more restrictive in response to critical habitat designation, resulting in a decline in harvest volumes relative to the baseline. To illustrate the potential for this effect, baseline harvest projections were scaled downward by 20 percent, resulting in a negative impact on timber harvest on Federal lands ranging from $2,650,000 to $6,480,000 on an annualized basis.

The USFS and BLM suggested certain alterations to the baseline timber harvest projections, based on differing assumptions regarding northern spotted owl occupancy in matrix lands and projected levels of timber harvest relative to historical yields. The FEA presents the results of a sensitivity analysis considering these alternative assumptions, which widen the range of annualized potential impacts to Federal timber harvest relative to the scenarios described above (IEC 2012b, pp. 4–37 to 4–39). This sensitivity analysis contemplated a situation in which 26.6 percent of northern spotted owl habitat on BLM matrix lands is unoccupied, and a 20 percent increase in baseline timber harvest in USFS Region 6 relative to historical yields. The range of incremental impacts under these alternative assumptions widens to a potential annualized increase of $0.7 million under Scenario 2, and an annualized decrease of $1.4 million under Scenario 3, relative to the results reported above.

Timber harvest was not anticipated to change on State lands in response to critical habitat designation. Timber harvest effects on private lands were highly uncertain, and were only identified qualitatively as potential negative impacts associated with regulatory uncertainty, and possibly (but speculative) new regulation in the State of Washington.

Under all three scenarios, linear projects reflected administrative costs only, ranging from $10,800 to $19,500 on an annualized basis.

Counties receive Federal lands payments from a subset of four programs: The U.S. Forest Service 25% Fund; the BLM O&C lands payments; Payment in Lieu of Taxes (PILT); and Secure Rural Schools and Community Self-determination Act (SRS) (please see FEA pp. 3–19 to 3–21 for a thorough discussion of these programs). Counties have the option of receiving either SRS of 25%/O&C payments, but not both. For reasons unrelated to proposed critical habitat, the future of the PILT and SRS programs is uncertain and depends on forces, including Congressional action, unrelated to critical habitat designation. If funding is not appropriated to PILT, or SRS is not reauthorized, payments from the USFS 25% Fund and the BLM O&C lands become relatively more important. Payments for these latter two programs are based on commercial receipts, main from timber generated on Federal lands; payments from PILT and SRS are not as closely linked to fluctuations in timber sales. In recent years, most counties have opted to receive SRS payments; for example, in FY 2009 all 18 counties in Oregon that contain BLM lands opted to receive SRS payments instead of the LBM O&C lands revenue-sharing payment. Therefore, it is difficult to quantify the effects that future changes in timber harvests from Federal lands resulting from critical habitat designation would have on counties if SRS and PILT payment programs ended and the counties were forced to rely on revenue-sharing payments only. Given the baseline uncertainty associated with the continuance of SRS and PILT payments, we were unable to quantify possible changes in county revenue payments that could result from the critical habitat designation. However, based on recent socioeconomic trends, we were able to identify those counties that may be more sensitive to future changes in timber harvests, industry employment, and Federal land payments. Potential timber harvest changes related to critical habitat designation, whether positive, negative, or neutral, are one potential aspect of this sensitivity. The counties identified as relatively more sensitive to future changes in timber harvests, employment, and payments were Del Norte and Trinity Counties, California; Douglas and Klamath Counties, Oregon; and Skamania County, Washington.

With regard to jobs, increases or decreases in timber harvests from Federal or private lands could result in positive or negative changes in jobs, respectively. The FEA notes that many factors affect timber industry employment (Chapter 6). The scope of our analysis was limited to the incremental effects of critical habitat within the area proposed for designation by the northern spotted owl. The FEA did not consider potential changes in timber activities outside the proposed critical habitat designation, and did not evaluate the potential effects related to the timber industry as a whole.

Based on our economic analysis of the potential effects of the proposed revised designation of critical habitat for the northern spotted owl, there is a range of potential outcomes, ranging from positive to negative impacts of the designation. Most potential economic impacts would occur, if at all, on Federal matrix lands managed by BLM and the Forest Service, although we note that the amount of Federal matrix lands has been reduced from the proposed rule, as described in Changes from the Proposed Rule, which would have the effect of reducing the range of potential economic impacts presented by the FEA. While there is uncertainty over whether such impacts will occur and to what extent, even assuming higher economic impacts suggested by some commenters, we would not exclude these lands from designation under section 4(b)(2) because a critical habitat designation on these lands will have benefits in conserving this essential habitat. In addition, our evaluation of these matrix lands clearly demonstrates their importance to the conservation of the northern spotted owl; as also discussed in the section Changes from the Proposed Rule, our evaluation of a habitat network with reduced areas of high value habitat on matrix lands indicated a significant increase in extinction risk to the species as a result.

A copy of the FEA with supporting documents may be obtained by contacting the Oregon Fish and Wildlife Office (see **ADDRESSES**) or by downloading from the Internet at *http://www.regulations.gov.*

National Security Impacts

Under section 4(b)(2) of the Act, we consider whether there are lands owned or managed by the Department of Defense (DOD) where a national security impact might exist. In preparing this final rule, we have determined that the only lands within the proposed revised designation of critical habitat for the northern spotted owl that are owned or managed by the Department of Defense have an active INRMP which provides a benefit to the species, and are thus exempt from critical habitat designation under section 4(a)(3) of the Act (see Exemptions, above). We therefore anticipate no impact on national security from this designation. Consequently, the Secretary is not exercising his discretion to exclude any additional areas from this final revised designation based on impacts to national security.

Relevant Impacts

Under section 4(b)(2) of the Act, we consider all relevant impacts, including but not limited to economic impacts and impacts on national security. We consider a number of factors including whether the landowners have developed any HCPs or other management plans for the area, or whether there are conservation partnerships that would be encouraged by designation of, or exclusion from, critical habitat. In addition, we look at any tribal issues, and consider the government-to-government relationship of the United States with tribal entities. We also consider any social impacts that might occur because of the designation.

Here we provide our analysis of areas that were proposed as revised designation of critical habitat for the northern spotted owl, for which there may be a greater conservation benefit to exclude rather than include in the designation. Our weighing of the benefits of inclusion versus exclusion considered all relevant factors in order to make our final determination as to what will result in the greatest conservation benefit to the owl. Depending on the specifics of each situation, there may be cases where the designation of critical habitat will not necessarily provide enhanced protection, and may actually lead to a net loss of conservation benefit.

Benefits of Designating Critical Habitat

The process of designating critical habitat as described in the Act requires that the Service identify those lands within the geographical area occupied by the species at the time of listing on which are found the physical or biological features essential to the conservation of the species that may require special management considerations or protection, and those areas outside the geographical area occupied by the species at the time of listing that are essential for the conservation of the species.

The identification of areas that contain the features essential to the conservation of the species, or are otherwise essential for the conservation of the species if outside the geographical area occupied by the species at the time of listing, is a benefit resulting from the designation. The critical habitat designation process includes peer review and public comment on the identified physical or biological features and areas, and provides a mechanism to educate landowners, State and local governments, and the public regarding the potential conservation value of an area. This helps focus and promote conservation efforts by other parties by clearly delineating areas of high conservation value for the species, and is valuable to land owners and managers in developing conservation management plans by describing the essential physical or biological features and special management actions or protections that are needed for identified areas. Including lands in critical habitat also informs State agencies and local governments about areas that could be conserved under State laws or local ordinances.

However, the prohibition on destruction or adverse modification under section 7(a)(2) of the Act constitutes the only Federal regulatory benefit of critical habitat designation. As discussed above, Federal agencies must consult with the Service on actions that may affect critical habitat and must avoid destroying or adversely modifying critical habitat. Federal agencies must also consult with us on actions that may affect a listed species and refrain from undertaking actions that are likely to jeopardize the continued existence of such species. The analysis of effects to critical habitat is a separate and different analysis from that of the effects to the species. Therefore, the difference in outcomes of these two analyses also represents the regulatory benefit of critical habitat. For some species, and in some locations, the outcome of these analyses will be similar because effects on habitat will often result in effects on the species. However, these two regulatory standards are different. The jeopardy analysis evaluates how a proposed action is likely to influence the likelihood of a species' survival and recovery. The adverse modification analysis evaluates how an action affects the capability of the critical habitat to serve its intended conservation function or purpose (USFWS, in litt. 2004). Although these standards are different, it has been the Service's experience that in many instances proposed actions that affect both a listed species and its critical habitat and that constitute jeopardy also constitute adverse modification. In some cases, however, application of these different standards results in different section 7(a)(2) determinations, especially in situations where the affected area is mostly or exclusively unoccupied critical habitat. Thus, critical habitat designations may provide greater benefits to the recovery of a species than would listing as endangered or threatened under the Act alone.

There are two limitations to the regulatory effect of critical habitat. First, a section 7(a)(2) consultation is required only where there is a Federal nexus (an action authorized, funded, or carried out by any Federal agency)—if there is no Federal nexus, the critical habitat designation of non-Federal lands itself does not restrict any actions that destroy or adversely modify critical habitat. Aside from the requirement that Federal agencies ensure that their actions are not likely to result in destruction or adverse modification of critical habitat under section 7, the Act does not provide any additional regulatory protection to lands designated as critical habitat.

Second, designating critical habitat does not create a management plan for the areas; does not establish numerical population goals or prescribe specific management actions (inside or outside of critical habitat); and does not have a direct effect on areas not designated as critical habitat. The designation only limits destruction or adverse modification of critical habitat, not all adverse effects. By its nature, the prohibition on adverse modification ensures that the conservation role and function of the critical habitat network is not appreciably reduced as a result of a Federal action.

Once an agency determines that consultation under section 7(a)(2) of the Act is necessary, the process may conclude informally when the Service concurs in writing that the proposed Federal action is not likely to adversely affect the species or critical habitat. However, if we determine through informal consultation that adverse impacts are likely to occur, then formal consultation is initiated. Formal consultation concludes with a biological opinion issued by the Service on whether the proposed Federal action is likely to jeopardize the continued existence of listed species or result in destruction or adverse modification of critical habitat.

For critical habitat, a biological opinion that concludes in a determination of no destruction or adverse modification may recommend additional conservation measures to minimize adverse effects to primary constituent elements, but such measures would be discretionary on the part of the Federal agency.

The designation of critical habitat does not require that any management or recovery actions take place on the lands included in the designation. Even in cases where consultation has been initiated under section 7(a)(2) of the Act because of effects to critical habitat, the end result of consultation is to avoid adverse modification, but not necessarily to manage critical habitat or institute recovery actions on critical habitat. On the other hand, voluntary conservation efforts by landowners can remove or reduce known threats to a species or its habitat by implementing recovery actions. We find that in many instances the regulatory benefit of critical habitat is minimal when compared to the conservation benefit that can be achieved through implementing HCPs under section 10 of the Act, or other voluntary conservation efforts or management plans. The conservation achieved through implementing HCPs, or other habitat management plans can be greater than what we achieve through multiple site-by-site, project-by-project section 7(a)(2) consultations involving project effects to critical habitat. Management plans can commit resources to implement long-term management and protection to particular habitat for at least one and possibly other listed or sensitive species. Section 7(a)(2) consultations commit Federal agencies to preventing adverse modification of critical habitat caused by the particular project; consultation does not require Federal agencies to provide for conservation or long-term benefits to areas not affected by the proposed project. Thus, implementation of any HCP, or management plan that incorporates enhancement or recovery as the management standard may often provide as much or more benefit than a consultation for critical habitat designation. After reviewing all current HCPs, SHAs, and any other active management plans or conservation agreements, and weighing the benefits of inclusion and exclusion (see below), we are excluding all State and private lands covered by such agreements from the final critical habitat designation.

We are also excluding under section 4(b)(2) congressionally-reserved natural areas such as national parks and wilderness areas, State parks, and other private lands that had been proposed for designation, for the reasons discussed below. These analyses are based in large part on the particular conservation requirements of the northern spotted owl or the State laws aimed at protecting this species, and are specific to this designation. Thus, our determination that the benefits of exclusion outweigh the benefits of inclusion in these cases, as well as the decision to exclude in these instances, do not necessarily have a bearing on any future critical habitat designations.

Table 8 identifies all lands excluded from the final rule.

TABLE 8—LANDS EXCLUDED FROM THE FINAL REVISED DESIGNATION OF CRITICAL HABITAT FOR THE NORTHERN SPOTTED OWL UNDER SECTION 4(B)(2) OF THE ACT

Type of agreement	Critical habitat unit	State	Land owner/agency	*Acres*	*Hectares*
Safe Harbor Agreement	WCC	WA	Port Blakely Tree Farms, L.P., Safe Harbor Agreement, Landowner Option Plan, Cooperative Habitat Enhancement.	195	79

Benefits of Excluding Lands With Safe Harbor Agreements

A Safe Harbor Agreement (SHA) is a voluntary agreement involving private or other non-Federal property owners whose actions contribute to the recovery of listed species. The agreement is between cooperating non-Federal property owners and the Service. In exchange for actions that contribute to the recovery of listed species on non-Federal lands, participating property owners receive formal assurances from the Service that, if they fulfill the conditions of the SHA, the Service will not require any additional or different management activities by the participants without their consent. In addition, at the end of the agreement period, participants may return the enrolled property to the baseline conditions that existed at the beginning of the SHA.

Because many endangered and threatened species occur exclusively, or to a large extent, on privately owned property, the involvement of the private sector in the conservation and recovery of species is crucial. Property owners are often willing partners in efforts to recover listed species. However, some property owners may be reluctant to undertake activities that support or attract listed species on their properties, due to fear of future property-use restrictions related to the Act. To address this concern, an SHA provides that future property-use limitations will not occur without the landowner's consent if the landowner is in compliance with the permit and agreement and the activity is not likely to result in jeopardy to the listed species.

Central to this approach is that the actions taken under the SHA must provide a net conservation benefit that contributes to the recovery of the covered species. Examples of conservation benefits include:

• Reduced habitat fragmentation;
• Maintenance, restoration, or enhancement of existing habitats;
• Increases in habitat connectivity;
• Stabilized or increased numbers or distribution;
• The creation of buffers for protected areas; and
• Opportunities to test and develop new habitat management techniques.

By entering into a SHA, property owners receive assurances that land use restrictions will not be required even if the voluntary actions taken under the agreement attract particular listed species onto enrolled properties or increase the numbers of distribution of those listed species already present on those properties. The assurances are provided through an enhancement of survival permit issued to the property owner, under the authority of section 10(a)(1)(A) of the Act. To implement this provision of the Act, the Service and National Marine Fisheries Service (NMFS) issued a joint policy for developing SHAs for listed species on June 17, 1999 (64 FR 32717). The Service simultaneously issued regulations for implementing SHAs on June 17, 1999 (64 FR 32706). A correction to the final rule was announced on September 30, 1999 (64 FR 52676). The enhancement of survival permit issued in association with an SHA authorizes incidental take of species that may result from actions undertaken by the landowner under the SHA, which could include returning the property to the baseline conditions at the end of the agreement. The permit also specifies that the Service will not require any additional or different management activities by participants without their consent if the permittee is in compliance with the requirements of the permit and the SHA and the permittee's actions are not likely to result in jeopardy.

The benefits of excluding lands with approved SHAs from critical habitat designation may include relieving landowners, communities, and counties of any additional regulatory burden that might be imposed as a result of the critical habitat designation. Even if any additional regulatory burden would be unlikely due to a lack of a Federal nexus, the designation of critical habitat could nonetheless have an unintended negative effect on our relationship with non-Federal landowners, due to the perceived imposition of government regulation. An additional benefit of excluding lands covered by approved SHAs from critical habitat designation is that it may make it easier for us to seek new partnerships with future SHA participants, including States, counties, local jurisdictions, conservation organizations, and private landowners, in cases where potential partners may be reluctant to encourage the development of habitat that supports endangered or threatened species. In such cases, we may be able to implement conservation actions that we would be unable to accomplish otherwise. By excluding these lands, we may preserve our current partnerships and encourage additional future conservation actions.

In weighing the benefits of inclusion versus the benefits of exclusion for lands subject to approved SHAs, it is important to note that a fundamental requirement of an SHA is an advance determination by the Service that the provisions of the SHA will result in a net conservation benefit to the listed species. Approved SHAs have, therefore, already been determined to provide a net conservation benefit to the listed species; in addition, the management activities provided in an SHA often provide conservation benefits to unlisted sensitive species as well. As described earlier, the designation of critical habitat may not provide any substantial realized conservation benefit to the species on non-Federal lands absent a Federal nexus for an activity. Especially where further Federal action is unlikely, the net conservation benefit provided by the terms of the SHA itself, considered in conjunction with the benefit of excluding lands subject to an SHA by preserving our working relationships with landowners who have entered into SHAs with the Service, and the benefit of laying the positive groundwork for possible future agreements with other landowners, may collectively outweigh the potentially limited benefit that would be realized on these lands from the designation of critical habitat. However, as with all potential exclusions under consideration, lands subject to an SHA will only be excluded if we determine that the benefits of exclusion outweigh the benefits of inclusion following a rigorous examination of the record on a case-by-case basis.

We note that permit issuance in association with SHA applications requires consultation under section 7(a)(2) of the Act, which would include the review of the effects of all SHA-covered activities that might adversely impact the species under a jeopardy standard, including possibly significant habitat modification (see definition of ''harm'' at 50 CFR 17.3), even without the critical habitat designation. In addition, all other Federal actions that may affect the listed species would still require consultation under section 7(a)(2) of the Act, and we would review these actions for possible significant habitat modification in accordance with the definition of harm, described in the *Benefits of Excluding Lands with Habitat Conservation Plans,* below.

We further note that SHAs may include a provision that the landowner may return the area to baseline conditions upon expiration of the permit. The term of the permit is thus an important consideration in weighing the relative benefits of inclusion versus exclusion from the designation of critical habitat. However, the Service has the right to revise a critical habitat designation at any time. Furthermore, the potential benefit of acknowledging the positive conservation contributions of landowners willing to enter into voluntary conservation agreements with the Service for the recovery of endangered or threatened species may nonetheless outweigh the loss of benefit that may be incurred through a possible return to baseline following permit expiration. As stated above, such circumstances require careful consideration on a case-by-case basis in order to make a final determination of the benefits of exclusion or inclusion in a critical habitat designation.

Below is a description of each SHA and our analysis of the benefits of including and excluding it from the critical habitat designation under section 4(b)(2) of the Act.

State of California

Forster-Gill, Inc., Safe Harbor Agreement

In this final designation, the Secretary has exercised his authority to exclude 238 ac (96 ha) of lands from critical habitat, under section 4(b)(2) of the Act, that are covered by the Safe Harbor Agreement (SHA) of Forster-Gill, Inc., within subunit 1 of the Redwood Coast CHU in Humboldt County, California. The enhancement of survival permit associated with this SHA was noticed in the **Federal Register** on March 22, 2002 (67 FR 13357), and issued June 18, 2002. The term of the agreement is 80 years, and the term of the permit is 90 years. The SHA provides for the creation and enhancement of habitat for the northern spotted owl on 238 ac (96 ha) of lands in Humboldt County, California, and provides for continued timber harvest on those lands. There are two baseline conditions that will be maintained under the SHA: (1) Protection of an 11.2-ac (5-ha) no-harvest area that will buffer the most recent active northern spotted owl nest site, but will also be maintained in the absence of a nest site; and (2) maintenance of 216 ac (87 ha) on the property such that the trees will always average 12 to 24 in (30 to 60 cm) dbh with a canopy cover of 60 to 100 percent. At the time of the agreement, forest conditions were on the lower end of the diameter and canopy cover ranges. By the end of the agreement, the property will be at the upper end of the diameter and canopy cover ranges. Under the SHA, Forster-Gill, Inc., agrees to: (1) Annually, survey and monitor for the location and reproductive status of northern spotted owls on the property; (2) protect all active nest sites (locations where nesting behavior is observed during any of the previous 3 years) with a no-harvest area that buffers the nest site by no less than 300 ft (90 m) and limits timber harvest operations within 1,000 ft (305 m) of an active nest site during the breeding season, allowing only the use of existing haul roads; and (3) manage the second-growth redwood timber on the property in a manner that maintains suitable northern spotted owl habitat, while creating, over time, the multilayered canopy structure with an older, larger tree component associated with high-quality northern spotted owl habitat. The SHA is expected to provide, maintain, and enhance for the 80-year life of the agreement over 200 ac (80 ha) of northern spotted owl habitat within a matrix of private timberland. The cumulative impact of the agreement and the timber management activities it covers, which are facilitated by the allowable incidental take, is expected to provide a net benefit to the northern spotted owl.

Benefits of Inclusion—We find there are minimal benefits to including these lands in critical habitat. As discussed above, the designation of critical habitat invokes the provisions of section 7. However, in this case, we find the requirement that Federal agencies consult with us and ensure that their actions are not likely to destroy or adversely modify critical habitat will not result in significant benefits to the species because the possibility of a Federal nexus for a project on these lands that might trigger such consultation is limited (there is little likelihood of an action that will involve Federal funding, authorization, or implementation). In addition, since the lands under the SHA in question are occupied by the northern spotted owl, if a Federal nexus were to occur, section 7 consultation would already be triggered and the Federal agency would consider the effects of its actions on the species through a jeopardy analysis. Because one of the primary threats to the northern spotted owl is habitat loss and degradation, the consultation process under section 7 of the Act for projects with a Federal nexus will, in evaluating effects to the northern spotted owl, evaluate the effects of the action on the conservation or functionality of the habitat for the species regardless of whether critical habitat is designated for these lands. The analytical requirements to support a jeopardy determination on excluded land are similar, but not identical, to the requirements in an analysis for an adverse modification determination on included land. However, the additional conservation that could be attained through the supplemental adverse modification analysis for critical habitat under section 7 would likely not be significant, and would be triggered only in the event of a Federal action. Furthermore, any such potential benefit would be small in comparison to the benefits derived from the SHA, which already incorporates measures that specifically benefit the northern spotted owl and its habitat, as described above, and remains in place regardless of the designation of critical habitat.

Another benefit of including lands in a critical habitat designation is that it serves to educate landowners, State and local governments, and the public regarding the potential conservation value of an area. This helps focus and promote conservation efforts by other parties by identifying areas of high conservation value for northern spotted owls. Any information about the northern spotted owl and its habitat that reaches a wider audience, including parties engaged in conservation activities, is valuable. However, in this case the landowners are aware of the needs of the species through the development of their SHA, in which they have agreed to take measures to protect the northern spotted owl on their property and create and enhance suitable habitat for the species as well. Any additional educational and information benefits that might arise from critical habitat designation have been largely accomplished through the public review of and comment on the SHA and the associated permit. The release of the Revised Recovery Plan for the Northern Spotted Owl in 2011 was also preceded by outreach efforts and public comment opportunities. In addition, the rulemaking process associated with critical habitat designation included several opportunities for public comment, and we also held multiple public information meetings across the range of the species. Through these outreach opportunities, land owners, State agencies, and local governments have become aware of the current status of and threats to the northern spotted owl, and the conservation actions needed for recovery.

The designation of critical habitat may also indirectly cause State or county jurisdictions to initiate their own additional requirements in areas identified as critical habitat. These measures may include additional permitting requirements or a higher level of local review on proposed projects. However, CALFIRE has indicated to us that it is unlikely to impose any new requirements on project proponents if critical habitat is designated in areas already subject to California Forest Practice Rules. Therefore, we believe this potential benefit of critical will be limited.

Benefits of Exclusion—The benefits of excluding from designated critical habitat the approximately 236 ac (96 ha) of lands currently managed under the SHA are substantial. We have created a close partnership with Forster-Gill through the development of the SHA, which incorporates protections and management objectives for the northern spotted owl and the habitat upon which it depends for breeding, sheltering, and foraging activities, as described above. The conservation approach identified in the Forster-Gill, Inc. SHA, along with our close coordination with the company, addresses the identified threats to northern spotted owl habitat on the covered lands that contain the physical or biological features essential to the conservation of the species.

The conservation measures identified within the SHA seek to achieve conservation goals for northern spotted owls and their habitat, and thus can be of greater conservation benefit than the designation of critical habitat, which does not require specific, proactive management actions. If there is a Federal nexus, consultation under critical habitat requires only that the action agency avoid actions that destroy or adversely modify critical habitat. In contrast, SHA conservation measures that provide a benefit to the northern spotted owl and its habitat have been, and will be, implemented continuously beginning with the enactment of the SHA in 2002 through the 80-year term of the ITP, through 2082, on all covered lands owned and managed by Forster-Gill, Inc. The key conservation measure is a provision that will lead to an approximate doubling of mean tree diameter from roughly 12 to 24 in (30 to 60 cm) on covered lands over the life of the permit, leading to enhancement of habitat suitability.

The designation of critical habitat could have an unintended negative effect on our relationship with non-Federal landowners due to the perceived imposition of redundant government regulation. If lands within the Forster-Gill SHA are designated as critical habitat, it would likely have a chilling effect on our continued ability to seek new partnerships with future participants including States, counties, local jurisdictions, conservation organizations, and private landowners, which together can implement various conservation actions (such as SHAs, HCPs, and other conservation plans, particularly large, regional Conservation Plans that involve numerous participants and/or address landscape-level conservation of species and habitats) that we would be unable to accomplish otherwise.

Excluding the approximately 238 ac (96 ha) owned and managed by Forster-Gill, Inc. from critical habitat designation will sustain and enhance the working relationship between the Service and this private lands partner. The willingness of Forster-Gill to work with the Service to manage federally listed species will continue to reinforce those conservation efforts and our partnership, which contribute toward achieving recovery of the northern spotted owl. We consider this voluntary partnership in conservation vital to our understanding of the status of species on non-Federal lands and necessary to implement recovery actions such as habitat protection and restoration, and beneficial management actions for species. By excluding these lands, we preserve our current conservation partnership with Forster-Gill and encourage additional conservation actions by this partner, and potentially others as well, in the future. We consider the positive effect of excluding proven conservation partners from critical habitat to be a significant benefit of exclusion.

The Benefits of Exclusion Outweigh the Benefits of Inclusion—We reviewed and evaluated the exclusion of approximately 238 ac (96 ha) of land owned and managed by Forster-Gill, Inc. from our designation of critical habitat. The benefits of including these lands in the designation are relatively small. The habitat on the covered lands is already being monitored and managed under the SHA to improve the habitat elements that are equivalent to the physical or biological features that are outlined in this critical habitat rule. The additional designation of critical habitat would provide unnecessarily duplicative protections, and would in any case be unlikely to be triggered under section 7, since there is little probability of a Federal nexus for any activity on these lands. Even if triggered, since the lands in question are occupied by the species, section 7 consultation would already be required under the jeopardy standard, and as noted, the analysis under the adverse modification standard would be unlikely to provide additional protections beyond those already in place under the SHA. The regulatory benefit of additional Federal review on individual proposed actions is episodic and confined to the scope and scale of the specific actions, whereas implementation of the SHA is continuous and affects the entire property.

Educational benefits are also limited. The landowner is already aware of the conservation needs of the species through development of the SHA. Because there is no public access to the land, we are not aware of any public constituency connected with this ownership which would derive informational benefits from the designation of critical habitat. However, as noted, we have conducted extensive outreach efforts, both in relation to the SHA and its associated permit, as well as our proposed critical habitat, which have provided opportunity for public education and comment on critical habitat for the northern spotted owl. As such, much of the potential educational benefit of critical habitat on these lands has already been accomplished.

On the other hand, the SHA has provisions for protecting and maintaining northern spotted owl habitat that far exceed the conservation benefits that could be obtained through section 7 consultation. These measures will not only prevent the degradation of essential features of the northern spotted owl, but they will maintain or improve these features over time. Furthermore, landowners always have the option not to return to baseline after the term of the SHA is over. Exclusion of these lands from critical habitat will help foster the partnership we have developed with Forster-Gill through the development and continuing implementation of the SHA, and may encourage the landowner to continue these cooperative efforts even after the term of the SHA. In addition, this partnership may serve as a model and aid in fostering future cooperative relationships with other parties in other locations for the benefit of listed species. For these reasons, we have determined that the benefits of exclusion of lands covered by the Forster-Gill, Inc. SHA outweigh the benefits of critical habitat designation.

Exclusion Will Not Result in Extinction of the Species—We have determined that the exclusion of 238 ac (96 ha) from the designation of critical habitat for the northern spotted owl of lands owned and managed by Forster-Gill, Inc., as identified in their SHA will not result in extinction of the species because current conservation efforts under the plan adequately protect the geographical areas containing the physical or biological features essential to the conservation of the species. For projects having a Federal nexus and affecting northern spotted owls in occupied areas, as in this case, the jeopardy standard of section 7 of the Act, coupled with protection provided under the terms of the SHA, would provide assurances that this species will not go extinct as a result of excluding these lands from the critical habitat designation. Based on the above discussion, the Secretary is exercising his discretion under section 4(b)(2) of the Act to exclude from this final critical habitat designation portions of the proposed critical habitat units or subunits that are within the Forster-Gill, Inc. SHA boundary totaling 238 ac (96 ha).

Van Eck Forest Foundation Safe Harbor Agreement

In this final designation, the Secretary has exercised his authority to exclude lands from critical habitat, under section 4(b)(2) of the Act, that are covered by the SHA between the Fred M. Van Eck Forest Foundation and the Service within subunit 1 of the Redwood Coast CHU in California. These lands are also protected under a conservation easement held by the Pacific Forest Trust. The enhancement of survival permit associated with this SHA was noticed in the **Federal Register** on July 8, 2008 (73 FR 39026), and issued August 18, 2008. The term of the permit and the agreement is 90 years. The SHA provides for the creation and enhancement of habitat for the northern spotted owl on 2,774 ac (1,122 ha) of lands in Humboldt County, California, and provides for continued timber harvest on those lands. At the time of the agreement, the lands under consideration supported 1,730 ac (700 ha) of northern spotted owl nesting and roosting habitat and one northern spotted owl activity center (a location where owls are observed nesting or roosting). We anticipate that under the northern spotted owl habitat creation and enhancement timber management regime proposed in the SHA that approximately 1,947 ac (788 ha) of nesting and roosting habitat and potentially up to five northern spotted owl activity centers could exist on the property at the end of 90 years. The SHA does not provide for a return to baseline conditions at the end of the agreement term. Instead, the agreement provides that if more than five northern spotted owl activity centers should become established on the property during the 90-year term, the landowner would be allowed to remove such additional activity centers during the agreement period.

Under the SHA, the Fred M. van Eck Forest Foundation agrees to: (1) Conduct surveys annually to determine the locations and reproductive status of any northern spotted owls; (2) protect up to five activity centers with a no-harvest area that buffers the activity center by no less than 100 ft (30 m); (3) utilize selective timber harvest methods such that suitable nesting habitat is maintained within 300 ft (91 m) of each activity center; (4) limit noise disturbance from timber harvest operations within 1,000 ft (305 m) of an active nest during the breeding season; and (5) manage all second-growth redwood timber on the property in a manner that maintains or creates suitable nesting and roosting habitat over time. The term of the SHA and ITP is 90 years; there is no term limitation on the easement deed held by the Pacific Forest Trust. Specific long-term management targets for second-growth timber are enumerated in the easement deed. All are expressed as propertywide averages; for example, a stocking target of 100,000 board feet (bf) per acre, 75 percent minimum conifer occupancy, 25 percent of standing inventory made up of trees greater than 200 years of age, 15 dominant conifers per acre 36-inches DBH or greater, 4 standing snags per acre 30-inches DBH or greater, 1,600 cubic feet per acre of dead and down logs. The cumulative impact of the SHA and the easement, is expected to provide a substantial net benefit to the northern spotted owl.

Benefits of Inclusion—We find there are minimal benefits to including these lands in critical habitat. As discussed above, the designation of critical habitat invokes the provisions of section 7. However, in this case, we find the requirement that Federal agencies consult with us and ensure that their actions are not likely to destroy or adversely modify critical habitat will not result in significant benefits to the species because the possibility of a Federal nexus for a project on these lands is limited (there is little likelihood of an action that will involve Federal funding, authorization, or implementation). In addition, since the lands under the SHA in question are occupied by the northern spotted owl, if a Federal nexus were to occur, section

7 consultation would already be triggered and the Federal agency would consider the effects of its actions on the species through a jeopardy analysis. Because one of the primary threats to the northern spotted owl is habitat loss and degradation, the consultation process under section 7 of the Act for projects with a Federal nexus will, in evaluating effects to the northern spotted owl, evaluate the effects of the action on the habitat for the species regardless of whether critical habitat is designated for these lands. The analytical requirements to support a jeopardy determination on excluded land are similar, but not identical, to the requirements in an analysis for an adverse modification determination on included land. However, the additional conservation that could be attained through the supplemental adverse modification analysis for critical habitat under section 7 would likely not be significant, and would be triggered only in the event of a Federal action. Furthermore, any such potential benefit would be small in comparison to the benefits already derived from the SHA, which already incorporates measures that specifically benefit the northern spotted owl and its habitat, as described above, and remains in place regardless of the designation of critical habitat.

Another benefit of including lands in a critical habitat designation is that it serves to educate landowners, State and local governments, and the public regarding the potential conservation value of an area. This helps focus and promote conservation efforts by other parties by identifying areas of high conservation value for northern spotted owls. Any information about the northern spotted owl and its habitat that reaches a wider audience, including parties engaged in conservation activities, is valuable. The landowners in this case are aware of the needs of the species through the development of their SHA, in which they have agreed to take measures to protect the northern spotted owl on their property and create and enhance suitable habitat for the species as well. Any additional educational and information benefits that might arise from critical habitat designation have been largely accomplished through the public review of and comment on the SHA and the associated permit. The release of the Revised Recovery Plan for the Northern Spotted Owl in 2011 was also preceded by outreach efforts and public comment opportunities. In addition, the rulemaking process associated with critical habitat designation included several opportunities for public comment, and we also held multiple public information meetings across the range of the species. Through these outreach opportunities, land owners, State agencies, and local governments have become aware of the current status of and threats to the northern spotted owl, and the conservation actions needed for recovery.

The designation of critical habitat may also indirectly cause State or county jurisdictions to initiate their own additional requirements in areas identified as critical habitat. These measures may include additional permitting requirements or a higher level of local review on proposed projects. However, CALFIRE has indicated to us that it is unlikely to impose any new requirements on project proponents if critical habitat is designated in areas already subject to California Forest Practice Rules. Therefore, we believe this potential benefit of critical will be limited.

Benefits of Exclusion—The benefits of excluding from designated critical habitat the approximately 2,774 ac (1,122 ha) of lands currently managed under the SHA are substantial. We have created a close partnership with the Foundation through the development of the SHA, which incorporates protections and management objectives for the northern spotted owl and the habitat upon which it depends for breeding, sheltering, and foraging activities, as described above. The conservation approach identified in the Van Eck Forest Foundation SHA, along with our close coordination with the Foundation, addresses the identified threats to northern spotted owl on covered lands that contain the physical or biological features essential to the conservation of the species.

The SHA conservation measures that provide a benefit to the northern spotted owl and its habitat have been, and will be, implemented continuously beginning with the enactment of the SHA in 2008 through the 90-year term of the ITP, through 2088, on all covered lands owned and managed by the Van Eck Forest Foundation. Such measures include the examples we identified above: A volume-based mean stocking target, mean conifer occupancy, mean percentages of standing inventory in older age classes, mean size and density of dominant conifers, mean size and density of standing snags, and mean volume of dead and down logs. The measures provided in the SHA are aimed at the maintenance and enhancement of suitable nesting and roosting habitat over time to benefit the northern spotted owl.

The designation of critical habitat could have an unintended negative effect on our relationship with non-Federal landowners due to the perceived imposition of redundant government regulation. If lands within the Van Eck Forest Foundation SHA are designated as critical habitat, it would likely have a chilling effect on our continued ability to seek new partnerships with future participants including States, counties, local jurisdictions, conservation organizations, and private landowners, which together can implement various conservation actions (such as SHAs, HCPs, and other conservation plans) that we would be unable to accomplish otherwise. Excluding the approximately 2,774 ac (1,122 ha) owned and managed by the Van Eck Forest Foundation from critical habitat designation will sustain and enhance this working relationship between the Service and the Foundation. The willingness of the Foundation to work with us to manage federally listed species will continue to reinforce those conservation efforts and our partnership, which contribute toward achieving recovery of the northern spotted owl. We consider this voluntary partnership in conservation vital to our understanding of the status of species on non-Federal lands and necessary for us to implement recovery actions, such as habitat protection and restoration, and beneficial management actions for species. Further, this partnership may aid in fostering future cooperative relationships with other parties in other locations for the benefit of listed species. We consider the positive effect of excluding proven conservation partners from critical habitat to be a significant benefit of exclusion.

The Benefits of Exclusion Outweigh the Benefits of Inclusion—We reviewed and evaluated the exclusion of approximately 2,774 ac (1,122 ha) of land owned and managed by the Van Eck Forest Foundation from our designation of critical habitat. The benefits of including these lands in the designation are relatively small, since the habitat on the covered lands is already being monitored and managed under the SHA to improve the habitat elements that are equivalent to the physical or biological features that are outlined in this critical habitat rule. The additional designation of critical habitat would provide unnecessarily duplicative protections, and would in any case be unlikely to be triggered under section 7, since there is little probability of a Federal nexus on these lands. Even if triggered, since the lands in question are occupied by the species, section 7 consultation would already be required under the jeopardy standard, and, as noted, the analysis under the adverse modification standard would be unlikely to provide additional protections beyond those already in place under the SHA.

Educational benefits are also limited. The landowner is already aware of the conservation needs of the species through development of the SHA. Because the Van Eck lands, for the most part, are not open to the general public, there is no public constituency that would derive informational benefits from the designation of critical habitat. However, as noted, we have conducted extensive outreach efforts, both in relation to the SHA and its associated permit, as well as our proposed revision of critical habitat, which have provided opportunity for public education and comment on critical habitat for the northern spotted owl. As such, much of the potential educational benefit of critical habitat on these lands has already been accomplished.

On the other hand, the conservation measures identified within the SHA seek to achieve conservation goals for northern spotted owls and their habitat, and thus can be of greater conservation benefit than the designation of critical habitat, which does not require specific, proactive actions. Thus, the implementation of the SHA provides a substantially greater benefit to the northern spotted owl than would be obtained through section 7 consultation. The measures provided in the SHA will not only prevent the degradation of essential features for the northern spotted owl, but they are designed to maintain or enhance these features over time. Furthermore, landowners always have the option not to return to baseline after the term of the SHA is over. Exclusion of these lands from critical habitat will help foster the partnership we have developed with the Van Eck Forest Foundation through the development and continuing implementation of the SHA and may encourage the landowner to continue these cooperative efforts even after the term of the SHA. In addition, this partnership may serve as a model and aid in fostering future cooperative relationships with other parties in other locations for the benefit of listed species. For these reasons we have determined that the benefits of exclusion of lands covered by the Van Eck Forest Foundation SHA outweigh the benefits of critical habitat designation.

Exclusion Will Not Result in Extinction of the Species—We have determined that the exclusion of 2,774 ac (1,122 ha) from the designation of critical habitat for the northern spotted owl of lands owned and managed by the Van Eck Forest Foundation, as identified in their SHA will not result in extinction of the species because current conservation efforts under the plan adequately protect the geographical areas containing the physical or biological features essential to the conservation of the species. For projects having a Federal nexus and affecting northern spotted owls in occupied areas, such as in this case, the jeopardy standard of section 7 of the Act, coupled with protection provided under the terms of the SHA and Conservation Easement Agreement, would provide assurances that this species will not go extinct as a result of excluding these lands from the critical habitat designation. Based on the above discussion, the Secretary is exercising his discretion under section 4(b)(2) of the Act to exclude from this final critical habitat designation portions of the proposed critical habitat units or subunits that are within the Van Eck Forest Foundation SHA boundary totaling 2,774 ac (1,122 ha).

State of Washington

Port Blakely Tree Farms L.P. (Morton Block) Safe Harbor Agreement, Landowner Option Plan, and Cooperative Habitat Enhancement Agreement

In this final designation, the Secretary has exercised his authority to exclude lands from critical habitat, under section 4(b)(2) of the Act, totaling approximately 195 ac (79 ha) that are covered under the Port Blakely Tree Farms (also known as Morton Block) SHA in the West Cascades Central CHU in Washington. The enhancement of survival permit associated with this SHA was noticed in the **Federal Register** on December 17, 2008 (73 FR 76680) and issued May 22, 2009. The SHA and permit include both the marbled murrelet (*Brachyramphus marmoratus*) and the northern spotted owl, and covers an area of 45,306 ac (18,335 ha) of managed forest lands known as the ''Morton Block,'' in Lewis and Skamania Counties. The term of the permit and SHA is 60 years.

The covered lands have been intensively managed for timber production and at the time the permit was issued were not known to be occupied by northern spotted owls. The environmental baseline was measured in terms of dispersal habitat. There are no known northern spotted owls nesting on Port Blakely lands. However, northern spotted owls have historically nested on adjacent Federal lands and the 1.82-mile (2.9-km) radius circles around those sites that are used for evaluating potential habitat availability for northern spotted owls extend onto Port Blakely lands. Because of this, Port Blakely Tree Farms conducted habitat evaluations of their properties to determine the amount of suitable northern spotted owl habitat present. The baseline estimate to be provided by the SHA is 8,360 ac (3,383 ha) of northern spotted owl dispersal habitat.

Under the SHA, Port Blakely is implementing conservation measures that are expected to provide net conservation benefits to the northern spotted owl and marbled murrelet. The SHA also provides that Port Blakely will manage their tree farm in a manner that contributes to the goals of the Mineral Block Northern Spotted Owl Special Emphasis Area (SOSEA) according to Washington Forest Practices Rules and Regulations (Washington Forest Practices Board 2002, WAC 222–16–080, WAC 222–16– 086). This area is intended to facilitate dispersal of juvenile northern spotted owls, as well as provide demographic support to core northern spotted owl populations.

Under the SHA, Port Blakely is implementing enhanced forest-management measures that would create potential habitat for the northern spotted owl and marbled murrelet, such as longer harvest rotations, additional thinning to accelerate forest growth, a snag-creation program, retention of more fallen wood than is required by Washington Forest Practices Rules, establishment of special management areas and special set-aside areas, and monitoring. The terms of the agreement are intended to produce conditions that will facilitate the dispersal of the northern spotted owl across the Port Blakely ownership.

At present, there are no known nesting sites for owls in the covered area. However, portions of the covered area are within owl management circles associated with site centers on adjacent ownerships. The majority of the stand-management units are composed of 20- to 60-year-old timber. There are no stands that would provide nesting opportunities for owls in the covered area, and very little young forest marginal habitat is present in the areas of the Morton Block with the potential for utilization by owls that may occur on adjacent ownerships. The young forest marginal habitat known to exist on Port Blakely's ownership is within circles that have greater than 40 percent suitable habitat and, thus, may be harvested under Washington State Forest Practices Rules.

The SHA landscape-management approach contributes to owl recovery by complementing the existing owl landscape-management strategies on adjacent Federal and State forestlands. The SHA goals and objectives for the northern spotted owl are to provide demographic interchange through dispersal and foraging habitat across their ownership on a dynamic basis, as well as higher-quality habitat in harvest set-asides. These habitats provide for both dispersal and demographic interchange. SOSEA goals are identified in the Washington State Forest Practices Rules and shown on the SOSEA maps (see WAC 222–16–086). SOSEA goals provide for demographic and dispersal support as necessary to complement the northern spotted owl protection strategies on Federal lands within or adjacent to the SOSEA (WAC 222–16–010).

Port Blakely will achieve these goals and objectives both in the near term and over the term of the SHA by immediately protecting special management areas and special set-aside areas of northern spotted owl habitat, and managing commercial forested lands in the plan area on an average rotation length of 60 years. In addition, the SHA provides silvicultural measures to benefit the northern spotted owl, including a thinning program and a snag-retention and creation program.

Port Blakely has agreed to collaborate with State and Federal biologists in research efforts to better understand how their management will influence dispersal habitat conditions in the plan area. Port Blakely is working cooperatively with the Service, WDFW, WDNR, and other entities that have expertise, in designing a statistically robust snag-monitoring study. Port Blakely will also map all leave tree areas, and mark a sample of snag and defective trees for use in snag-monitoring studies. The SHA acknowledges uncertainty in some aspects of anticipated results. Areas of uncertainty include the likelihood that green retention trees will become snags during the period between commercial thinning and future entries, as well as the recruitment success and persistence of snags. Port Blakely has committed to work collaboratively with agencies in these matters. The SHA also contains monitoring and reporting requirements.

Benefits of Inclusion—Critical habitat designation on private lands introduces a higher level of Federal scrutiny under the interagency consultation process in section 7 of the Act. This higher level of scrutiny can arise through two avenues. Under section 7(a)(2) of the Act, Federal agencies that grant funds or issue permits for proposed actions on private lands, whether or not those lands are designated critical habitat, are required to consult with the Service to ensure that the proposed action ''* * * is not likely to jeopardize the continued existence of any endangered species or threatened species * * *'' When lands are designated critical habitat, the section 7(a)(2) consultation requirement is expanded so that the granting or permitting Federal agencies and the Service are required to ensure that the proposed action will not ''* * * result in the destruction or adverse modification of critical habitat * * *'' of any endangered species or threatened species. Critical habitat designation adds a new element to the Federal consultation: The consideration and analysis of adverse effects to habitat that might potentially arise from the proposed action. In evaluating the effects of proposed actions on critical habitat, the Service must be satisfied that the essential physical or biological features of the critical habitat likely will not be altered or destroyed by proposed activities to the extent that the conservation function of the designated critical habitat would be appreciably diminished. Briefly, if the land potentially affected by the proposed action is not designated critical habitat, the scope of the consultation must include a consideration of ''jeopardy'' to threatened or endangered species; but if the same land is designated critical habitat, the consultation must include considerations of both ''jeopardy'' and ''adverse modification'' of critical habitat.

We find that the conservation achieved through implementing these types of agreements is typically greater than would be achieved through multiple site-by-site, project-by-project, section 7 consultations involving consideration of critical habitat. In addition, it is unlikely that Federal projects would be proposed on these relatively remote forest lands unless it was a linear project such as a powerline, pipeline, or transportation project. Due to the scope of such projects, they would likely already have a Federal nexus regardless whether these lands are designated as critical habitat. While the SHA lands may not have nesting sites on them at this time, degradation of the habitats on the SHA or adjacent lands could be considered an adverse effect to the species. Because one of the primary threats to the northern spotted owl is habitat loss and degradation, the consultation process under section 7 of the Act for projects with a Federal nexus likely would, in evaluating effects to the northern spotted owl, evaluate the effects of the action on the conservation or functionality of the habitat for the species, regardless of whether critical habitat is designated for these lands. The analytical requirements to support a jeopardy determination on excluded land are similar, but not identical, to the requirements in an analysis for an adverse modification determination on land designated as critical habitat. However, the amount of conservation that could be attained through the addition of a critical habitat analysis to the section 7 consultation would be relatively low in comparison to the conservation provided by the SHA. The additional benefits of inclusion on the section 7 process are therefore relatively small.

The benefits of inclusion are further minimized because, as mentioned above, the Port Blakely SHA provides for the needs of the northern spotted owl by protecting and preserving landscape levels of suitable northern spotted owl nesting, roosting, and foraging habitat, as well as foraging and dispersal habitat over the term of the SHA in strategic landscapes, and implementing species-specific conservation measures designed to avoid and minimize effects to northern spotted owls. A fundamental requirement of an SHA is a determination by the Service that the provisions of the SHA will result in a net conservation benefit to the listed species. Approved SHAs have, therefore, already been determined to provide a net conservation benefit to the listed species. In addition, monitoring will track SHA progress over the term of the permit and provide feedback on management actions. Therefore, designation of critical habitat would be redundant on these lands, and would not provide additional measureable protections.

Another benefit of including lands in a critical habitat designation is that it serves to educate landowners, State and local governments, and the public regarding the potential conservation value of an area. This helps focus and promote conservation efforts by other parties by identifying areas of high conservation value for northern spotted owls. Designation of critical habitat could inform State agencies and local governments about areas that could be conserved under State laws or local ordinances, such as the Washington State Growth Management Act, which encourage the protection of ''critical areas'' including fish and wildlife habitat conservation areas. However, not only has the public process for this rulemaking provided information to the landowner, State agencies and local governments and the public about the importance of this area, but the process for approving a SHA, which requires public notice and comment, has served this educational function as well. Through these opportunities, land owners, State agencies, and local governments have become more aware of the status of and threats to listed species, and the conservation actions needed for recovery particularly as it relates to this property. For this reason, we believe that the educational benefits that might accrue from critical habitat designation would be minimal.

Thus, we find that there is minimal benefit from designating critical habitat for the northern spotted owl within the Port Blakely SHA.

Benefits of Exclusion—The benefits of excluding from designated critical habitat the approximately 195 ac (79 ha) of lands currently managed under the SHA are substantial and include maintaining our partnership with this landowner. This is important because it may encourage the company not to return to baseline immediately after expiration of the SHA.

Excluding lands with SHAs from critical habitat designation may also enhance our ability to seek new partnerships with future participants including States, counties, local jurisdictions, conservation organizations, and private landowners, which together can implement conservation actions that we would be unable to accomplish otherwise. If lands within the plan area are designated as critical habitat, it could have a negative effect on our ability to work with various companies to accomplish our goals for the SHA program and recovery of the northern spotted owl. This SHA is located in a key landscape between the Mineral Block and other Federal lands, and represents a unique opportunity to maintain northern spotted owls at the western extreme of the Cascades, which may support dispersal between the Cascades and Olympics. This SHA contributes meaningfully to the recovery of the northern spotted owl and serves as an example to other industrial companies. This SHA was the first to combine a Federal SHA effort with similar planning processes under State jurisdiction and serves as a role model in combining SHA planning with State processes. By excluding these lands, we preserve our current private and local conservation partnerships and encourage additional conservation actions in the future.

Benefits of Exclusion Outweigh the Benefits of Inclusion—In summary, we determine that the benefits of excluding the Port Blakely SHA from the designation of critical habitat for the northern spotted owl outweigh the benefits of including this area in critical habitat. We find that including the Port Blakely SHA would result in minimal, if any, additional benefits to the northern spotted owl, as explained above. We also find that the benefits of including these lands are further minimized by the fact that the management strategies of the Port Blakely SHA are designed to maintain and enhance habitat for the northern spotted owl. The SHA includes species-specific avoidance and minimization measures, monitoring requirements to track success and ensure proper implementation, and forest-management practices and habitat conservation objectives that benefit the northern spotted owl and its habitat, which exceeds any conservation value provided as a result of a critical habitat designation. Furthermore, encouraging landowners to enter into voluntary conservation agreements with the Service for the recovery of endangered or threatened species which we believe would be one of the benefits of exclusion may outweigh the loss of benefit that may be incurred through a possible return to baseline following permit expiration.

Therefore, in consideration of the factors discussed above in the Benefits of Exclusion section, including the relevant impact to current and future partnerships, we have determined that the benefits of exclusion of lands covered by the Port Blakely SHA outweigh the benefits of critical habitat designation.

Exclusion Will Not Result in Extinction of the Species—We have determined that exclusion of a net of approximately 195 ac (79 ha) of lands within the Port Blakely SHA will not result in extinction of the northern spotted owl because current and future conservation efforts under the agreement provide management to facilitate dispersal of juvenile northern spotted owls, as well as provide demographic support to core northern spotted owl populations. Further, should nesting populations of the owl become reestablished in this area (and projects subsequently planned that have a Federal nexus and would potentially affect northern spotted owls), the jeopardy standard of section 7 of the Act, coupled with protection provided by the Port Blakely SHA, would provide a level of assurance that this species will not go extinct as a result of excluding these lands from the critical habitat designation. Based on the above discussion, the Secretary is exercising his discretion under section 4(b)(2) of the Act to exclude from this final critical habitat designation portions of the proposed critical habitat units or subunits that are within the Port Blakely SHA totaling about 195 ac (79 ha).

SDS Company LLC and Broughton Lumber Company Safe Harbor Agreement

In this final designation, the Secretary has exercised his authority to exclude lands from critical habitat, under section 4(b)(2) of the Act, lands totaling about 2,035 ac (824 ha) that are covered under the SDS Lumber Company LLC and its registered business name Stevenson Land Company (together SDS) and Broughton Lumber Company (in total are related companies and are herein known as ''the Companies'') SHA, in Washington and Oregon. (Note the proposed rule contained an error, in which we mistakenly identified approximately 16,031 ac (6,487 ha) of SDS and Broughton lands for potential exclusion). The enhancement of survival permits associated with this SHA were noticed in the **Federal Register** on August 21, 2012 (77 FR 50526) and issued to the Companies on October 26, 2012. The term of each of the permits is 60 years. The Companies collectively manage approximately 83,000 ac (33,589 ha) of forestland in Skamania and Klickitat Counties in Washington, and Hood River and Wasco Counties in Oregon. Much of this ownership is composed of potential habitat outside of any owl circles and, therefore, is currently available for harvest under Washington State Forest Practices Rules. However, 30 northern spotted owl home ranges overlap some portion of the Companies' land base. Most site centers are currently located on Federal or State ownership; only one site center is located on Companies' ownership. Because the Companies have committed to manage their commercial forest lands for a substantially longer rotation than the typical 45-year rotation, and to implement additional conservation measures, northern spotted owls could occupy the covered area in the future under the SHA.

The Companies' landscape management approach contributes to owl recovery by complementing the existing owl landscape-management strategies on adjacent Federal and State forestlands. The Companies' SHA goals and objectives for the northern spotted owl are to provide dispersal and young forest marginal habitat across their ownership on a dynamic basis, as well as submature and higher quality habitat in harvest set-asides. These habitats provide both dispersal and demographic support, an established goal for lands within the two northern spotted owl special emphasis areas (SOSEAs). SOSEA goals are identified in the Forest Practices Rules and shown on the SOSEA maps (see WAC 222–16–086). SOSEA goals provide for demographic and/or dispersal support as necessary to complement the northern spotted owl protection strategies on Federal lands within or adjacent to the SOSEA (WAC 222–16–010).

The Companies will achieve these goals and objectives both in the near term and over the term of the SHA by immediately protecting special set-aside areas of northern spotted owl habitat and managing commercial forested lands in the plan area on an average rotation length of 60 years. In addition, the SHA provides silvicultural measures to benefit the northern spotted owl, including a snag-retention and creation program.

The SHA includes an elevated baseline, provisions for a 240-acre nesting set-aside and a 411-acre reserve in the White Salmon SOSEA, a 10-year deferral of harvest of any habitat in the 0.7-mile circle of the four site centers in which the Companies' covered lands comprise greater than 15 percent, future nest site protection, and the support and enhancement of existing conservation agreements. The SHA will include a monitoring and reporting schedule to ensure that the anticipated benefits will accrue both in the near term and over the term of the SHA.

Benefits of Inclusion—We find that there is minimal benefit from designating critical habitat for the northern spotted owl within the SDS SHA. It is unlikely that Federal projects would be proposed on these relatively remote forest lands unless it was a linear project such as a powerline, pipeline, or transportation project. Due to the scope of such projects, they would likely already have a Federal nexus regardless whether these lands are designated as critical habitat. Even where the SHA lands may not have nesting sites on them at this time, degradation of the habitats on the SHA or adjacent lands could be considered an adverse effect to the species. Because one of the primary threats to the northern spotted owl is habitat loss and degradation, the consultation process under section 7 of the Act for projects with a Federal nexus likely would, in evaluating effects to the northern spotted owl, evaluate the effects of the action on the conservation or functionality of the habitat for the species, regardless of whether critical habitat is designated for these lands. The analytical requirements to support a jeopardy determination on excluded land are similar, but not identical, to the requirements in an analysis for an adverse modification determination on land designated as critical habitat. However, the amount of conservation that could be attained through the addition of a critical habitat analysis to the section 7 consultation would be relatively low in comparison to the conservation provided by the SHA, as discussed below. The additional benefits of inclusion on the section 7 process are therefore relatively small.

The benefits of inclusion are further minimized because this SHA provides for the needs of the northern spotted owl by protecting and preserving landscape levels of suitable northern spotted owl nesting, roosting, and foraging habitat, as well as foraging and dispersal habitat over the term of the SHA in strategic landscapes, and implementing species-specific conservation measures designed to avoid and minimize effects to northern spotted owls. A fundamental requirement of an SHA is a determination by the Service that the provisions of the SHA will result in a net conservation benefit to the listed species. Approved SHAs have, therefore, already been determined to provide a net conservation benefit to the listed species. In addition, funding for management is ensured through the Implementation Agreement. Such assurances are typically not provided by section 7 consultations, which in contrast to SHAs, do not commit the project proponent to long-term, special management practices or protections. In addition, monitoring will track SHA progress over the term of the permit and provide feedback on management actions. Therefore, designation of critical habitat would be redundant on these lands, and would not provide additional measureable protections.

Another benefit of including lands in a critical habitat designation is that it serves to educate landowners, State and local governments, and the public regarding the potential conservation value of an area. This helps focus and promote conservation efforts by other parties by identifying areas of high conservation value for northern spotted owls. Designation of critical habitat could inform State agencies and local governments about areas that could be conserved under State laws or local ordinances, such as the Washington State Growth Management Act, which encourage the protection of ''critical areas'' including fish and wildlife habitat conservation areas. However, not only has the public process for this rulemaking provided information to the landowner, State agencies and local governments and the public about the importance of this area, but the process for approving a SHA, which also requires public notice and comment, has served this educational function too. Through these opportunities, land owners, State agencies, and local governments have become more aware of the status of and threats to listed species, and the conservation actions needed for recovery particularly as it relates to this property. For these reasons, we believe that the educational benefits that might accrue from critical habitat designation would be minimal.

Therefore, we find that there is minimal benefit from designating critical habitat for the northern spotted owl within this SHA.

Benefits of Exclusion—The benefits of excluding from designated critical habitat the approximately 2,035 ac (824 ha) of lands currently managed under the SHA are substantial and include maintaining our partnership with this landowner. This is important because it may encourage the company not to return to baseline immediately after expiration of the SHA.

Excluding lands with SHAs from critical habitat designation may also enhance our ability to seek new partnerships with future participants including States, counties, local jurisdictions, conservation organizations, and private landowners, which together can implement conservation actions that we would be unable to accomplish otherwise. If lands within the plan area are designated as critical habitat, it could have a negative effect on our ability to work with various companies to accomplish our goals for the SHA program and recovery of the northern spotted owl. This SHA is located in key northern spotted owl landscapes and contributes meaningfully to the recovery of the northern spotted owl. Two SOSEAs, the White Salmon and Columbia Gorge SOSEAs, encompass approximately 54 percent of the Companies' lands in Skamania and Klickitat Counties. The Companies' landscape-management approach contributes to northern spotted owl recovery by complementing the existing northern spotted owl landscape-management strategies on adjacent Federal and State forestlands. With the Companies' participation in northern spotted owl conservation, it will be the first time in these SOSEAs, that a private landowner has joined State and Federal land managers to implement a landscape approach for northern spotted owl habitat. The Companies' lands provide a major link in the goal of managing both the Columbia River and White Salmon SOSEAs under a unified landscape-management regime rather than a competitive harvesting regime under owl-circle management.

The designation of critical habitat could nonetheless have an unintended negative effect on our relationship with non-Federal landowners due to the perceived imposition of redundant government regulation. If lands within the SDS SHA plan area are designated as critical habitat, it would likely have a negative effect on our ability to establish new partnerships to develop SHAs, HCPs, and other conservation plans, particularly plans that address landscape-level conservation of species and habitats. This SHA is being observed by other land and timber companies in Washington and Oregon and may serve as a model for ongoing and future efforts. By excluding these lands, we preserve our current private and local conservation partnerships and encourage additional conservation actions in the future.

Benefits of Exclusion Outweigh the Benefits of Inclusion—In summary, we determine that the benefits of excluding the SDS SHA from the designation of critical habitat for the northern spotted owl outweigh the benefits of including this area in critical habitat. We find that including it would result in minimal, if any, additional benefits to the northern spotted owl, as explained above. We also find that the benefits of including these lands are further minimized by the fact that the management strategies of the SHA are designed to maintain and enhance habitat for the northern spotted owl. The SHA includes species-specific avoidance and minimization measures, monitoring requirements to track success and ensure proper implementation, and forest-management practices and habitat conservation objectives that benefit the northern spotted owl and its habitat, which exceeds any conservation value provided as a result of a critical habitat designation. Furthermore, encouraging landowners to enter into voluntary conservation agreements with the Service for the recovery of endangered or threatened species which we believe would be one of the benefits of exclusion may outweigh the loss of benefit that may be incurred through a possible return to baseline following permit expiration.

Therefore, in consideration of the factors discussed above in the Benefits of Exclusion section, including the relevant impact to current and future partnerships, we have determined that the benefits of exclusion of lands covered by the Port Blakely SHA outweigh the benefits of critical habitat designation.

Exclusion Will Not Result in Extinction of the Species—We have determined that exclusion of a net of approximately 2,035 ac (824 ha) of lands within the SDS SHA will not result in extinction of the northern spotted owl because, under this agreement, the landscape management approach contributes to owl recovery by complementing the existing owl landscape-management strategies on adjacent Federal and State forestlands. The SDS SHA goals and objectives for the northern spotted owl are to provide dispersal and young forest marginal habitat across their ownership on a dynamic basis, as well as submature and higher quality habitat in harvest set-asides. These habitats provide both dispersal and demographic support, an established goal for lands within the two northern spotted owl special emphasis areas (SOSEAs). Further, for projects having a Federal nexus and affecting northern spotted owls in occupied areas, the jeopardy standard of section 7 of the Act, coupled with protection provided by the SDS SHA, would provide a level of assurance that this species will not go extinct as a result of excluding these lands from the critical habitat designation. We find that exclusion of these lands within the SDS SHA will not result in extinction of the northern spotted owl. Based on the above discussion, the Secretary is exercising his discretion under section 4(b)(2) of the Act to exclude from this final critical habitat designation portions of the proposed critical habitat units or subunits that are within the SDS SHA totaling about 2,035 ac (824 ha).

How We Evaluate Lands Protected Under HCPs for Exclusion

The consultation provisions under section 7(a)(2) of the Act constitute a regulatory benefit of critical habitat. Federal agencies must consult with us on actions that may affect critical habitat and must avoid destroying or adversely modifying critical habitat. In areas without designated critical habitat, Federal agencies consult with us on actions that may affect a listed species and must refrain from undertaking actions that are likely to jeopardize the continued existence of the species. Thus, the analysis of effects to critical habitat is a separate and different analysis from that of the effects to the species. The difference in outcomes of these two analyses represents the regulatory benefit of critical habitat. For some species, and in some locations, the outcome of these analyses will be similar, because effects on habitat will often result in effects on the species. However, the regulatory standard is different: The jeopardy analysis looks at the action's impact on survival and recovery of the species, while the adverse modification analysis looks at the action's effects on the designated habitat's contribution to the species' conservation. This will, in some instances, lead to different results or consultation where it might not have otherwise occurred (e.g. in habitat not currently occupied by the species).

Once an agency determines that consultation under section 7 of the Act is necessary, the process may conclude informally when we concur in writing that the proposed Federal action is not likely to adversely affect critical habitat. However, if the action agency determines through informal consultation that adverse effects are likely to occur, then it would initiate formal consultation, which would conclude when we issue a biological opinion on whether the proposed Federal action is likely to result in destruction or adverse modification of critical habitat. A biological opinion that concludes in a determination of no destruction or adverse modification may contain discretionary conservation recommendations to minimize adverse effects to critical habitat, but it would not contain any mandatory reasonable and prudent measures or terms and conditions because these do not apply to critical habitat. In addition, we suggest reasonable and prudent alternatives to the proposed Federal action only when our biological opinion finds that the action may destroy or adversely modify critical habitat.

The process of designating critical habitat as described in the Act requires, in part, that the Service identify those lands occupied at the time of listing on which are found the physical or biological features essential to the conservation of the species, which may require special management considerations or protection and any unoccupied lands that are essential to the conservation of the species. In identifying those lands, the Service must consider the recovery needs of the species. Once critical habitat has been designated, Federal agencies must consult with the Service under section 7(a)(2) of the Act on their actions that may adversely affect the species or critical habitat to ensure that their actions are not likely to adversely modify critical habitat or jeopardize the continued existence of the species.

We find that in some cases, the conservation benefits to a species and its habitat that may be achieved through the designation of critical habitat are less than those that could be achieved through the implementation of a habitat conservation management plan that includes specific provisions based on enhancement or recovery as the management standard. Consequently, the implementation of any HCP or management plan that considers enhancement or recovery as the management standard will often provide as much or more benefit than a section 7(a)(2) consultation under the Act. There may be some regulatory benefit that results from designating critical habitat in the areas covered by the HCPs because of section 7 consultation requirements; however, they are often minimal compared to the benefits of exclusion.

Non-Federal landowners are often motivated to work with the Service collaboratively to develop HCPs because of the regulatory certainty provided by an incidental take permit under section 10(a)(1)(B) of the Act, including assurances under the No Surprises Policy (63 FR 8859; February 23, 1998). The No Surprises Policy sets forth a clear commitment to incidental take permittees that, to the extent consistent with the Act and other Federal laws, the government will not seek additional mitigation under an approved HCP where the permittee is implementing the HCP's terms and conditions. Although the HCP process can be complex and time-consuming, the benefit to landowners in undertaking this extensive process is not only incidental take authorization but the resulting regulatory certainty, which translates into real savings for private landowners in terms of opportunity costs, as well as direct savings and avoided costs. Designation of critical habitat within the boundaries of already approved HCPs may be viewed as a disincentive by other entities currently developing HCPs or contemplating them in the future, because it may be perceived as imposing duplicative regulatory burdens. In discussions with the Service, HCP permittees have indicated they view critical habitat designation as an unnecessary additional intrusion on their property, and have expressed concern that the Service may request new conservation measures for the northern spotted owl, even though they have an existing HCP and associated incidental take permit that has already gone through NEPA and the section 7 consultation process already in place.

Although parties whose actions may take listed species may still desire incidental take permits to avoid liability under section 9 of the Act, failure to exclude HCP lands from critical habitat could reduce the conservation value of the HCP program in several ways. First, parties may be less willing to seek a section 10 (a)(2) permit and develop an HCP where they are not certain their actions will cause incidental take in order to avoid involving the Federal government when that involvement could lead to future section 7 consultations because of critical habitat designation. Second, in any given HCP, applicants may reduce the amount of protection to which they are willing to agree, in effect holding some additional protective measures ''in reserve'' for use in any future discussions to address critical habitat. The failure to exclude qualified HCP lands from critical habitat designations could decrease the program's efficacy and have profound effects on our ability to establish and maintain important conservation partnerships with stakeholders.

Excluding qualified HCP lands from critical habitat provides permittees with the greatest possible certainty, and thereby may help foster the cooperation necessary to allow the HCP program to achieve the greatest possible conservation benefit. Thus, excluding the lands covered by HCPs may improve the Service's ability to enter into new partnerships. In addition, permittees who trust and benefit from the HCP process may encourage future HCP participants, such as States, counties, local jurisdictions, conservation organizations, and private landowners, leading to new HCPs that may result in implementation of conservation actions we would be unable to accomplish otherwise.

Excluding lands covered under HCPs from the critical habitat designation may also relieve landowners from the possibility of any additional regulatory burden and costs associated with the preparation of section 7 documents related to critical habitat. While the costs of providing these additional documents to the Service is minor, there may be resulting delays that generate perceived or very real costs to private landowners in the form of opportunity costs, as well as direct costs.

HCPs can provide other important conservation benefits, including the development of important biological information needed to guide conservation efforts and assist in species conservation outside the HCP planning area. Each of the HCPs evaluated below have some component of adaptive forest management to address uncertainties in achieving their agreed-upon conservation objectives for the northern spotted owl. The adaptive management strategy helps to ensure management will continue to be consistent with agreed-upon northern spotted owl conservation objectives.

Below is a brief description of each HCP and the lands proposed as critical habitat covered by each plan that we have excluded from critical habitat designation under section 4(b)(2) of the Act.

State of California

Green Diamond Resource Company Habitat Conservation Plan

In this final designation, the Secretary has exercised his authority to exclude lands from critical habitat, under section 4(b)(2) of the Act, that are covered under the Green Diamond Resource Company Northern Spotted Owl Habitat Conservation Plan of 1992. The Green Diamond Resource Company (Green Diamond, formerly Simpson Timber Company) operates under a northern spotted owl HCP within the Redwood Coast Critical Habitat Unit in California. The Incidental Take Permit (ITP) issued in association with this HCP was initially noticed in the **Federal Register** on May 27, 1992 (57 FR 22254) and issued September 17, 1992. Both the HCP and the permit had a term of 30 years, with a comprehensive review scheduled after 10 years to review the efficacy of the plan. The permit allows incidental take of up to 50 pairs of northern spotted owls and their habitat during the course of timber harvest operations on 369,384 ac (149,484 ha) of forest lands in Del Norte and Humboldt Counties.

At the time the permit was issued, more than 100 northern spotted owl nest sites or activity centers were known or suspected on the property. The Service determined that the projected growth and harvest rates indicated more habitat of the age class primarily used by northern spotted owls would exist on the property at the end of the 30-year permit period. In addition, the HCP provided that nest sites would be protected during the breeding season, and no direct killing or injuring of owls was anticipated. Green Diamond also agreed to continue their monitoring programs, in which more than 250 adult owls and more than 100 juveniles were already banded, as well as analyses of timber stands used by owls. As required by the terms of the HCP, Green Diamond and the Service conducted a comprehensive review of the first 20 years of implementation, including a comparison of actual and estimated levels of owl displacement, a comparison of estimated and actual distribution of habitat, a reevaluation of the biological basis for the HCP's conservation strategy, an examination of the efficacy of and continued need for habitat set-asides, and an estimate of future owl displacements. During the comprehensive review, Green Diamond requested an amendment to the 1992 ITP to allow incidental take of up to eight additional northern spotted owl pairs. This request was noticed in the **Federal Register** on February 26, 2007 (72 FR 8393) and the modified permit was issued in October 2007.The original Green Diamond Northern Spotted Owl HCP relied on extensive monitoring and research to inform development of more comprehensive conservation strategies for their lands. The outcome of 20 years of implementation of Green Diamond's 1992 informed the Service and Green Diamond on how to develop new, or modify the original, conservation strategies to further benefit the northern spotted owl.

On April 16, 2010, we announced our intent to prepare an Environmental Impact Statement (EIS) under the National Environmental Policy Act (NEPA) in response to an expected new HCP from Green Diamond, which would include provisions for the northern spotted owl and possibly the Pacific fisher (*Martes pennanti*), a species that may be considered for listing during the term of the HCP. This new HCP, if completed and approved, would replace the 1992 HCP, and would require the issuance of a new incidental take permit. The proposed new HCP is intended to address the retention of suitable northern spotted owl nesting habitat, the development of older forest habitat elements and habitat structures, and future establishment of northern spotted owl nest sites in streamside retention zones. In addition, the new plan will help cluster owl sites in favorable habitat areas, and initiate future research on other wildlife species such as fishers and barred owls. Since this new draft HCP has not yet been completed, the draft HCP does not serve as the basis for exclusion and we only provide this information in terms of demonstrating the progression of involvement and partnership between the Service and Green Diamond. The existing HCP, originally completed in 1992, is still in effect as of this date and serves, in part, as the basis for this exclusion.

Since approval of the 1992 HCP, personnel from Green Diamond, along with academic and research institutions, have been the largest single contributor of scientific information on the ecology of northern spotted owls and their habitats on managed forest lands in the redwood region, in the form of graduate theses and peer-reviewed papers. Since the initial listing of the northern spotted owl in 1990, Green Diamond has maintained on their lands 1 of the 11 demographic study areas within the range of the northern spotted owl that have been used for rangewide monitoring and evaluation of populations and population trends in the Pacific northwest. This important demographic information is reported in a continuing series of monographs, the most recent being Forsman *et al.* (2011).

Benefits of Inclusion—We find there are minimal benefits to including these lands in critical habitat. As discussed above, the designation of critical habitat invokes the provisions of section 7. However, in this case, we find the requirement that Federal agencies consult with us and ensure that their actions are not likely to destroy or adversely modify critical habitat will not result in significant benefits to the species because the possibility of a Federal nexus for a project on these lands that might trigger such consultation is limited; there is little likelihood of an action that will involve Federal funding, authorization, or implementation. In addition, since the lands under the HCP in question are occupied by the northern spotted owl, if a Federal nexus were to occur, section 7 consultation would already be triggered and the Federal agency would consider the effects of its actions on the species through a jeopardy analysis. While the jeopardy and adverse modification standards are different, the additional conservation that could be attained through the supplemental adverse modification analysis for critical habitat under section 7 would not be significant in light of the benefits of the HCP, which already incorporates protections and management objectives for the northern spotted owl and the habitat upon which it depends for breeding, sheltering, and foraging activities. The conservation approach identified in the Green Diamond HCP, along with our close coordination with the company, addresses the identified threats to northern spotted owl on lands covered by the HCP that contain the physical or biological features essential to the conservation of the species. The conservation measures identified within the HCP seek to achieve conservation goals for northern spotted owls and their habitat, and thus can be of greater conservation benefit than the designation of critical habitat, which does not require specific, proactive actions. HCPs typically provide for greater conservation benefits to a covered species than section 7 consultations because HCPs ensure the long-term protection and management of a covered species and its habitat. In addition, funding for such management is ensured through the Implementation Agreement. Such assurances are typically not provided by section 7 consultations, which in contrast to HCPs, often do not commit the project proponent to long-term, special management practices or protections. Thus, a section 7 consultation typically does not afford the lands it covers similar extensive benefits as an HCP. In addition, the protections of critical habitat come into play only in the event of a Federal action, whereas the protections of an HCP are in continuous force.

Another potential benefit of including lands in a critical habitat designation is that the designation can serve to educate landowners, State and local government agencies, and the public regarding the potential conservation value of an area, and may help focus conservation efforts on areas of high conservation value for certain species. Any information about the northern spotted owl and its habitat that reaches a wider audience, including parties engaged in conservation activities, is valuable. However, in this case the educational value of critical habitat is limited. Green Diamond has already made substantial contributions to our knowledge of the species through research and monitoring without critical habitat designated on their lands. In addition, the educational and informational benefits that might arise from critical habitat designation have been largely accomplished through the public review and comment on the HCP and associated documents. The release of the Revised Recovery Plan for the Northern Spotted Owl in 2011 was also preceded by outreach efforts and public comment opportunities. Furthermore, we conducted extensive outreach efforts on the proposed revision of critical habitat, including multiple public information meetings and opportunities for public comment. Through these outreach opportunities, land owners, State agencies, and local governments have become aware of the status of and threats to the northern spotted owl, and the conservation actions needed for recovery.

The designation of critical habitat may also indirectly cause State or county jurisdictions to initiate their own additional requirements in areas identified as critical habitat. These measures may include additional permitting requirements or a higher level of local review on proposed projects. However, CALFIRE has indicated to us that it is unlikely to impose any new requirements on project proponents if critical habitat is designated in areas already subject to California Forest Practice Rules. Therefore, we believe this potential benefit of critical will be limited.

Benefits of Exclusion—The benefits of excluding from designated critical habitat the approximately 369,864 ac (149,484 ha) of lands currently managed under the Green Diamond HCP are significant. We have created a close partnership with Green Diamond through development of the HCP, and they have proven to be an invaluable partner in the conservation of the northern spotted owl. Green Diamond has made a significant contribution to our knowledge of the northern spotted owl through their support of continuing research on their lands. Excluding the approximately 369,864 ac (149,484 ha) owned and managed by Green Diamond from critical habitat designation will sustain and enhance the working relationship between the Service and Green Diamond. The willingness of Green Diamond to work with the Service in innovative ways to conduct solid scientific research and manage federally listed species will continue to reinforce those conservation efforts and our partnership, which contribute toward achieving recovery of the northern spotted owl. Due to the important research they are facilitating, we consider this voluntary partnership in conservation vital to our understanding of the northern spotted owl status of species on non-Federal lands and necessary for us to implement recovery actions such as habitat protection and restoration, and beneficial management actions for species.

The designation of critical habitat could have an unintended negative effect on our relationship with non-Federal landowners due to the perceived imposition of redundant government regulation. If lands within the Green Diamond HCP are designated as critical habitat, it would likely have a negative effect on our continued ability to seek new partnerships with future participants including States, counties, local jurisdictions, conservation organizations, and private landowners, which together can implement various conservation actions (such as SHAs, HCPs, and other conservation plans) that we would be unable to accomplish otherwise. In addition, our conservation partnership with Green Diamond may serve as a model and aid in fostering future cooperative relationships with other parties in other locations for the benefit of listed species. We consider the positive effect of excluding proven conservation partners from critical habitat to be a significant benefit of exclusion.

The Benefits of Exclusion Outweigh the Benefits of Inclusion—We reviewed and evaluated the exclusion of approximately 369,864 ac (149,484 ha) of land owned and managed by the Green Diamond Resource Company from our designation of critical habitat. The benefits of including these lands in the designation are comparatively small, since the habitat on the covered lands is already being monitored and managed under the current HCP to improve the habitat elements that are equivalent to the physical or biological features outlined in this critical habitat rule. Any potential regulatory benefits of critical habitat would be minimal, at best, as additional Federal review on individual proposed actions is episodic and confined to the scope and scale of the specific Federal actions that take the form of project review or granting of funds. In any case, any potential regulatory benefit that would be gained from a supplemental adverse modification analysis, should section 7 be triggered, would likely be minimal since the protections afforded by critical habitat would be duplicative with the protections provided through the HCP. Educational benefits to the company that might be attributed to critical habitat designation are limited because the company already has an active program of research and analysis that is embedded in company planning. In addition, extensive outreach efforts that have already occurred in conjunction with the HCP, Revised Recovery Plan, and the proposed revision of critical habitat have raised awareness of the current status of and threats to the northern spotted owl, and the conservation actions needed for recovery. Green Diamond has made a significant contribution to the body of scientific information about the northern spotted owl in the redwood region.

In this instance, the regulatory and educational benefits of inclusion in critical habitat are minimal compared to the significant benefits gained through our conservation partnership with Green Diamond. In addition, the conservation measures of their HCP serves not only an educational function for the company and local and State regulatory jurisdictions, but also provides for significant conservation and management of northern spotted owl habitat and contributes to the recovery of the species. The HCP provisions for protecting and maintaining northern spotted owl habitat far exceed the conservation benefits that would be obtainable through section 7 consultation. The company's current program of research on the northern spotted owl habitat and demographics could not be obtained through section 7 consultation.

Exclusion of these lands from critical habitat will help foster the partnership we have developed with Green Diamond, partly through the development and continuing implementation of the HCP, and partly through the encouragement of elective actions by the company that are unconnected to the HCP. For example, Green Diamond's elective role in maintaining a demographic study area, which is a key part of the network of demographic study areas essential to determining the rangewide population trends of the northern spotted owl, is integral to continuing research on the species. Our partnership with Green Diamond not only provides a benefit for the conservation of the northern spotted owl, but it may also serve as a model and aid in fostering future cooperative relationships with other parties in other locations for the benefit of listed species. For these reasons, we have determined that the benefits of exclusion of lands covered by the Green Diamond Resource Company HCP outweigh the benefits of critical habitat designation.

Exclusion Will Not Result in Extinction of the Species—We have determined that the exclusion of 369,864 ac (149,484 ha) from the designation of critical habitat for the northern spotted owl of lands owned and managed by the Green Diamond Resource Company, as identified in their HCP, will not result in extinction of the species because current conservation efforts under the plan adequately protect the geographical areas containing the physical or biological features essential to the conservation of the species. For those infrequent projects having a Federal nexus and affecting northern spotted owls on these lands, which are occupied by the species, the jeopardy standard of section 7 of the Act, coupled with protection provided by the current Green Diamond HCP, would provide a level of assurance that this species will not go extinct as a result of excluding these lands from the critical habitat designation. Based on the above discussion, the Secretary is exercising his discretion under section 4(b)(2) of the Act to exclude from this final critical habitat designation portions of the proposed critical habitat units or subunits that are within the Green Diamond HCP boundary totaling 369,864 ac (149,484 ha).

Humboldt Redwood Company Habitat Conservation Plan

In this final designation, the Secretary has exercised his authority to exclude lands from critical habitat, under section 4(b)(2) of the Act, that are covered under the Humboldt Redwood Company (formerly Pacific Lumber) HCP in the Redwood Coast CHU in California. The permit under this HCP with a term of 50 years was noticed on July 14, 1998 (63 FR 37900) and issued on March 1, 1999. The HCP includes 208,172 ac (84,244 ha) of commercial timber lands in Humboldt County, essentially all of the formerly Pacific Lumber timberlands outside of the Headwaters Reserve, which is currently under Bureau of Land Management administration. The Humboldt Redwood Company HCP includes nine nonlisted species (including one candidate species) and three listed species, including the northern spotted owl. Activities covered by the HCP include forest management activities and mining or other extractive activities. With regard to the northern spotted owl in particular, the HCP addresses the harvest, retention, and recruitment of requisite habitat types and elements within watershed assessment areas and individual northern spotted owl activity sites. The management objectives of the HCP are to minimize disturbance to northern spotted owl activity sites, monitor to determine whether these efforts maintain a high-density and productive population of northern spotted owls, and apply adaptive forest management provisions as necessary to evaluate or modify existing conservation measures. In addition, there are specific habitat retention requirements to conserve habitat for foraging, roosting, and nesting at northern spotted owl activity sites. The other conservation elements of the HCP are also expected to aid in the retention and recruitment of potential foraging, roosting, and nesting habitat in watersheds across the ownership. For example, the HCP establishes a network of marbled murrelet conservation areas, outlines silvicultural requirements associated with riparian management zones and mass wasting avoidance areas, imposes cumulative effects/disturbance index restrictions, and contains a retention standard of 10 percent late seral habitat in each watershed assessment. Each of these measures is likely to provide additional suitable habitat for the northern spotted owl.

Benefits of Inclusion—We find there are minimal benefits to including these lands in critical habitat. As discussed above, the designation of critical habitat invokes the provisions of section 7. However, in this case, we find the requirement that Federal agencies consult with us and ensure that their actions are not likely to destroy or adversely modify critical habitat will not result in significant benefits to the species because the possibility of a Federal nexus for a project on these lands that might trigger such consultation is limited since there is little likelihood of an action that will involve Federal funding, authorization, or implementation. In addition, since the lands under the HCP in question are occupied by the northern spotted owl, if a Federal nexus were to occur, section 7 consultation would already be triggered and the Federal agency would consider the effects of its actions on the species through a jeopardy analysis. Although the jeopardy and adverse modification standards are different, the additional conservation that could be attained through the supplemental adverse modification analysis for critical habitat under section 7 would not be significant because the HCP incorporates protections and management objectives for the northern spotted owl and the habitat upon which it depends for breeding, sheltering, and foraging activities. The conservation approach identified in the HCP, along with our close coordination with the Humboldt Redwood Company, addresses the identified threats to northern spotted owl on lands covered by the HCP that contain the physical or biological features essential to the conservation of the species. The conservation measures identified within the HCP seek to achieve conservation goals for northern spotted owls and their habitat, and thus can be of greater conservation benefit than the designation of critical habitat, which does not require specific, proactive actions. HCPs typically provide for greater conservation benefits to a covered species than section 7 consultations because HCPs ensure the long-term protection and management of a covered species and its habitat. In addition, funding for such management is ensured through the Implementation Agreement. Such assurances are typically not provided by section 7 consultations, which in contrast to HCPs, often do not commit the project proponent to long-term, special management practices or protections. Thus, a section 7 consultation typically does not afford the lands it covers similar extensive benefits as an HCP. In addition, the protections of critical habitat come into play only in the event of a Federal action, whereas the protections of an HCP are in continuous force.

The HCP conservation measures that provide direct and indirect benefits to the northern spotted owl and its habitat have been implemented continuously since 1999 on all covered lands owned and managed by the Humboldt Redwood Company. Northern spotted owl conservation measures are subject to re-evaluation and modification through active adaptive forest management provisions in the Plan, which can be initiated by the Service or by the Company.

Another benefit of including lands in a critical habitat designation is that it serves to educate landowners, State and local governments, and the public regarding the potential conservation value of an area. This helps focus and promote conservation efforts by other parties by identifying areas of high conservation value for northern spotted owls. Any information about the northern spotted owl and its habitat that reaches a wider audience, including parties engaged in conservation activities, is valuable. The landowners in this case are aware of the needs of the species through the development of their HCP, in which they have agreed to take measures to protect the northern spotted owl and its habitat. Any additional educational and information benefits that might arise from critical habitat designation have been largely accomplished through the public review of and comment on the HCP and the associated permit. The release of the Revised Recovery Plan for the Northern Spotted Owl in 2011 was also preceded by outreach efforts and public comment opportunities. In addition, the rulemaking process associated with critical habitat designation included several opportunities for public comment, and we also held multiple public information meetings across the range of the species. Through these outreach opportunities, land owners, State agencies, and local governments have become aware of the current status of and threats to the northern spotted owl, and the conservation actions needed for recovery.

The designation of critical habitat may also indirectly cause State or county jurisdictions to initiate their own additional requirements in areas identified as critical habitat. These measures may include additional permitting requirements or a higher level of local review on proposed projects. However, CALFIRE has indicated to use that it is unlikely to impose any new requirements on project proponents if critical habitat is designated in areas already subject to California Forest Practice Rules. Therefore, we believe this potential benefit of critical will be limited.

Benefits of Exclusion—The benefits of excluding from designated critical habitat the approximately 208,172 ac (84,244 ha) of lands currently managed under the Humboldt Redwood Company (formerly Pacific Lumber Company) HCP are significant. Although the HCP was originally negotiated with Pacific Lumber, we have developed a good working rapport with Humboldt Redwood Company, and expect this conservation partnership to continue through the implementation of the HCP. We consider conservation partnerships with private landowners to represent an integral component of recovery for listed species. However, the designation of critical habitat could have an unintended negative effect on our relationship with non-Federal landowners due to the perceived imposition of redundant government regulation. If lands within the Humboldt Redwood Company HCP are designated as critical habitat, it would likely have a chilling effect on our continued ability to seek new partnerships with future participants including States, counties, local jurisdictions, conservation organizations, and private landowners, which together can implement various conservation actions (such as SHAs, HCPs, and other conservation plans) that we would be unable to accomplish otherwise.

Excluding the approximately 208,172 ac (84,244 ha) owned and managed by the Humboldt Redwood Company from critical habitat designation will sustain and enhance the working relationship between the Service and the Company, and will bolster our ability to pursue additional conservation partnerships for the benefit of listed species. The willingness of the Humboldt Redwood Company to work with us to manage their forest lands for the benefit of the northern spotted owl will continue to reinforce those conservation efforts and our partnership, which contributes to the recovery of the species. We consider this voluntary partnership in conservation important to our understanding of the status of northern spotted owls on non-Federal lands and necessary for us to implement recovery actions such as habitat protection and restoration, and beneficial management actions for species. In addition, as noted above, our conservation partnership with the Humboldt Redwood Company may serve as a model and aid in fostering future cooperative relationships with other parties in other locations for the benefit of listed species. We consider the positive effect of excluding proven conservation partners from critical habitat to be a significant benefit of exclusion.

The Benefits of Exclusion Outweigh the Benefits of Inclusion—We have reviewed and evaluated the exclusion, from critical habitat designation, of approximately 208,172 ac (84,244 ha) of land owned and managed by the Humboldt Redwood Company. The benefits of including these lands in the designation are comparatively small, since the habitat on the covered lands is already being monitored and managed under the current HCP to improve the habitat elements that are equivalent to the physical or biological features that are outlined in this critical habitat rule. Because one of the primary threats to the northern spotted owl is habitat loss and degradation, the consultation process under section 7 of the Act for projects with a Federal nexus in areas occupied by the species, such as is the case here, will, in evaluating effects to the northern spotted owl, evaluate the effects of the action on the conservation or function of the habitat for the species regardless of whether critical habitat is designated for these lands. The analytical requirements to support a jeopardy determination on excluded land are similar, but not identical, to the requirements in an analysis for an adverse modification determination on included land. However, the HCP provides habitat conservation measures that apply for the benefit of northern spotted owl. In addition, educational benefits are limited, since outreach efforts associated with various conservation actions for this species have been extensive, and members of the public, as well as State and local agencies, are likely familiar with the species and its biological needs. Company personnel are knowledgeable in the ecology of the northern spotted owl and have contributed to the body of scientific information about the northern spotted owl in the redwood region. In this case, the regulatory and education benefits of inclusion are less than the continued benefit of this conservation partnership.

Humboldt Redwood Company has made important contributions to our understanding of the ecology of the northern spotted owl and its habitats in the redwood region, and continues to do so through HCP implementation and long-term monitoring. The Service recognizes the conservation value of partnerships with non-Federal landowners, such as the Humboldt Redwood Company, which allow us to achieve conservation measures that would not otherwise be attainable on these private lands. We have determined that our conservation partnership with the Humboldt Redwood Company HCP, in conjunction with the conservation measures provided in the HCP, provide a greater benefit than would the regulatory and educational benefits of critical habitat designation. Furthermore, we have determined that the additional regulatory benefits of designating critical habitat, afforded through the section 7(a)(2) consultation process, are minimal because of limited Federal nexus and because conservation measures specifically benefitting the northern spotted owl and its habitat are in place through the implementation of the HCP. Therefore, in consideration of the factors discussed above in the Benefits of Exclusion section, including the relevant impact to current and future partnerships, we have determined that the benefits of exclusion of lands covered by the Humboldt Redwood Company HCP outweigh the benefits of critical habitat designation.

Exclusion Will Not Result in Extinction of the Species—We have determined that the exclusion of 208,172 ac (84,244 ha) from the designation of critical habitat for the northern spotted owl of lands owned and managed by the Humboldt Redwood Company, as identified in their HCP, will not result in extinction of the species because current conservation efforts under the plan adequately protect the geographical areas containing the physical or biological features essential to the conservation of the species. For projects having a Federal nexus and affecting northern spotted owls in occupied areas, which is the case here, the jeopardy standard of section 7 of the Act, coupled with protection provided by the current Humboldt Redwood Company HCP, would provide a high level of assurance that this species will not go extinct as a result of excluding these lands from the critical habitat designation. Based on the above discussion, the Secretary is exercising his discretion under section 4(b)(2) of the Act to exclude from this final critical habitat designation portions of the proposed critical habitat units or subunits that are within the Humboldt Redwood Company HCP boundary totaling 208,172 ac (84,244 ha).

Regli Estate Habitat Conservation Plan

In this final designation, the Secretary has exercised his authority to exclude lands from critical habitat, under section 4(b)(2) of the Act, that are covered under the Regli Estate HCP in the Redwood Coast CHU. The permit issued under this HCP in 1995 (noticed July 17, 1995 (60 FR 36432) and issued August 30, 1995) covers 484 ac (196 ha) in Humboldt County, California, to be used for forest management activities.

Two listed species, the marbled murrelet and northern spotted owl, as well as two nonlisted species, are covered under the incidental take permit. Provisions in the HCP for the northern spotted owl include the mitigation of impacts from forest management activities by using single-tree selection silviculture that would retain owl foraging habitat suitability in all harvested areas; protecting an 80-ac (32-ha) core nesting area for one of the two owl pairs known to exist in the HCP area; and planting conifer tree species on approximately 73 ac (30 ha) of currently nonforested habitat within the HCP area, which would result in a net increase in forested habitat over time. In addition, take of owls would be minimized using seasonal protection measures specified in the HCP.

Benefits of Inclusion—We find there are minimal benefits to including these lands in critical habitat. As discussed above, the designation of critical habitat invokes the provisions of section 7. However, in this case, we find the requirement that Federal agencies consult with us and ensure that their actions are not likely to destroy or adversely modify critical habitat will not result in significant benefits to the species because the possibility of a Federal nexus for a project on these lands that might trigger such consultation is limited since there is little likelihood of an action that will involve Federal funding, authorization, or implementation. In addition, since the lands under the HCP in question are occupied by the northern spotted owl, if a Federal nexus were to occur, section 7 consultation would already be triggered and the Federal agency would consider the effects of its actions on the species through a jeopardy analysis. The additional conservation that could be attained through the supplemental adverse modification analysis for critical habitat under section 7 would not be significant because this HCP incorporates measures that specifically benefit the northern spotted owl and its habitat. The HCP incorporates protections and management objectives for the northern spotted owl designed to produce a net increase in forested habitat for the species over time. The conservation measures identified within the HCP seek to achieve conservation goals for northern spotted owls and their habitat can be of greater conservation benefit than the designation of critical habitat, which does not require specific, proactive actions. HCPs typically provide for greater conservation benefits to a covered species than section 7 consultations because HCPs ensure the long-term protection and management of a covered species and its habitat. In addition, funding for such management is ensured through the Implementation Agreement. Such assurances are typically not provided by section 7 consultations, which in contrast to HCPs, often do not commit the project proponent to long-term, special management practices or protections. Thus, a section 7 consultation typically does not afford the lands it covers similar extensive benefits as an HCP. In addition, the protections of critical habitat come into play only in the event of a Federal action, whereas the protections of an HCP are in continuous force.

Another benefit of including lands in a critical habitat designation is that it serves to educate landowners, State and local governments, and the public regarding the potential conservation value of an area. This helps focus and promote conservation efforts by other parties by identifying areas of high conservation value for northern spotted owls. Any information about the northern spotted owl and its habitat that reaches a wider audience, including parties engaged in conservation activities, is valuable. The landowners in this case are aware of the needs of the species through the development of their HCP, in which they have agreed to take measures to protect the northern spotted owl and its habitat. Any additional educational and information benefits that might arise from critical habitat designation have been largely accomplished through the public review of and comment on the HCP and the associated permit. The release of the Revised Recovery Plan for the Northern Spotted Owl in 2011 was also preceded by outreach efforts and public comment opportunities. In addition, the rulemaking process associated with critical habitat designation included several opportunities for public comment, and we also held multiple public information meetings across the range of the species. Through these outreach opportunities, land owners, State agencies, and local governments have become aware of the current status of and threats to the northern spotted owl, and the conservation actions needed for recovery.

The designation of critical habitat may also indirectly cause State or county jurisdictions to initiate their own additional requirements in areas identified as critical habitat. These measures may include additional permitting requirements or a higher level of local review on proposed projects. However, CALFIRE has indicated to us that it is unlikely to impose any new requirements on project proponents if critical habitat is designated in areas already subject to California Forest Practice Rules. Therefore, we believe this potential benefit of critical will be limited.

Benefits of Exclusion—The benefits of excluding from critical habitat designation the approximately 484 ac (196 ha) of lands currently managed under the HCP are greater than those that would accrue from inclusion. We have developed a conservation partnership with Regli Estate through the development and implementation of the HCP. The conservation measures that provide a benefit to the northern spotted owl and its habitat have been, and will continue to be, implemented continuously beginning with the issuance of the Incidental Taking Permit in 1995 and continuing through the 20-year term of the permit, through 2015. These measures include use of single-tree selection silviculture to retain owl foraging habitat suitability, protection of an 80-ac (32-ha) core nesting area for one of the two known owl pairs, and reforestation of approximately 73 ac (30 ha) of ''old-field'' grasslands, the latter which has already been accomplished and will result in a net increase in forested habitat over time. A significant benefit of exclusion would be the increased likelihood of this landowner continuing with conservation actions for the northern spotted owl and its habitat, such as the development of a new HCP and application for a new incidental take permit upon the expiration of their current permit.

The HCP incorporates protections and management objectives for the northern spotted owl and the habitat upon which it depends for breeding, sheltering, and foraging activities. The approach used in the HCP, along with our close coordination with the landowner, addresses the identified threats to northern spotted owl on covered lands that contain the physical or biological features essential to the conservation of the species. The conservation measures identified within the HCP seek to maintain or surpass current habitat suitability for northern spotted owls, and thus can be of greater conservation benefit than the designation of critical habitat, which does not require specific, proactive actions.

Excluding the approximately 484 ac (196 ha) of this covered land from critical habitat designation will sustain and enhance the working relationship between the Service and the owner, and will increase the likelihood that the owner will update the HCP and apply for a new incidental take permit when the current permit expires in 2015. The willingness of the landowner to work with the Service to manage federally listed species will continue to reinforce those conservation efforts and our partnership, which contribute toward achieving recovery of the northern spotted owl. We consider this voluntary partnership in conservation important in maintaining our ability to implement recovery actions such as habitat protection and restoration, and beneficial management actions for species on non-Federal lands. The Service recognizes the importance of non-Federal landowners in contributing to the conservation and recovery of listed species, and seeks to maintain and promote these partnerships for the benefit of all threatened and endangered species.

We consider conservation partnerships with private landowners to represent an integral component of recovery for listed species. However, the designation of critical habitat could have an unintended negative effect on our relationship with non-Federal landowners due to the perceived imposition of redundant government regulation. If lands within the Regli Estate HCP are designated as critical habitat, it would likely have a chilling effect on our continued ability to seek new partnerships with future participants including States, counties, local jurisdictions, conservation organizations, and private landowners, which together can implement various conservation actions (such as SHAs, HCPs, and other conservation plans) that we would be unable to accomplish otherwise. We therefore consider the positive effect of excluding proven conservation partners from critical habitat to be a significant benefit of exclusion.

The Benefits of Exclusion Outweigh the Benefits of Inclusion—We reviewed and evaluated the exclusion of approximately 484 ac (196 ha) of land owned and managed by Regli Estate from our designation of critical habitat. The benefits of including these lands in the designation are relatively small. Because one of the primary threats to the northern spotted owl is habitat loss and degradation, the consultation process under section 7 of the Act for projects with a Federal nexus in areas occupied by the species, such as is the case here, will, in evaluating effects to the northern spotted owl, evaluate the effects of the action on the conservation or function of the habitat for the species regardless of whether critical habitat is designated for these lands. The analytical requirements to support a jeopardy determination on excluded land are similar, but not identical, to the requirements in an analysis for an adverse modification determination on included land. However, the HCP provides habitat conservation measures that apply for the benefit of northern spotted owl, and remains in place regardless of critical habitat. In addition, for the reasons described above, the educational benefits of designation in this instance are minimal.

Exclusion of these lands from critical habitat will help foster the partnership we have developed with the company, through the continuing implementation of the HCP. Furthermore, we believe exclusion of these lands from critical habitat will increase the likelihood that the owner will update the HCP and apply for a new incidental take permit when the current permit expires in 2015, thereby ensuring continuing benefits to the northern spotted owl and its habitat on these lands. The HCP has provisions for protecting and maintaining northern spotted owl habitat that exceed the conservation benefits that could be obtained through section 7 consultation. These measures will not only prevent the degradation of essential features of the northern spotted owl, but they will maintain or improve these features over time. Finally, this partnership may serve as a model and aid in fostering future cooperative relationships with other parties in other locations for the benefit of listed species.

In summary, we have determined that our conservation partnership with the Regli Estate, in conjunction with the conservation measures provided in the HCP, provide a greater benefit than would the regulatory and educational benefits of critical habitat designation. We have determined that the additional regulatory benefits of designating critical habitat, afforded through the section 7(a)(2) consultation process, are minimal because the probability of a Federal nexus for projects on this land is limited in scope and will occur episodically at most. On the other hand, the conservation measures specifically benefitting the northern spotted owl and its habitat are in continuous effect throughout the lands covered by this HCP. Finally, the Service acknowledges the importance of conservation partnerships with private landowners in achieving the recovery of listed species, such as the northern spotted owl, and recognizes the positive benefits that accrue to conservation through the exclusion of recognized conservation partners from critical habitat. Therefore, in consideration of the factors discussed above in the *Benefits of Exclusion* section, including the relevant impact to current and future partnerships, we have determined that the benefits of exclusion of lands covered by the Regli Estate Habitat Conservation Plan outweigh the benefits of critical habitat designation.

Exclusion Will Not Result in Extinction of the Species—We have determined that the exclusion of 484 ac (196 ha) of Regli Estate lands from the designation of critical habitat for the northern spotted owl, as identified in their HCP, will not result in extinction of the species because current conservation efforts under the plan adequately protect the geographical areas containing the physical or biological features essential to the conservation of the species. For projects having a Federal nexus and affecting northern spotted owls in occupied areas, as is the case here, the jeopardy standard of section 7 of the Act, coupled with protection provided under the terms of the HCP, would provide assurances that this species will not go extinct as a result of excluding these lands from the critical habitat designation. Based on the above discussion, the Secretary is exercising his discretion under section 4(b)(2) of the Act to exclude from this final critical habitat designation portions of the proposed critical habitat units or subunits that are within the Regli Estate Habitat Conservation Plan boundary totaling 484 ac (196 ha).

Terra Springs Habitat Conservation Plan

In this final designation, the Secretary has exercised his authority to exclude 39 ac (16 ha) of lands from critical habitat, under section 4(b)(2) of the Act, that are covered under the Terra Springs LLC HCP in subunit 6 of the Interior California Coast CHU. The permit issued in association with this HCP (noticed October 29, 2002 (67 FR 65998), and issued in 2004) has a term of 30 years and includes a total of 76 ac (31 ha) of covered land second-growth forest lands in Napa County, California. This HCP addresses the effects of timber harvest and conversion of forest lands to vineyard and subsequent maintenance, in perpetuity, of suitable northern spotted owl habitat characteristics on the remaining 39 ac (16 ha) of mature (80–120 years) Douglas-fir forest on covered lands. The HCP provides a conservation program to minimize and mitigate for the covered activities, including a deed restriction that requires management in perpetuity of 39 ac (16 ha) of the property as nesting and roosting quality habitat for the northern spotted owl. In addition to mitigation, the Plan also includes measures to minimize take of the northern spotted owl.

Benefits of Inclusion—We find there are minimal benefits to including these lands in critical habitat. As discussed above, the designation of critical habitat invokes the provisions of section 7. However, in this case, we find the requirement that Federal agencies consult with us and ensure that their actions are not likely to destroy or adversely modify critical habitat will not result in significant benefits to the species because the possibility of a Federal nexus for a project on these lands that might trigger such consultation is limited since there is little likelihood of an action that will involve Federal funding, authorization, or implementation. In addition, since the lands under the HCP in question are occupied by the northern spotted owl, if a Federal nexus were to occur, section 7 consultation would already be triggered and the Federal agency would consider the effects of its actions on the species through a jeopardy analysis. The additional conservation that could be attained through the supplemental adverse modification analysis for critical habitat under section 7 would not be significant because this HCP incorporates measures that specifically benefit the northern spotted owl and its habitat. The HCP incorporates protections and management objectives for the northern spotted owl designed to maintain suitable habitat on the property for the species in perpetuity. The conservation measures identified within the HCP seek to achieve conservation goals for northern spotted owls and their habitat that can be of greater conservation benefit than the designation of critical habitat, which does not require specific, proactive actions. HCPs typically provide for greater conservation benefits to a covered species than section 7 consultations because HCPs ensure the long-term protection and management of a covered species and its habitat. In addition, funding for such management is ensured through the Implementation Agreement. Such assurances are typically not provided by section 7 consultations, which in contrast to HCPs, often do not commit the project proponent to long-term, special management practices or protections. Thus, a section 7 consultation typically does not afford the lands it covers similar extensive benefits as an HCP. In addition, the protections of critical habitat come into play only in the event of a Federal action, whereas the protections of an HCP are in continuous force.

Another benefit of including lands in a critical habitat designation is that it serves to educate landowners, State and local governments, and the public regarding the potential conservation value of an area. This helps focus and promote conservation efforts by other parties by identifying areas of high conservation value for northern spotted owls. The landowners in this case are aware of the needs of the species through the development of their HCP, in which they have agreed to take measures to protect the northern spotted owl and its habitat. Any additional educational and information benefits that might arise from critical habitat designation have been largely accomplished through the public review of and comment on the HCP and the associated permit. The release of the Revised Recovery Plan for the Northern Spotted Owl in 2011 was also preceded by outreach efforts and public comment opportunities. In addition, the rulemaking process associated with critical habitat designation included several opportunities for public comment, and we also held multiple public information meetings across the range of the species. Through these outreach opportunities, land owners, State agencies, and local governments have become aware of the current status of and threats to the northern spotted owl, and the conservation actions needed for recovery.

The designation of critical habitat may also indirectly cause State or county jurisdictions to initiate their own additional requirements in areas identified as critical habitat. These measures may include additional permitting requirements or a higher level of local review on proposed projects. However, CALFIRE has indicated to use that it is unlikely to impose any new requirements on project proponents if critical habitat is designated in areas already subject to California Forest Practice Rules. Therefore, we believe this potential benefit of critical will be limited.

Benefits of Exclusion—The benefits of excluding from designated critical habitat the approximately 39 ac (16 ha) of lands currently managed under the HCP are substantial. We have developed a conservation partnership with Terra Springs through the development and implementation of the HCP.

Excluding the approximately 39 ac (16 ha) owned and managed by Terra Springs, LLC from critical habitat designation will sustain and enhance the working relationship between the Service and the company. The willingness of the company to work with the Service to manage federally listed species will continue to reinforce those conservation efforts and our partnership, which contribute toward achieving recovery of the northern spotted owl. We consider this voluntary partnership in conservation important in maintaining our ability to implement recovery actions, such as habitat protection and restoration, and beneficial management actions for species on non-Federal lands. The Service recognizes the importance of non-Federal landowners in contributing to the conservation and recovery of listed species, and seeks to maintain and promote these partnerships for the benefit of all threatened and endangered species.

We consider conservation partnerships with private landowners to represent an integral component of recovery for listed species. However, the designation of critical habitat could have an unintended negative effect on our relationship with non-Federal landowners due to the perceived imposition of redundant government regulation. If lands within the Terra Springs HCP are designated as critical habitat, it would likely have a chilling effect on our continued ability to seek new partnerships with future participants including States, counties, local jurisdictions, conservation organizations, and private landowners, which together can implement various conservation actions (such as SHAs, HCPs, and other conservation plans) that we would be unable to accomplish otherwise. We therefore consider the positive effect of excluding proven conservation partners from critical habitat to be a significant benefit of exclusion.

The Benefits of Exclusion Outweigh the Benefits of Inclusion—We reviewed and evaluated the exclusion of approximately 39 ac (16 ha) of land owned and managed by Terra Springs, LLC from our designation of critical habitat. The benefits of including these lands in the designation are relatively small. Because one of the primary threats to the northern spotted owl is habitat loss and degradation, the consultation process under section 7 of the Act for projects with a Federal nexus in areas occupied by the species, such as is the case here, will, in evaluating effects to the northern spotted owl, evaluate the effects of the action on the conservation or function of the habitat for the species regardless of whether critical habitat is designated for these lands. The analytical requirements to support a jeopardy determination on excluded land are similar, but not identical, to the requirements in an analysis for an adverse modification determination on included land. However, the HCP provides habitat conservation measures that apply for the benefit of northern spotted owl, and remains in place regardless of critical habitat. These measures will not only prevent the degradation of essential features of the northern spotted owl, but will preserve some suitable northern spotted owl habitat in perpetuity.

We have determined that the preservation of our conservation partnership with Terra Springs, in conjunction with the conservation measures provided by the HCP, provide a greater benefit than would the regulatory and educational benefits of critical habitat designation. The additional regulatory benefits of designating critical habitat, afforded through the section 7(a)(2) consultation process, are minimal because there is little probability of a Federal nexus on these private lands. On the other hand, the conservation measures specifically benefitting the northern spotted owl and its habitat are in continuous effect throughout the lands covered by this HCP. Finally, the Service acknowledges the importance of conservation partnerships with private landowners in achieving the recovery of listed species, such as the northern spotted owl, and recognizes the positive benefits that accrue to conservation through the exclusion of recognized conservation partners from critical habitat. Therefore, in consideration of the factors discussed above in the *Benefits of Exclusion* section, including the relevant impact to current and future partnerships, we have determined that the benefits of exclusion of lands covered by the Terra Springs Habitat Conservation Plan outweigh the benefits of critical habitat designation.

Exclusion Will Not Result in Extinction of the Species—We have determined that the exclusion of 39 ac (16 ha) from the designation of critical habitat for the northern spotted owl of lands owned and managed by Terra Springs, LLC, as identified in their HCP, will not result in extinction of the species because current conservation efforts under the plan adequately protect the geographical areas containing the physical or biological features essential to the conservation of the species. For projects having a Federal nexus and affecting northern spotted owls in occupied areas, as is the case here, the jeopardy standard of section 7 of the Act, coupled with protection provided under the terms of the HCP would provide assurances that this species will not go extinct as a result of excluding these lands from the critical habitat designation. Based on the above discussion, the Secretary is exercising his discretion under section 4(b)(2) of the Act to exclude from this final critical habitat designation portions of the proposed critical habitat units or subunits that are within the Terra Springs, LLC Habitat Conservation Plan boundary totaling 76 ac (31 ha).

State of Oregon

No lands covered under an HCP in the State of Oregon are designated as critical habitat.

State of Washington

Cedar River Watershed Habitat Conservation Plan in King County, Washington

In this final designation, the Secretary has exercised his authority to exclude lands from critical habitat, under section 4(b)(2) of the Act, totaling approximately 3,244 ac (1,313 ha) that are covered under the Cedar River Watershed HCP (Cedar River HCP) in King County, Washington. The permit associated with this HCP was noticed in the **Federal Register** on December 11, 1998 (63 FR 68469), and issued on April 21, 2000. The term of the permit and HCP is 50 years. The plan was prepared to address declining populations of salmon, steelhead, bull trout, northern spotted owl, marbled murrelet, and 76 unlisted species of fish and wildlife in the Cedar River watershed. The City of Seattle's HCP covers 90,535 ac (36,368 ha) of City-owned land in the upper Cedar River watershed and the City's water supply and hydroelectric operations on the Cedar River, which flows into Lake Washington. Participants involved in the development and implementation of the Cedar River HCP include the City of Seattle, Seattle City Light, Seattle Public Utilities, Washington Department of Fish and Wildlife, Washington Department of Ecology, Muckelshoot Indian Tribe, King County, and several conservation-oriented nongovernmental organizations.

At the time the HCP was approved, the 90,535 ac (36,638 ha) in upper Cedar River Watershed, owned and managed by the City of Seattle as a closed-watershed, consisted of approximately 13,889 ac (5,620 ha) of old growth forest (190–800 years old), 91 ac (37 ha) of late-successional (120–189 years old), 1,074 ac (435 ha) of mature forests (80–119 years old), and 70,223 ac (28,418 ha) of second growth forests (greater than 80 years old). Conservation strategies in the HCP for covered lands are centered around protecting and preserving the remaining old growth, late-successional, and mature forest habitats; accelerating the development of mature forest characteristics in the existing second growth forests though a combination of riparian, ecological, and restoration thinnings; and minimizing human disturbance through road closures and road abandonments, elimination of commercial harvest on covered lands, and continued management of the covered lands as a closed municipal watershed.

At the time the HCP was approved, only two northern spotted owl reproductive site centers and two single-resident site centers had been identified on covered lands. In addition, two reproductive site enters located outside the watershed boundary had owl circles that partially overlap the Cedar River watershed. The boundaries of all known reproductive site centers are protected by the City of Seattle's commitment to conservation strategies and species-specific measures in the Cedar River HCP. The objectives of the northern spotted owl conservation strategy are to avoid, minimize, and mitigate impacts of watershed activities to northern spotted owls, provide a long-term net benefit to the northern spotted owl, and contribute to the owl's recovery. These objectives are to be accomplished by protecting existing habitat; enhancing and recruiting significantly more nesting, roosting, foraging, and dispersal habitat in the Cedar River watershed; and protecting nest sites, reproductive pairs, and their offspring from disturbances. In addition, the City of Seattle committed to implementing a monitoring and research program that will be used to help determine if the conservation strategies for the northern spotted owl achieve their conservation objectives and support the adaptive management program designed to provide a means by which conservation measures could be altered to meet these conservation objectives. Elements of the monitoring and research program important to northern spotted owls include a project to improve the City's forest habitat inventory and data base, a project to track changes in forest habitat characteristics, a study to classify old-growth types in the Cedar River watershed, and projects to monitor all forest restoration efforts.

Benefits of Inclusion—We find that there is minimal benefit from designating critical habitat for the northern spotted owl within the Cedar River HCP because, as explained above, these covered lands are already managed for the conservation of the species over the term of the HCP. As discussed above, the inclusion of these covered lands as critical habitat could provide some additional Federal regulatory benefits for the species consistent with the conservation standard based on the Ninth Circuit Court's decision in Gifford Pinchot. A benefit of inclusion would be the requirement of a Federal agency to ensure that their actions on these non-Federal lands would not likely result in the destruction or adverse modification of critical habitat. However, this additional analysis to determine whether a Federal action is likely to result in destruction or adverse modification of critical habitat is not likely to be significant because these covered lands are not under Federal ownership making the application of section 7 less likely, and we are not aware of any other potential Federal nexus. In addition, any Federal agency proposing a Federal action on these covered lands would have to consider the conservation restrictions on these lands and incorporate measures necessary to ensure the conservation of these resources, thereby reducing any incremental benefit critical habitat may have.

The incremental benefit from designating critical habitat for the northern spotted owl within the Cedar River HCP is further minimized because, as explained above, these covered lands are already managed for the conservation of the species over the term of the HCP and the conservation measures provided by the HCP will provide greater protection to northern spotted owl habitat than the designation of critical habitat.

The Cedar River HCP provides for the needs of the northern spotted owl by protecting and preserving thousands of acres of existing suitable northern spotted owl habitat in the Cedar River watershed, committing to the enhancement and recruitment of approximately 70,000 ac (28,328 ha) of additional habitat over the term of the Cedar River HCP, and implementing species-specific conservation measures designed to avoid and minimize impacts to northern spotted owls. Monitoring and research and adaptive management programs were developed to track HCP progress over the term of the permit and provide critical feedback on management actions that allow for management changes in response to this feedback or to larger trends outside the HCP boundaries such as climate change. Therefore, designation of critical habitat would be redundant on these lands, and would not provide additional measureable protections.

Another benefit of including lands in a critical habitat designation is that it serves to educate landowners, State and local governments, and the public regarding the potential conservation value of an area. This helps focus and promote conservation efforts by other parties by identifying areas of high conservation value for northern spotted owls. Designation of critical habitat would inform State agencies and local governments about areas that could be conserved under State laws or local ordinances, such as the Washington State Growth Management Act, which encourage the protection of ''critical areas'' including fish and wildlife habitat conservation areas. Any information about the northern spotted owl and its habitat that reaches a wider audience, including parties engaged in conservation activities, is valuable. However, the additional educational and informational benefits that might arise from critical habitat designation here have been largely accomplished through the public review and comment of the HCP, Environmental Impact Statement, and Implementation Agreement. Through these processes, this HCP included intensive public involvement.

The designation of critical habitat may also indirectly cause State or county jurisdictions to initiate their own additional requirements in areas identified as critical habitat. These measures may include additional permitting requirements or a higher level of local review on proposed projects. However, in Washington, State forest practices regulations provide an exemption for review for lands managed under an HCP. Thus, even should the State respond to designation of critical habitat by instituting additional protections, the HCP will not be subject to those protections as the species is considered already addressed, and therefore no additional benefit would accrue through State regulations.

Benefits of Exclusion—Compared to the minimal benefits of inclusion of this area in critical habitat, the benefits of excluding from designated critical habitat the approximately 3,244 ac (1,313 ha) of lands currently managed under the HCP are more substantial.
