#### Abstract

Predation by fish on fish salvaged at the John E. Skinner Delta Fish Protective Facility could reduce this facility's ability to mitigate the entrainment loss of listed fishes such as delta smelt (Hypomesus transpacificus). This study attempted to determine if predation by fish within the facility was significant during the collection, handling, transport, and release phase (CHTR phase) of salvage operations during spring 2005 and winter 2006. A diet study determined if predators fed during the CHTR phase and described the extent of predation. A digestion study evaluated whether characteristics of digested fish could be used to determine if the diet items were consumed during the CHTR phase. Predators fed during the CHTR phase. Comparison of mean diet contents from predators did not show significant differences between CHTR phases. Striped bass (Morone saxatilis) preyed selectively on Chinook salmon (Oncorhynchus tshawytscha), threadfin shad (Dorosoma petenense), delta smelt, prickly sculpin (Cottus asper), western mosquitofish (Gambusia affinis), and largemouth bass (Micropterus salmoides), but only the occurrence of threadfin shad and delta smelt were found to be density dependent. Most indices of digestion were not effective in determining when a prey item was eaten relative to the CHTR phase. Values for frequency of occurrence and the relative degree of body digestion suggest that the predation of rare species such as delta smelt may be low in the CHTR phase. Stomach contents suggest that overall consumption within the fish facility were comparable to that reported outside of facilities. Differences in seasonal diet composition and prey selection were noted and explanations for these differences discussed.

## ACKNOWLEDGMENTS

Special thanks to the CALFED Bay Delta Program for their funding of this study and other CHTR studies. I thank Virginia Afentoulis, Michael Garcia, Jennifer Messineo, Derek Stein, Robert Fujimura, Robert Vincik, Jerry Morinaka, Ramiro Soto, Caley Costello, Anthony Marrone, Jason DuBois, Bryan Crouch, Jamie Gannon, Justin Graham, Roxanne Kessler and Jim Sanches for their reliable field work. This study was made possible by the cooperation with DWR’s Delta Field Division and Division of Engineering, especially Jim Odom and Don Kurosaka. Valuable help in developing the sampling design was provided by Mark Bowen and Robert Fujimura. I also thank the members of Central Valley Fish Facilities Review Team and IEP Management Team for their technical advice and support during the proposal review phase. I acknowledge the CHTR Coordination Team, Brent Bridges, Bradd Bridges, and Don Portz for their support and helpful comments during the implementation of this study. I thank Virginia Afentoulis, Brent Bridges, Gonzalo Castillo, Joe Cech, Javier Miranda, Russell Gartz, Chuck Armor and Randy Baxter for providing their helpful comments on the manuscript. I acknowledge technical and editorial work provided by Robert Fujimura and Marty Gingras and the manuscript assistance provided by Jason DuBois and Dustin Dinh.

## INTRODUCTION

The John E. Skinner Delta Fish Protective Facility (Skinner Fish Facility) is the fish-collection facility to the State Water Project's (SWP) California Aqueduct located in Byron, California (Figure 1). Its purpose is to reduce the number of fish lost into the California Aqueduct. Fish are collected at the facility, trucked away from the immediate influence of the export pumps, and released back into the Sacramento-San Joaquin Estuary.

Figure 1 Location of the John E. Skinner Delta Fish Protective Facility

Increased fish predation has been associated with structures such as dams and water diversions (Stevens 1959; Blackwell and Juanes 1998; Tucker and others 1998). These structures can provide hydraulic refuges for predators to rest and to ambush concentrated numbers of prey.

Predation within the Skinner Fish Facility has been of special concern since the facility concentrates prey and provides feeding habitat for predators. Predation on juvenile Chinook salmon (Oncorhynchus tshawytscha) and delta smelt (Hypomesus transpacificus) were of particular interest due to their federal and state Endangered Species Act listings. Both species are prey of striped bass (Morone saxatilis) in the Sacramento-San Joaquin Estuary and Sacramento River (Stevens 1966; Tucker and others 1998).

The SWP salvage process consists of a series of sequential steps that fish must negotiate successfully to survive and be returned to the Delta. As water flows from Clifton Court Forebay (CCF) towards the export pumps, fish are diverted by a set of primary louvers into a bypass channel (Figure 2). Fish are guided from the secondary channel by either screens or louvers into holding tanks. Fish are held in the tanks for a period generally ranging from 8 to 24 hours (holding tank phase). Water is drained from holding tanks into loading buckets (collection phase = C). Loading buckets are raised via a crane and moved to trucks into which contents of the bucket are released (handling phase $=\mathrm{H}$ ). The trucks are driven approximately 50 minutes to one of 2 release sites in the Delta (transport phase $=T$ ). Fish are discharged from trucks through a pipe into the Delta (release phase = R) away from the hydraulic influence of the pumps (Aasen 2004).

Figure 2 Schematic diagram of the John E. Skinner Delta Fish Protective Facility

The collection, handling, transport, and release (CHTR) phase was of particular interest because delta smelt were considered to be sensitive to handling (Moyle 2002). The process was believed to cause harm through mortality, stress, and possibly predation (Raquel 1989). Resource and water managers were concerned that delta smelt might be suffering high rates of mortality during this phase of fish salvage. The Department of Fish and Game (in 2013, the department changed it's name to California Department of Fish and Wildlife) initiated a series of integrated studies to assess the acute and sublethal effects of the CHTR phase to delta smelt and determine whether these impacts could be mitigated through improved or new fish salvage technologies.

Most predation studies on the export facilities of the SWP have focused on fish loss occurring in CCF. Kano (1990) reported that 7 species of potential predators were present in CCF including white catfish (Ameiurus catus), striped bass, channel catfish (Ictalurus punctatus), black crappie (Pomoxis nigromaculatus), largemouth bass (Micropterus salmoides), brown bullhead (A. nebulosus), and Sacramento pikeminnow (Ptychocheilus grandis). Predation in CCF has been studied for juvenile Chinook salmon (Gingras 1997) and studies have recently been completed for steelhead trout (Oncorhynchus mykiss) and delta smelt. Prescreen loss estimates for juvenile Chinook salmon ranged from $63.3 \%$ to $98.7 \%$. Predation by striped bass is thought to be the largest component of these losses (Tillman 1994; Gingras 1997) although predation by birds has not been measured.

Predation has been documented in the channels and collection tanks of fish facilities. Liston and others (1994) reported that stomachs removed from striped bass at the Central Valley Project's Tracy Fish Collection Facility contained prey fish including striped bass, shimofuri goby (Tridentiger bifasciatus), threadfin shad (Dorosoma petenense), American shad (Alosa sapidissima), bigscale logperch (Percina macrolepida), and possibly delta smelt.

Little is known about predation during the later phases of fish salvage operations, because previous CHTR studies used mortality estimate methods that did not include predation losses (Raquel 1989; Coulston and others 2004). No previous studies have focused on predation occurring in the CHTR phase. It was hypothesized that predation is a likely mortality source because predator and prey fish are concentrated, held, transported, and released at the highest densities experienced during the fish salvage process (Coulston and others 2004).

The main objectives of this study were to determine if predators fed during the CHTR phase and to quantify the extent of predation. The diets of predatory fish (diet study) were examined during the CHTR process and concurrent experimental feeding experiments were conducted to quantify the state of digestion of consumed fish within a time period associated with the CHTR phase (digestion study). This study had 5 original hypotheses to test:

- Hypothesis 1: Predators feed during the CHTR process.
- Hypothesis 2: Predation varies by salvage component (CH versus CHTR phase).
- Hypothesis 3: Predation is affected by variations in densities of predators and prey.
- Hypothesis 4: Predation is affected by prey life stage and season.
- Hypothesis 5: Predation is affected by diel period (day and night).

The last hypothesis was not tested because haul outs at night did not consistently occur.

## METHODS

To assess whether predators fed during CHTR (Hypothesis 1), I first needed to examine the digestion rates and devise means to distinguish fish eaten during the relatively short CHTR period ( $\leq 2 \mathrm{~h}$ ) from fish ingested in the holding tank or upstream of the fish-collection building. I conducted a digestion study to document the digestive process at time intervals necessary to distinguish fish eaten during the CHTR from fish eaten prior. Digestion trials were conducted with captive predatory fish to evaluate whether characteristics of consumed fish could be used to determine when they were consumed.

I also conducted a diet study to describe the stomach contents of predators collected from the CHTR process and characteristics of consumed items. Diet contents of predators were sampled at 2 points during and after the CHTR process.

Field work was performed during 2 seasons: April through July 2005 and December 2005 through March 2006. The winter and spring seasons were chosen to coincide with the period when delta smelt are normally entrained into the SWP.

The field collections for the diet studies were conducted on site of the Skinner Fish Facility on the State Water Project's (SWP) California Aqueduct located in Byron, California or at their salvaged-fish release site at Horseshoe Bend (Figure 1).

## Diet Study

The study design used 2 predator samples taken during a single CHTR process per day. During the handling phase, the contents of each holding tank were drained into a loading bucket. Holding times prior to sampling varied from 8 to 24 hours depending on the presence of delta smelt (8 hours maximum), Chinook salmon (12 hours), or low salvage with no presence of species of special interest ( 24 hours).

Predators were collected from the bucket by 3 staff using dip nets for 2 minutes. A sub-sample of predators was removed from the loading bucket with dip nets (CH sample). Up to 4 holding tanks were sampled per day. No sampling was attempted prior to the collection phase since staff was forbidden to enter holding tanks. Any non-predator caught was returned to the bucket alive.

After the first predator samples were taken, the contents of the loading buckets were placed into the truck and driven for 50 minutes to simulate routine transportation to a release site. After the simulated haul was completed, the truck released its contents into a 45,425-L pool on Skinner Fish Facility grounds. Water from the pool was drained through a screened outlet and predators were collected with dip nets. In the spring 2005, the later sample represented the remaining fish that underwent the entire CHTR phase (CHTR sample).

In winter 2006, the second predator sample was collected from the truck at the release sites in the Sacramento-San Joaquin Estuary instead of the release pool to reduce costs. Although fish in these collections did not undergo the release phase, I considered these to be equivalent to the

CHTR samples for analysis purposes. Sampling was done by 2 staff using dip nets for 6 minutes. Facility counts were compared to concurrent CHTR Acute Mortality Study release-pool counts (Morinaka, personal communication, see "Notes").

Stomachs from predators were immediately removed by incisions to the esophagus and upper intestine and preserved at low temperature $\left(-30^{\circ} \mathrm{C}\right)$ using dry ice. Predator size was measured (fork length, FL or total length, TL) to the nearest millimeter and weighed to the nearest tenth of a gram. Stomach samples were stored in an ultra-low temperature freezer until they were prepared for dissection at the CHTR test building. After stomachs were thawed to room temperature, a lengthwise incision was made to the stomach, and the number of identifiable prey fish per stomach was recorded. Prey fish were removed and identified to nearest taxa. We used a photographic cleithrum key to help identify partially-digested fish. A stereo dissecting microscope (Bausch \& Lomb StereoZoom 5) was used to identify small prey items and an electronic balance scale (Acculab Balance VIC-4mq) was used to obtain the wet weight (g) of each consumed fish. Each prey was measured and recorded for standard length (mm). Standard length of prey was converted to a length measurement (FL or TL) commonly used for each species if length conversion factors existed (Froese and Pauly 2007).

Each prey was inspected visually in the laboratory and the percent of scales digested, percent of body digested, the degree of color fading, and the extent of fin digestion was determined. Based on these determinations, rank scores were assigned for percent of scales digested and percent of body digested. The extent of fin digestion was recorded as attribute data (Table 1). The rank and attribute categories were determined from pilot study results. Color fading is not reported here since virtually all were faded regardless of digestion time.

Table 1 Rank or attribute values for digestion indices

| Scale digestion (\%) | Body digestion (\%) | Fin digestion |
| :--- | :--- | :--- |
| $0=$ Scales intact | $0=$ Flesh intact | $0=$ Fins intact |
| $1=<1$ | $1=<10$ | $1=$ Fins frayed |
| $2=11-25$ | $2=11-25$ | $2=$ Pelvic fully digested |
| $3=26-50$ | $3=26-50$ | $3=$ Pectoral fully digested |
| $4=51-75$ | $4=51-75$ | $4=$ Anal fully digested |
| $5=76-100$ | $5=76-100$ | $5=$ Dorsal fully digested |
|  |  | $7=$ Caudal fully digested |
|  |  | $7=$ All fins fully digested |

To document prey available for consumption (Hypothesis 3), all non-predators were identified to species, counted, and measured to the nearest millimeter (FL or TL) in the spring 2005 trials. When non-predators were too numerous to process individually, volumetric counts were obtained by measuring the number of fish per deciliter based on a count of 50 fish and then multiplied by
the total volume of fish collected. In the winter of 2006, prey composition, abundance, and size distributions were estimated from routine salvage data.

To determine if facility operations affected predation, these parameters were noted: Primary and secondary channel water velocities and bypass ratios, collection tanks in use or sampled, collection tank water depths, and collection tank flows. Those parameters affect salvage efficiency and the number of fish collected in the salvage operations. Those factors may also affect the condition of fish collected.

To determine whether environmental conditions affected predation, these parameters were recorded: Water temperature ( ${ }^{\circ} \mathrm{C}$ ), dissolved oxygen ( $\mathrm{mg} / \mathrm{L}$ ), and specific conductivity ( $\mu \mathrm{S} / \mathrm{cm}$ ) were measured using a water quality meter (YSI Model 556 Multi-Probe System). Water clarity (cm) was measured by a 120 cm Secchi tube. Measurements were taken in the collection tank and from the release pool prior to the tank release in spring 2005 and from the truck in winter 2006. Type and weight ( kg ) of debris were also recorded in spring 2005.

The principal approach to determine the extent of predation occurring in the CHTR phase (Hypotheses 1 and 2) was to compare the magnitude of stomach contents between CH and CHTR samples. The number of prey fish per stomach was determined for each paired CH and CHTR sample. I compared the results by season-year to determine seasonal differences in predator diet (Hypothesis 4).

The diet data was determined to be parametric or nonparametric based upon inspection of frequency distributions. A Mann-Whitney significance test was used (Zar 1999), since the data did not appear to be normally distributed due to a high number of zero samples. Only prey judged to have been eaten within 2 hours of CHTR were included in the analysis, because CHTR takes approximately 2 hours. By extrapolating the results from the predator digestion study, prey with more than $51 \%$ body digestion were consumed prior to CHTR. A Mann-Whitney test was used to determine if differences in the mean number of prey per stomach during CH and CHTR were significant at $\alpha=0.05$. If mean prey per stomach in CHTR was significantly greater than in CH, it would infer that predation in CHTR was occurring at a significant level.

The diets of predators were analyzed in 3 groups: all predators, striped bass, and adult white catfish (all predators, striped bass, and white catfish will be in italics when referring only to these 3 analysis groups). Frequency of occurrence, which is the proportion of predators that contained a given prey, was calculated for certain species and for all prey combined. Striped bass were grouped into 3 season-specific categories: young ( 6 to 14 cm in spring 2005 and 12 to 23 cm in winter 2006), juvenile ( 15 to 26 cm in spring 2005 and 24 to 35 cm in winter 2006), and sub-adult ( 27 to 47 cm in spring 2005 and 36 to 47 cm in winter 2006). The striped bass stomach contents were otherwise pooled to increase sample size due to zero or low numbers of prey per stomach. A Strauss selectivity index, $L=r_{i}-p_{i}$, where $r_{i}$ is the relative abundance of prey type $j$ in the diet and $p_{i}$ is the relative abundance of prey type $;$ in the environment, was used to determine prey selectivity of predator fish (Bowen 1996). The pi value was calculated as the number of given prey divided by total number of all prey available collected during CHTR. The $r_{i}$ value was calculated as the number of particular prey divided by total number of prey. Predators were considered to display positive selectivity if $\mathrm{L}>0.100$ or negative selection if $\mathrm{L}<-0.100$ for a
given prey species; neutral selectivity would be near 0.000 . Simple linear correlation coefficients were calculated to determine if the relationships between environmental parameters and the mean number of prey per stomach were significant at the $\alpha=0.05$ level.

I plotted the combined mean prey per stomach as a function of available prey fish density for samples from which predators were derived and used linear regression to determine if the relationship was significant at the $\alpha=0.05$ level (Zar 1999). No regression analysis was attempted if the criteria of the regression models were not met such as a high incident of zero samples (obviously non-linear). The length distributions for consumed prey and prey fish available in the CHTR environment were compared to determine if predators selected prey by size.

## Digestion Study

Several digestion indices were developed to determine when individual prey from predator stomachs were consumed relative to when predators were sampled (CHTR). The extent and degree of digestion for each index was empirically determined through feeding seasonallyavailable prey fish, delta smelt, and splittail (Pogonichthys macrolepidotus) to captive striped bass and white catfish. The predators were euthanized and their stomachs were dissected after either 1 hour (the minimum time it would take to complete the CHTR phase), 2 hours (the maximum time it would take to complete the CHTR phase), or 4 hours (feeding during the holding tank period or earlier). The digestion of prey was evaluated to see if digestion indices could accurately predict whether prey items were consumed during the holding tank period or during the CHTR phase.

Based on pilot study results, these 4 digestion parameters were evaluated for utility in documenting digestion time: percent of scales digested, percent of body digested, degree of fin digestion, and color fading (Table 1). Color fading results were not included in the analysis since the majority of prey were faded within 1 hour of time interval trials (Appendix M). A total of 56 digestion experiments were conducted in spring 2005 and 68 experiments were completed in the winter of 2006. By determining the digestion characteristics of prey fish after 1,2 , and 4 hours, a digestion criterion was selected and used to determine if individual prey fish were consumed during or prior to the CHTR phase.

Striped bass and white catfish were also used in digestion experiments. Subject fish were collected during predator removals from the Skinner Fish Facility's salvage operation and from CCF by angling. Predators were held without food in 1,363-L circular tanks for at least 5 days to purge their stomachs and encourage feeding. At the start of each experiment, 3 predators were placed in a 341-L tank and were offered 10 prey fish. Only predators less than 440 mm FL in length and prey less than 80 mm FL in length were used. The tank was left undisturbed and checked after 10 minutes to see if any of the prey were eaten. If no prey were eaten, another 10 minutes was allowed for predators to feed. If no feeding occurred after 20 minutes, the experiment was ended. If feeding occurred, all remaining prey were removed and predators were euthanized after either 1,2 , or 4 hours of digestion. Water temperature, dissolved oxygen, and specific conductivity were measured and recorded during the digestion period.

Fish length and weight measurements, the laboratory methods for processing the stomach samples, and the scoring method for the digestion indices were consistent with those used in the diet study. The same inspection method was used to evaluate the statistical properties of the digestion data.

Inspection of the digestion scores indicated that non-parametric significance testing was appropriate. Kruskal-Wallis significance tests were used to determine whether there were statistically significant differences in digestion scores between 1, 2, and 4 hour digestion intervals at the $\alpha=0.05$ level (Zar 1999). Nonparametric multiple comparison tests were used to determine which digestion intervals were significantly different (Zar 1999). A nonparametric MannWhitney significance test was used to determine if the occurrence of feeding varied significantly with water temperature.

## Predator and Prey Estimates

Seasonal estimates of predator-sized striped bass and juvenile Chinook salmon salvage at the Skinner Fish Facility were compared to examine their relative abundances and to evaluate their potential predation. Monthly estimates of juvenile Chinook salmon and predator-sized striped bass salvage during winter and spring of 2005 and 2006 were obtained from the Skinner Fish Facility by querying the Department of Fish and Game's salvage databases (Aasen 2008). Monthly estimates of predator-sized striped bass salvage were determined by selecting the minimum predator size necessary to consume the smallest Chinook salmon. Striped bass can eat prey approximately half their size; therefore, the minimum size of striped bass considered predatory was set by multiplying the minimum monthly length of juvenile Chinook salmon by 2. The proportions of striped bass greater than or equal to these minimum sizes were used to estimate the number of predatory striped bass by month. The monthly totals of Chinook salmon and predator-sized striped bass salvage were analyzed to determine the predation potential during the juvenile Chinook salmon-salvage season.

## Quality Control Methods

The YSI meter was calibrated for specific conductance before and once during the study using a factory-prepared $1,430 \mu \mathrm{~S} / \mathrm{cm} \mathrm{KCl}$ solution. Dissolved oxygen measurements were calibrated daily by entering the barometric pressure and using the instrument's calibration routine. The electronic balance was calibrated daily using a 200 g certified weight. The operator's "accuracy" was calculated from determining the difference between a measurement made by technician and a second QC value recorded by the lead person. Mean accuracy and standard deviation were calculated and reported. Acceptable performance goals were achieved when mean accuracy was below stated acceptable performance goal precision levels (Table 2). A minimum of 5\% of the field and laboratory data observations were checked, and relative accuracy of duplicate measurements during both study elements were determined for most of the study parameters. Performance measurements for precision were not attempted for any parameters.

## Data Entry and Data Analysis

Field and laboratory data sheets were reviewed for completeness and legibility prior to key entry. Observations regarding accuracy were recorded on the data sheets. Study data were entered into

MS Access databases by a key entry operator and checked line-by-line for accuracy. Key entry accuracy was audited a second time by subsampling $10 \%$ of the data entered, comparing values against the original data sheets, and calculating a percent error rate. Data were summarized using MS Excel spreadsheets or analyzed using Systat Version 9. Some nonparametric analyses were performed manually using procedures described by Zar (1999). Written and electronic documentation on the data files and the data analyses were developed and maintained at the Stockton DFG Bay Delta Region office.

Table 2 Quality control performance goals

## RESULTS

## Diet Study

## Species Composition

The spring 2005 collections showed greater numbers and diversity in both predator and prey species compared to collections in winter 2006. From 17 paired collections, a total of 216 predators were sampled during the spring of 2005. Striped bass were the most numerous of the 11 predator species sampled (Table 3 and Figure 3). The spring 2005 stomach samples yielded 204 identifiable fish representing 17 species or taxa (Table 4). In descending order, the most numerous prey fish in the diet were juvenile Chinook salmon, unidentified prey, threadfin shad, delta smelt, prickly sculpin (Cottus asper), striped bass, American shad, and largemouth bass.

Table 3 Number and mean length (FL or TL) of predators sampled in spring 2005 and winter 2006

| Species | Number | Mean length (mm + SE) |
| :--- | :--- | :--- |
| Spring 2005 |  |  |
| Striped bass | 100 | $188.7 \pm 7.8$ |
| White catfish | 62 | $259.0 \pm 6.7$ |
| Yellowfin goby | 18 | $77.1 \pm 7.0$ |
| Pacific staghorn sculpin | 10 | $78.7 \pm 3.3$ |
| Black crappie | 9 | $126.2 \pm 13.9$ |
| Prickly sculpin | 6 | $45.6 \pm 6.6$ |
| Largemouth bass | 4 | $146.8 \pm 59.6$ |
| Channel catfish | 2 | $111.7 \pm 14.1$ |

Table 3 (Cont.) Number and mean length (FL or TL) of predators sampled in spring 2005 and winter 2006

| Species | Number | Mean length (mm + SE) |
| :--- | :--- | :--- |
| Spring 2005 |  |  |
| Brown bullhead | 2 | $213.7 \pm 7.8$ |
| Warmouth | 1 | $91.0 \pm 3.0$ |
| Black bullhead | -216 | 277.0 |
| Annual total |  |  |
| Winter 2006 | 526 | $147.2 \pm 2.8$ |
| Striped bass | 77 | $179.8 \pm 2.6$ |
| Yellowfin goby | 40 | $268.4 \pm 11.2$ |
| White catfish | 15 | $275.1 \pm 24.5$ |
| Channel catfish | 9 | $231.1 \pm 23.9$ |
| Black crappie | 1 | 272.0 |
| Largemouth bass | 1 | 280.0 |
| Black bullhead | ---- |  |
| Annual total | 669 |  |

Figure 3 Proportions of predator species in spring 2005 and winter 2006

The higher numbers of predator collections performed and predators sampled in the winter of 2006 reflected the change in collection procedures (Table 3). In the winter of 2006, 669 predators were sampled from 42 paired collections. Out of the 7 predator species observed, striped bass were the most numerous species, representing over $78 \%$ of the predators sampled (Table 3 and Figure 3). Despite the larger number of stomachs sampled, fewer prey fish ( $\mathrm{n}=84$ ), species (8) and fewer unidentified fish (4) were observed from the winter 2006 stomach samples (Table 4).

Table 4 Prey fish consumed by all predators in spring 2005 and winter 2006

## Operational and Environmental Conditions

The observed conditions for specific conductivity, dissolved oxygen, primary channel flow, holding tank flow, and export rates were generally consistent with operational or environmental
conditions either measured independently at the Skinner Fish Facility or expected under normal seasonal conditions. Observed water temperatures varied from 14.1 to $25.6^{\circ} \mathrm{C}$ in the spring of 2005 and from 8.8 to $14.3^{\circ} \mathrm{C}$ in the winter 2006 (Appendix E and F). Primary velocities ranged from 1,130 to 8,660 cfs in the spring 2005 and from 1,130 to 9,415 cfs in the winter 2006 (Table 5). Observed water temperatures were higher than those reported at the Skinner Fish Facility in winter 2006, but the differences were probably due to calibration errors with the Skinner Fish Facility's monitoring equipment. Mean salvage collection times in the holding tanks prior to initial sampling were 10.6 hours in 2005 and 18.1 hours in 2006.

Table 5 Operational parameters at the John E. Skinner Delta Fish Protective Facility in spring 2005 and winter 2006

| Date | Collection tank time (h) | Export rate (AF) | Primary channel flow (cfs) | Collection tank flow (cfs) |

| 4/3/2006 | 24 | 3,837 | 5,650 | 8.7 |

## Predator Size

During the spring of 2005, predators were generally small and ranged from 45.6 mm mean TL for prickly sculpin to 277 mm mean TL for black bullhead (Table 3). Striped bass, white catfish, yellowfin goby, channel catfish, largemouth bass, and warmouth were predominantly juveniles. Pacific staghorn sculpin, black crappie, prickly sculpin, brown bullhead, and black bullhead were predominantly adults.

Predators collected during the winter of 2006 were generally larger compared to the spring of 2005 (Table 3). The mean size of predators ranged from 147.2 mm FL for striped bass to 280 mm TL for black bullhead (Table 3).

## Mean Prey per Stomach Comparisons

No significant differences were observed between the mean number of prey per stomach from CH and CHTR samples (Table 6).

The winter 2006 results showed that mean number of prey per stomach was equal for the two groups tested. Mean number of prey per stomach was not significantly different during CH and CHTR for all predators or striped bass (Table 6). White catfish did not feed in either the CH or the CHTR samples.

Table 6 Mean prey per stomach for CH and CHTR samples with corresponding U statistic, degrees of freedom, and probability

| Predator species | Mean prey per stomach $\pm$ SE |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |

| Winter 2006 |  |  |  |  |  |
| All predators |  |  |  |  |  |
| All prey | $0.09 \pm 0.02$ | $0.09 \pm 0.03$ | 900.5 | 1 | 0.49 |
| Striped bass | $0.19 \pm 0.10$ | $0.09 \pm 0.03$ | 811.0 | 1 | 0.52 |

## Effects of Environmental and Operational Factors on Predation

Mean numbers of prey per stomach were correlated with water temperature and dissolved oxygen for striped bass, white catfish, and all predators combined. No significant correlations were observed between the number of prey per stomach and specific conductance, debris load, collection tank time, export rate, primary channel flow, or collection tank flow (Tables 7 and 8). Water clarity was correlated with the number of prey per stomach for white catfish and striped bass, but not for all predators.

Table 7 Correlation coefficients and probabilities for the relationship between mean prey per stomach for all predators and selected operational parameters. Asterisks indicate significant differences at $\mathbf{a}=0.05$

| Species/parameter | $\boldsymbol{r}$ | $\boldsymbol{p}$ |
| :--- | :--- | :--- |
| All predators |  |  |

| Collection tank flow |  |  |

## Selectivity Indices

In winter 2005, positive selection was observed for juvenile Chinook salmon, delta smelt, threadfin shad, and largemouth bass (Table 9) when all predators were pooled. Striped bass, white catfish, bluegill, prickly sculpin, western mosquitofish (Gambusia affinis), and shimofuri goby were eaten in proportion to their abundance. Predators tended not to eat American shad and splittail. The selectivity indices were similar when calculated for predatory striped bass (Table 10). White catfish exhibited a different set of selection values compared to those observed for striped bass (Table 11).

Table 9 Strauss selectivity index values for prey fish consumed by all predators in spring 2005

| Species name | Prey number | Prey environment | Pi | Eaten prey | Total prey eaten | $\mathrm{R}_{\mathrm{i}}$ | Selectivity |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

| American shad | 10,267 | 31,470 | 0.326 | 0 | 13 | 0 | -0.326 |

In the winter of 2006 when all predators were combined, prickly sculpin and western mosquitofish were among the selected species instead of delta smelt and largemouth bass (Table 12). Inland silversides were only observed in 2006 collections and were selected for. Similar to spring 2005, juvenile Chinook salmon were selected in proportion to their abundance. In contrast, striped bass and American shad were selected against.

Table 12 Strauss selectivity index values for prey fish consumed by all predators in winter 2006

| Species | Prey <br> number | Prey <br> environment | $\mathbf{P i}_{\mathbf{i}}$ | Eaten <br> prey | Total <br> prey <br> eaten | $\mathbf{R}_{\mathbf{i}}$ | Selectivity |

Because striped bass were the most numerous predator sampled in winter 2006, the selectivity values for all predators category were similar to those reported for striped bass. Striped bass showed a strong preference for western mosquitofish and juvenile Chinook salmon (Table 13). Inland silversides were a new prey item and were selected by striped bass. In contrast, striped bass and American shad were selected against. No selectivity index was calculated for delta smelt or threadfin shad since the 2006 facility counts were markedly different from those observed concurrently during counts of non-predatory fish species collected from the release pool during the CHTR Acute Mortality Study (Morinaka, personal communication, see "Notes").

## Prey Abundance Regression

The mean number of delta smelt found in the stomachs of all predators was directly proportional to the abundance of available delta smelt (Figure 4). The mean number of threadfin shad per stomach increased at high numbers of available threadfin shad (Figure 4). Typical of other relationships not presented, Chinook salmon data displayed a fan-shaped distribution with unequal variance and consequently did not fit any regression models (Figure 5).

Similar to the results for all predators, mean numbers of delta smelt found in the stomachs of striped bass were significantly higher (Table 14) with increased numbers of delta smelt (Figure 6). No regression analysis was attempted using white catfish since prey species either were not present in many samples or their scatter plots did not show linear patterns.

Figure 4 Regression plots for available delta smelt and threadfin shad by all predators in spring 2005

Figure 5 Scatter plot for available and consumed Chinook salmon by all predators in spring 2005

| Striped bass: |  |  | 1 |  |
| Delta smelt | 0.37 | 16 |  |  |

Figure 6 Regression plot for available and consumed delta smelt by striped bass in spring 2005

## Prey Length Frequency Distributions

In the spring of 2005, all predators and striped bass fed on smaller prey individuals compared to the size distribution of prey available with delta smelt as the exception (Figures 7 and 8). This trend was observed with juvenile Chinook salmon, young striped bass, juvenile American shad, juvenile threadfin shad, and juvenile prickly sculpin (Figures 7 and 8). Predators fed frequently on juvenile fish in the 10 to 40 mm size range such as American shad, threadfin shad, and prickly sculpin. In contrast, all predators fed throughout the range of available size classes of juvenile and adult delta smelt (Figure 8). Almost all of the consumed fish were less than 80 mm in length. Similarly, white catfish fed on prey individuals less than 80 mm in length.

Figure 7 Length frequencies of Chinook salmon, striped bass, and American shad available and consumed by striped bass in spring 2005

Figure 8 Length frequencies of threadfin shad, delta smelt, and prickly sculpin available and consumed by all predators in spring 2005

Winter 2006 prey size distributions tended to be more unimodal in 2006 (Figures 9 and 10) whereas the distributions in spring 2005 were bimodal. Fish less than 100 mm in length dominated the diet compared to the majority of the larger fish found in the salvage collections.

Figure 9 Length frequencies of threadfin shad and bluegill available and consumed by all predators in winter 2006

Figure 10 Length frequencies of threadfin shad available and consumed by striped bass in winter 2006

## Frequency of Occurrence

For all predators examined in the spring of 2005, a little over one-third of the stomachs contained prey fish (Table 15). Frequency of occurrence of each prey fish species in stomachs was generally low, ranging from 0 to $7.4 \%$. Juvenile Chinook salmon (7.4\%) had the highest frequency of occurrence followed by delta smelt (6.0\%) and largemouth bass (4.2\%). Nearly half (42.6\%) of the striped bass had fish in their stomachs. Juvenile Chinook salmon had the highest frequency of occurrence followed by American shad and largemouth bass. Juvenile and sub-adult striped bass had higher frequencies of stomach items than younger fish (Table 16). Prey fish were found less frequently in the stomachs of white catfish and the percentages of species of prey fish were low. Delta smelt and juvenile Chinook salmon were the 2 species most frequently found in the stomachs of white catfish.

Table 15 Frequency of occurrence of prey species in spring 2005

|  | Prey occurrence (\%) |  |  |
| :--- | :--- | :--- | :--- |
| Prey species | All <br> predators | Striped <br> bass | White <br> catfish |
| Chinook salmon | 7.4 | 14.8 | 0.0 |
| Striped bass | 4.1 | 4.9 | 3.2 |
| American shad | 3.7 | 6.9 | 0.0 |
| Threadfin shad | 2.8 | 4.9 | 1.6 |
| Splittail | 0.9 | 3.2 | 0.9 |
| Bluegill | 1.4 | 1.9 | 1.6 |
| Largemouth bass | 4.2 | 5.9 | 0.0 |

| Delta smelt | 6.0 | 1.6 | 6.9 |
| Prickly sculpin | 3.2 | 3.9 | 1.6 |
| Any prey fish | 33.7 | 42.6 | 14.5 |

Table 16 Frequency of occurrence for all prey species combined for striped bass of different sizes

| Season | Young | Juvenile | Sub-adult |
| :--- | :--- | :--- | :--- |
| Spring 2005 | 26.9 | 46.4 | 52.6 |
| Winter 2006 | 5.5 | 31.6 | 28.6 |

Prey items were found less frequently in the stomachs of all predators in winter 2006 (Table 17). Frequencies of individual prey fish species in stomachs were about one-fifth less than those observed in spring 2005, ranging from 0 to $1.3 \%$. Unlike the spring of 2005, threadfin shad, American shad, and inland silverside were found most frequently in these later diet studies. Not surprising given their dominance in the predators observed, the percentages of individual prey species found in the stomachs of striped bass generally mirrored those reported for all predators. Few prey fish were found in the stomachs of young striped bass in winter 2006 (Table 17).

Table 17 Frequency of occurrence of prey species in winter 2006

| Shimofuri goby | 0.0 | 0.0 |
| Percent containing prey fish | 7.1 | 7.4 |

## Prey Digestion Observations

The digestion scores of selected prey items from predatory fish collected from the CHTR collections appear to vary by prey species and digestion indices (Figure 11; Appendixes I to L). High proportions of eaten delta smelt, threadfin shad, and Chinook salmon had most of their scales digested. Partially or completely digested ventral fins were common for delta smelt and Chinook salmon. Body digestion commonly ranged between 0 to 50\% digested (Figure 11).

Figure 11 Digestion scores for selected prey species consumed by wild predators in spring 2005

## Predatory Striped Bass

Predatory striped bass salvage was highest in January and decreased progressively until June of 2005 and 2006 (Table 18). Conversely, Chinook salmon salvage increased to peak levels in May and June. Therefore, juvenile Chinook salmon were exposed to the lowest numbers of predatory striped bass during the spring of 2005 and 2006.

Table 18 Chinook salmon, striped bass, and predator-sized striped bass salvage estimates

| Year/month | Striped bass salvage | Predatory striped bass | Juvenile <br> Chinook salmon salvage | Ratio predator: Chinook salmon | Minimum <br> Chinook salmon size ( mm FL) |

## Digestion Study

## Spring 2005

During the spring of 2005, I performed a total of 56 experiments using predator-sized striped bass. Twenty-nine experiments were done with delta smelt as prey and 27 experiments were done with splittail as prey. Striped bass size varied from 191 to 429 mm FL. Eaten delta smelt ranged in size from 35 to 74 mm SL. Eaten splittail ranged in size from 35 to 76 mm SL. The water
temperature during these experiments ranged from 11.0 to $22.4^{\circ} \mathrm{C}$. White catfish largely did not feed. No significant differences $(\mathrm{U}=626,1 \mathrm{df}, \mathrm{p}=0.09)$ were observed between occurrence of feeding and water temperature.

There were significant differences in both percentages of scales and body digested between 1, 2, and 4 hours from the feeding experiments involving striped bass and delta smelt (Table 19). Multiple comparison tests showed that there were significant differences in these digestion indicators between 1 and 4 hours (Table 20). Conversely, there was no significant difference observed in degree of fin digestion (Table 19).

Table 19 Kruskal-Wallis test results for the comparison of striped bass digestion categories 1, 2, and 4 hours. Asterisks indicate significant differences at $\mathbf{a}=0.05$

| Prey species | n | H | df | $p$ |
| :---: | :---: | :---: | :---: | :---: |
| Spring 2005 |  |  |  |  |
| Delta smelt |  |  |  |  |
| \% Scales digested | 29 | 8.8 | 2 | 0.01* |
| Type of fins digested | 45 | 5.4 | 2 | 0.06 |
| \% Body digested | 29 | 13.7 | 2 | 0.001* |
| Splittail |  |  |  |  |
| \% Scales digested | 27 | 0.6 | 2 | 0.73 |
| Type of fins digested | 56 | 2.6 | 2 | 0.26 |
| \% body digested | 27 | 8.5 | 2 | 0.01* |
| Winter 2006 |  |  |  |  |
| Delta smelt |  |  |  |  |
| \% Scales digested | 73 | 0.8 | 2 | 0.64 |
| Type of fins digested | 95 | 10.0 | 2 | 0.007* |
| \% Body digested | 74 | 4.1 | 2 | 0.12 |

Similar to the delta smelt trials, eaten splittail significantly differed in the percent of body digested between 1 and 4 hours (Table 20). In contrast, trials using splittail as prey showed no significant difference in percent of scales digested between 1, 2, and 4 hours and no significant difference was observed in the degree of fin digestion (Table 19).

The lack of significance between digestion intervals was not surprising. Percentages of scale digestion and degree of fin digestion showed large overlaps in digestion responses with no distinct differences between 1, 2, and 4 hour experiments for delta smelt and splittail (Figures 12 and 13). However, the results for the percent of body digested categories, 0 ("flesh intact") and 1
("less than $10 \%$ of body digested") showed that $73.9 \%$ of delta smelt and $47.6 \%$ of splittail consumed fell into these categories after 2 hours.

Figure 13 Digestion scores for splittail consumed by captive striped bass in spring 2005

## Winter 2006

A total of 68 experiments were conducted using striped bass from 89 to 404 mm FL in the winter of 2006. Eaten delta smelt ranged in size from 26 to 77 mm SL. Feeding experiments were conducted in water temperatures ranging from 9.3 to $13.9^{\circ} \mathrm{C}$. No significant differences ( $\mathrm{u}=$ $2492,1 \mathrm{df}, \mathrm{p}=0.49$ ) were observed between occurrence of feeding and water temperatures. No significant differences were observed in the percentages of scales or body digested between the three time intervals (Table 19). A significant difference occurred in the degree of fin digestion. Multiple comparison testing determined that a significant difference was observed between 1 and 4 hours (Table 20). Frequency plots of the percentages of scale and fin digestion showed large overlaps of the ranks with no clear differences between the digestion periods (Figure 14). 94.3\% of the consumed delta smelt exposed to digestion up to 2 hours were ranked as having flesh intact or less than $10 \%$ of body digested (Figure 14).

## Quality Control

## Diet Study

A total of $9.8 \%$ of the field observations underwent quality control checks for both seasons and were deemed to have met quality control expectations for accuracy. The following field parameters were checked: predator and non-predatory species counts, species identification, fish length and weight measurements, water temperature, dissolved oxygen, specific conductivity, water clarity, and debris load. These measurement checks were within their specified precision range and the results are given in Tables 21 to 25 .

A total of $7.5 \%$ of the laboratory observations underwent quality control checks during this study. Much of the QC checks were performed on empty stomachs since most predators did not eat. Of the 39 predator stomachs which underwent quality control, only 1 stomach contained prey fish (Table 24) and therefore performance on digestion attributes or biological parameters were underrepresented. QC checks on prey counts, species identification, prey length and prey weight measurements were within their specified performance ranges. No deviations or mistakes were found for digestion parameters for percent scales digested, type of fins digested, and percent of body digested on the contents of the single stomach examined (Table 24).

## Digestion Study

A total of $8.4 \%$ of the field observations underwent quality control checks during the 2 years of study and were deemed to have met quality control expectations. Predator counts, species identification, predator length and weight measurements, water temperature, dissolved oxygen, and specific conductivity were examined and specific results are presented in Tables 21 to 25.

A total of $5.0 \%$ of the laboratory observations underwent quality control checks. The contents of three predator stomachs for a total of 3 prey items were examined (Table 24). Checks on prey count, species identification, and prey weight measurements were within their specified accuracy range which met quality control expectations. Prey length measurements did not meet expectation and the appropriate personnel were informed and re-trained. No deviations or mistakes were found for digestion parameters for percent scales digested, degree of fins digestion, and percent of body digested (Table 25).

## Data Entry and Analysis

A total of $10.0 \%(\mathrm{n}=4,512)$ of the key entered data was checked for accuracy by comparison with the original data sheets for both diet and digestion studies. The audit showed that a high degree of key entry accuracy was achieved in the studies databases and the measured performance exceeded expectations. Only 3 entry errors were found for an error rate of 0.066\%.

## DISCUSSION

## Predation in the CHTR Phase

The digestion study and CHTR sampling results made it difficult to distinguish digestion time using the digestion indices selected. The small numbers of weakly digested prey items obtained
from predators from the CHTR samples suggest that some predators fed within this period. The primary method used to measure the magnitude of the predation did not demonstrate an increase in mean prey number during the CHTR phase. Although not statistically different, the mean number of prey per stomach tended to be higher for the CH sample than the CHTR sample for all predators and striped bass, opposite of expectations assuming that predators feed during this process. Predators undergoing the full CHTR phase would have the greatest opportunity to feed on smaller prey fish based on fish densities. Possible explanations for these unexpected findings include an artifact of changing the method of sampling after the CHTR period, regurgitation of stomach contents, or that predatory fish did not feed during the CHTR period. The author doubts that sampling biases caused this difference. Although regurgitation was not observed in these studies, others have reported predators regurgitating prey during predator removals at the Tracy Fish Collection Facility (Bridges, personal communication, see "Notes").

## Signific ance of the Observed Predation

This study provides no evidence that predation was occurring during the CHTR phase at a level detectable using the study's methods or that predation was occurring in the CHTR phase at a greater level than reported from other environments. The majority of the predator stomachs sampled was empty. The frequency of occurrence of prey in young, juvenile and sub-adult striped bass stomachs from this study were lower than reported by Thomas (1967) who found that $50 \%$ of all age striped bass stomachs contained prey based on sampling in the Sacramento-San Joaquin Estuary during all seasons from 1957 through 1961. At the Red Bluff Diversion Dam on the Sacramento River, Tucker and others (1998) found about the same percentage of adult striped bass stomachs (59\%) contained prey fish. Similar to this study, Turner (1966) reported that 5.8\% of juvenile and adult white catfish stomachs contained prey fish during all seasons in the Sacramento-San Joaquin Estuary. Stevens (1959) found a significantly higher proportion (64.4\%) of white catfish stomachs contained prey during winter and spring in the Santee-Cooper Reservoir, South Carolina. These results would support the conclusion that although predation occurred in the Skinner Fish Facility and the CHTR phase, it was at or below frequency of occurrence levels for striped bass and white catfish from other environments. Although frequency of occurrence does not directly equate to predation in the CHTR phase as defined by prey per stomach, it may indicate that predation in the CHTR phase may not be a major loss source.

To explore the significance of the diet and digestion studies’ results, I developed a crude model to estimate the frequency of occurrence for striped bass that fed on delta smelt during the CHTR phase. I first developed a model to estimate the proportion of eaten delta smelt that were consumed during the CHTR phase. This equation states that:
(1) Percentage of delta smelt consumed in the CHTR phase $=(\mathrm{A} \times \mathrm{B}) \times 100 \%$, where:

A = the proportion of delta smelt that have undergone 2 hours of digestion and displayed less than $10 \%$ of the body digested during the digestion study

B = the proportion of delta smelt found in the diet study that scored less than $10 \%$ of the body digested
(2) Substituting results from the spring 2005 trials, where:
$A=73.9 \%$ of delta smelt showed less than $10 \%$ body digested from the digestion study
$B=38.4 \%$ of delta smelt had less than $10 \%$ of the body digested from the diet study
Therefore the estimated percentage of delta smelt consumed in the 2005 CHTR samples $=(0.739$ $\mathrm{x} 0.384) \times 100 \%=28.3 \%$.

The second step was to develop an estimate for the frequency of occurrence of striped bass that fed on delta smelt in the CHTR phase using the following equation:
(3) Frequency of occurrence of striped bass that fed on delta smelt during CHTR $=(\mathrm{A} x \mathrm{~B} \times \mathrm{C}) \mathrm{x}$ 100\%, where:
$C=$ the frequency of occurrence of delta smelt in the diet of striped bass
Using the observed frequency of delta smelt from striped bass collected from the 2005 diet study, the estimated delta smelt frequency of occurrence from predatory striped bass in the CHTR = $(0.739 \times 0.384 \times 0.016) \times 100 \%=0.45 \%$. Although more research is needed to directly link laboratory feeding experiments with observational diet studies, the result of this model suggests that the probability that a predator will consume a specific rare prey item such as delta smelt may be relatively low in the CHTR phase.

## Predation and Prey Density

Only threadfin shad and delta smelt predation were density dependent where predation increased with higher relative densities of these 2 species in the CHTR phase. The higher salvage of Chinook salmon from the Skinner Fish Facility during spring 2005 may explain the higher frequency of occurrence for this species in the diet of predators. Stevens (1966) reported that juvenile and sub-adult striped bass in the Sacramento-San Joaquin Delta selected for threadfin shad and striped bass at a rate more directly related to their densities, but also fed on small quantities of delta smelt and Chinook salmon in the spring. Wilde and Paulson (1989) also reported that sub-adult striped bass selected for threadfin shad in Lake Mead in proportions to their abundance in the reservoir. As in this study, Stevens (1966) and Thomas (1967) also found that striped bass avoided American shad as prey for unknown reasons despite high densities. The low salvage of delta smelt in the winter of 2006 may also explain the low frequency of delta smelt found in the diet of predators. Despite the low incidence of predation in the diet study, evidence of density dependence suggests that delta smelt would be more vulnerable to predation if densities increased in the CHTR phase.

## Predator Life Stage or Size Relationships

Differences in the frequency of occurrence of prey varied by life stage of striped bass and the observed frequencies appear to differ from previous diet studies. The percent frequency of young, juvenile, and sub-adult striped bass stomachs which contained prey fish for both CH and CHTR samples were $26.9 \%, 46.4 \%$, and $52.6 \%$ in the spring and $5.5 \%, 31.6 \%$, and $28.6 \%$ in winter,
respectively. Stevens (1966) reported that percent frequency of young, juvenile, and sub-adult striped bass stomachs from the south Delta, which contained prey were $87 \%, 64 \%$, and $3 \%$ in the spring and $88 \%, 78 \%$, and $75 \%$ in winter, respectively.

## Seasonal Changes

This study observed a different pattern of seasonal diet than previous studies. Stevens (1966) reported a higher occurrence of items in striped bass stomachs during winter than in spring. Higher frequencies of occurrence in striped bass during winter than in spring has been attributed to decreased feeding during spawning in April through June and a decrease in prey-fish abundance (Moyle 2002; Stevens 1966). Walter III and others (2003) reported that striped bass reduced but did not cease feeding in spring during the spawning period. The relatively-high frequencies of occurrence I observed during spring may be due to the fact that most striped bass collected at the Skinner Fish Facility were not likely reproductive.

Turner (1966) reported a slightly-higher occurrence of items in white catfish stomachs during winter than in spring. Stevens (1959) - reporting about juvenile and adult white catfish from the Santee-Cooper Reservoir - noted that the fraction with food in their stomachs was higher in the winter than in the spring.

The marked increase in the number of prey per striped bass stomach in spring 2005 may be due to the exclusion of the release phase in the 2006 winter trials. The release phase may have provided an additional opportunity for predators to capture prey. In spring 2005, it took approximately 1 hour to drain and remove predators from the release pool and it is conceivable that limited feeding could have occurred during this time span.

Seasonal changes in specific conductance, debris load, collection tank time, export rate, primary channel flow, or collection tank flow probably had little effect on predation during spring 2005 and winter 2006. However, increased water temperature and dissolved oxygen were significantly correlated with increased mean number of prey per stomach in spring. Bucknel and others (1995) showed under controlled laboratory conditions that young-of-the-year bluefish increased their consumption of Atlantic silversides with increased temperatures ranging from 17 to $30^{\circ} \mathrm{C}$. Increased feeding in warmer spring months may also be related more to opportunistic feeding than to temperature dependence since juvenile fish salvage at the Skinner Fish Facility is higher in spring than in the winter (Gartz, personal communication, see "Notes"; Bay-Delta Fishery Project 1981). White catfish did not consume any prey in winter 2006, possibly because water temperatures were colder than white catfish prefer (i.e., $21^{\circ} \mathrm{C}$; Moyle 2002).

## Diet Composition and Prey Selection

Differences in the diet composition were evident between this study and other studies conducted in the Sacramento-San Joaquin Estuary. Stevens (1966) reported that threadfin shad were the only prey fish consumed by sub-adult striped bass in the winter and none in the spring in the south Delta. Thomas (1967) reported that prey fish consumed by striped bass (of all ages) in the Delta consisted of unknown species of lamprey (Lampetra species), striped bass, threadfin shad, and unknown species of fish in the winter, but only striped bass and unknown species of fish in the spring. This study found a greater range of prey species consumed for both seasons.

Although the estuary has undergone drastic changes in species richness due to introduced species since the Turner (1966) and Stevens (1966) studies, the differences in seasonal frequency of occurrence and the diversity of prey species found in diet studies from the Estuary and from the Skinner Fish Facility may be explained by prey density and opportunistic feeding. The Skinner Fish Facility is designed to crowd fish with different habitats and life strategies to facilitate collection and transport. The author hypothesizes that the artificially higher densities of prey and predators in the CHTR phase causes predatory interactions not typically seen in the natural environment. Striped bass are highly opportunistic in their diet preference, and their diet can vary greatly within a small geographical area (Moyle 2002). High concentrations of juvenile fish are collected at the Skinner Fish Facility in the spring and provide a rich environment for opportunistic feeding (Gartz, personal communication, see "Notes"; Bay-Delta Fishery Project 1981). Striped bass are predominantly pelagic fishes and they do not normally feed on shoreoriented prey fish such as bluegill and western mosquitofish (Moyle 2002). The SWP's ability to entrain species from different habitats and the salvage facility's function to concentrate predators and prey into the same space may increase predation between species normally separated by habitat preference.

The size distributions of predators and prey were major factors in prey composition and selection. Predators fed predominantly on smaller juvenile fish, less than 80 mm FL in spring 2005 and less than 100 mm FL in winter 2006, compared to the size distribution of prey available. Stevens (1966) also reported that juvenile, sub-adult, and adult striped bass fed on smaller sized prey, primarily striped bass and threadfin shad, in the Sacramento-San Joaquin Estuary. Striped bass and white bass (Morone chrysops) hybrids were reported to feed selectively on smaller size classes in controlled experiments even when larger prey were available (Gleason and Bentson 1996; Dettmers and others 1998). This feeding strategy is usually attributed to less energy and effort needed to catch smaller prey than larger prey which are faster and have better endurance.

The relatively small size of predators sampled in this study may also explain the selection for smaller prey. For instance, the dimension 'snout to end of abdominal cavity' in striped bass is approximately half of total length and striped bass were rarely observed with prey larger than this relationship. Given the mean sizes of striped bass in spring 2006 ( 188.7 mm ) and winter 2006 ( 147.2 mm ), 80 mm or less was comparable to half the total length. Other researchers have noted similar predator-prey size relationships. Chervinski and others (1989) reported that striped bass ate redbelly tilapia (Tilapia zilli; deep-bodied) less than $30 \%$ of its length and common carp (Cyprinus carpio; slender-bodied) less than $44 \%$ of its length. Fausch (2000) found that a 400 mm striped bass can eat common carp up to 150 mm while a 200 mm striped bass can eat common carp up to 73 mm . When feeding on juvenile American shad, juvenile and adult threadfin shad, and prickly sculpin, striped bass fed opportunistically on the most- abundant size classes. This trend was not observed for white catfish which fed infrequently on multiple size classes.

The seasonal predator-prey size distributions appear to have influenced prey selection by striped bass. The change in selectivity from threadfin shad, largemouth bass, and delta smelt in spring 2005 to western mosquitofish and prickly sculpin appears to be related to growth and the larger size of prey in winter 2006 and a decrease in predator size. As threadfin shad, American shad, and delta smelt increased in size, small predators selected for smaller prey such as Chinook salmon
and western mosquitofish. Juvenile Chinook salmon were selected during both years, most likely due to the relatively small size of smolts ( $<100 \mathrm{~mm}$ FL) salvaged at the facility during winter and spring (Bay-Delta Fishery Project 1981). The higher Chinook salmon selection in spring 2005 than in winter 2006 may be explained by the markedly-higher abundance of juvenile Chinook salmon compared to predator-sized striped bass in the spring.

## Digestion Indicator Performance

The digestion indicators used did not produce sufficient differences to distinguish between prey eaten 2-4 hours earlier from one eaten more recently. However, a gradual increase in digestion for scales, body, and fins was seen over the 1,2 , and 4 hour experiments. Macdonald and others (1982) found that digestion rates increased with time for bivalves, amphipods, and polychaetes consumed by Atlantic cod (Gadus morhua), ocean pout (Macrozoarces americanus), and winter flounder (Hippoglossoides platessoides). The percentage of the body digested showed the greatest potential to separate fish between 1 and 4 hour experiments in this study. Controlled digestion studies using other indicators and using many other prey species will be needed to achieve the original objective of pin-pointing the time of prey consumption within a short time interval.

## RECOMMENDATIONS

No significant differences in the indices used to estimate predation in the CHTR phase of the Skinner Fish Facility were observed and the predation was low compared to other locations within and outside the Skinner Fish Facility. Given these findings, attempts to determine the predation in the CHTR phase or other components of the Skinner Fish Facility should use traditional mark-recovery techniques. The release and recapture of marked fish would allow the researcher to control prey density and size. Known numbers of prey fish released into the CHTR phase would likely reduce the variance of predation estimates and increase the statistical power. Although predation on delta smelt and winter run Chinook salmon was found to be relatively low in CHTR, CHTR is only a small component of predation associated with fish entrainment; thus, management actions to reduce predation mortality associated with the SWP may be warranted.

Given this preliminary evidence that predation in the CHTR phase is not substantial and given on-going observations that predators are abundant immediately preceding the CHTR phase, efforts to reduce predation in the fish-salvage process preceding the CHTR phase may be more beneficial than reducing predation in the CHTR phase. Current operations periodically remove predatory fish from secondary channels and associated bypass pipes through dewatering, hydraulic flushing, and manual netting. Electrofishing, gill-netting, chemical treatment, and light barriers have been considered as predator-management measures in the primary louver channel to discourage residency. Mechanical means to separate larger predators from smaller prey thereby reducing predation mortality within the holding tanks or CHTR phase - have been discussed as facility improvements or features in new facilities. Fausch (2000) discussed the expected performance of a grading system to be used in conjunction with the federal fish salvage facility. He estimated that striped bass as small as 145 to 165 mm would be excluded from the salvage holding tanks using a 19 mm grader screen. Striped bass in this size range could eat fish up to 65 mm , so larger prey fish such as Chinook salmon smolts over 65 mm could see reductions in facility-associated predation while smaller-sized adult delta smelt ( 60 to 70 mm ) would see less benefit. The relatively-high ratio of predator-sized striped bass to juvenile Chinook salmon
salvaged in winter also suggests use of mechanical means to separate larger predators from prey. Frequent predator removals from the secondary channels and bypass systems would likely be the most beneficial and cost effective method to lower predation within the Skinner Fish Facility, since predator removal involves only a small personnel cost and no alterations to the facility.
